FPFI-P3-15

DualEEM: a novel surface science technique for simultaneous ultrafast electron spectromicroscopy, nanospectroscopy and diffraction.

Breaking News

#FPFI-P3-15

K. Grzelakowski.

OPTICON Nanotechnology - Wroclaw (Poland).

BREAKING NEWS

We present experimental proof of the novel dual emission electron microscopy (DEEM) technique [1] based on photoemission (PEEM) [2] and low energy electron microscopy (LEEM) [3]. utilizes the idea of the aberration free spherical analyzer α -SDA [4], that assures not only the selection of characteristic energy for imaging, but also an electron optical separation into two imaging channels: energy-selective real image and reciprocal (diffraction) image. Their quasi- simultaneous acquisition in DualEEM offers an unique opportunity to investigate ultrafast dynamic processes on the surface under these two aspects on the sub-femtosecond scale [5]. The idea and its realization is illustrated in Fig.1. An electron gun located inside the immersion objective lens (b) allows a unique electron beam sample illumination and thus, opens a new application field for electron spectromicroscopy under laboratory conditions.

The first test results (<45nm resolution in the spectroscopic modus) obtained from 2 μ m Pd/Si in ultrahigh vacuum are collected and described in Fig.2. (final res. <10nm, $\Delta E < 100$ meV)

BREAKING NEWS

Silicene, a 2D honeycomb allotrope by Si, can acquire the Dirac fermion character as graphene [1]. Recently, many works about silicene synthesis on the Ag(111) surface have been reported in rapid succession[2]. As silicene forms into a buckling structure, the interaction with the substrate depends on the site in the unit cell strongly. Thus, silicene on Ag(111) tends to lose its chiral symmetry and thus its Dirac fermion character. We have found that both monolayer and bilayer silicene sheets lose the Dirac fermion character on Ag(111) through the spectroscopy measurement with STM [3,4]. In the spectra of the monolayer silicene on Ag(111), the Landau level related peaks that must appear if system acquires the 2D Dirac fermions were not observed [3]. The STS mapping for the bilayer silicene just showed the usual parabolic band, which should be assigned to the Si-modified silver electronic band. The DFT based calculations, which reproduce the geometric structure determined with the dynamical LEED measurement extremely well [5], have shown strong hybridization between the electronic band of silicene and the underlying Ag(111) substrate. These justify our experimental results showing lack of the Dirac fermion character in silicene on the Ag surfaces.

BREAKING NEWS

The scanning tunneling microscope (STM) is now widely used not only for single atom/molecule imaging in real space, but also for different types of atomic manipulation on the nanoscale. We recently established a surprising non-local mechanism for STM induced molecular desorption in a model system, chlorobenzene (PhCl) chemisorption on Si(111)-7x7 at room temperature [1,2]. Here we focus on the phenomenon of the suppression of the non-local desorption probability in a range of 50 Å from the charge injection site (tip position).

Specifically, we report the effect of the tip-surface electric field on the depth and width (range) of the suppression region. The field was changed by varying the tunneling current between 200 pA and 10 nA where the voltage on the specimen was kept constant (i.e. the tip-surface distance is varied). We find that (i) the decay length of the non-local desorption does not change with increasing current (thus field) while (ii) the same is true for the range of the tip-induced suppression of desorption. These results imply the influence of the field on the dynamic is minor. Instead we propose a mechanism in which desorption proceeds through a physisorbed intermediate state and is hindered by the physical proximity of the STM tip which returns molecules efficiently to the Si surface.

BREAKING NEWS

Nitrogen oxide (NO_x) is a by-product of fossil fuel combustion and forms nitric acid in the air, which is the main reason for acid rain and smog. Thus, understanding the reduction process of NO_x on surfaces to form less hazardous gases is of utmost importance. It is well known that precious metals (such as Rh, Pd and Pt) work well to reduce the emission of NO_x. However, reducing the cost of environment-friendly vehicles is an important issue for automobile companies and the expensive cost of the precious metals hinders mass production. Therefore, a more readily available and inexpensive material with comparable, if not better, catalytic performance is needed.

In this work, we announce the latest results of our ongoing work on the development of a new catalyst technology without the use of expensive precious metals. Employing computational materials design using density functional theory, we investigated the reduction of NO on Cu-based catalysts [1-3]. Our results show that NO dissociation on Cu-terminated Cu₂O (111) and Cu-terminated CuO (110) surfaces is comparable with its dissociation on Rh (111) [4], which is characterized by a transition state below the reference energy (surface and gas phase NO), as shown in Fig. 1. This is due to the modified electronic and geometric structure of the surface Cu atoms in comparison with that of Cu (111). The density of states (d orbital) of the surface Cu atoms in the oxides are shifted towards the Fermi energy.

We believe this is responsible for their better reactivity. Moreover, in Cu (111), there is a large energy barrier for NO dissociation, thus desorption is more likely.

This ongoing work is made through the initiative of the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of the Japanese government through the Elements Science and Technology (EST) Project, in collaboration with different research groups from the industry and the academe. One aim of the EST Project is to understand the efficient performance of expensive materials used in the energy and automobile industries. Under the EST, we are part of the “Development of Novel Self-Forming Nanoparticle Catalyst without Precious Metals” group that deals with purification of automobile exhausts. Our study on developing these precious metal-free catalysts has also gained recognition as it ranked first in the Technology Trend Survey announced by Nikkei Shinbun. This shows that technologies dealing with alternative materials for scarce resources are of high importance.

Insight into ridges and wrinkles in multilayers epitaxial graphene on SiC

Breaking News

#NST/SS-P1-25

B. Lalmi ¹, J.C. Girard ¹, M.G. Silly ², F. Sirotti ², A. Ouerghi ¹.

¹CNRS-Laboratoire de Photonique et de Nanostructures (LPN) - Marcoussis (France), ²Synchrotron-SOLEIL - Gif Sur Yvette Cedex (France).

The two dimensional (2D) honeycomb lattice of carbon atoms, which is widely referred to as graphene, has received great interest during the last years [1-6]. This new most fascinating nano-carbon material has distinctive proprieties; such as very high carrier mobility, efficient heat dissipation, half-integer quantum Hall effect at room temperature and spin transport [5,6], making it a one of the most promising candidate to replace silicon in all kind of devices.

Among the various methods to produce graphene, the graphitization of hexagonal SiC surfaces provides a viable alternative for the synthesis of wafer-sized graphene for mass device production. During later stages of growth, ridges and wrinkles are often observed on the graphene layers (see Fig.1) as a result of bending and buckling to relieve the strain between the graphene and its supporting substrate SiC. Such strain is due to the mismatch of its lattice and thermal coefficient with the SiC substrate.

In the present work, we report a further detailed study of the topological defects (ridges and wrinkles) and their associated effects on the epitaxial multilayers graphene grown on the Si face of 6H-SiC. Using near-field microscopy techniques (AFM/STM), we give insight into the nature and the structural proprieties of such nanostructures. We further show that their structures can be manipulated by the pressure exerted by the STM tip during imaging.

Moreover, combining uniquely spectroscopy tools (STS, XPS, ARPES), the impact of these nanostructures on the electronic properties of epitaxial graphene on SiC(0001) will be presented.

BREAKING NEWS

With an increasing concern to limit the emissions of volatile organic compounds (VOCs) and odors present in confined environments, established processes such as thermal and thermocatalytical oxidation or actual technologies based on filtration/adsorption are not economically adapted. The treatment of polluted air streams containing VOCs by the coupling of non-thermal plasma (NTP) with an adsorbent bed is an attractive alternative for dilute VOC oxidation and surface regeneration.

A two stage system with the adsorbent bed placed downstream from the NTP reactor is used to investigate i) the surface modification of activated carbon under ozone exposure and ii) the adsorption properties and oxidation of acetone. FTIR spectroscopy is used for the real time analysis of the gas output. The studies are conducted in dry and humid conditions in order to evaluate the influence of humidity in the given processes.

After undergoing a 1h30min pretreatment at 150°C to guarantee surface repeatability amongst the different samples, activated carbon is exposed to approximately 20ppm of ozone for 20 hours. It is shown that in both dry and humid conditions, the surface undergoes irreversible site modification upon prolonged ozone exposure. Figure 1 shows that in the case of air with 50% relative humidity, the surface is no longer able to dissociate ozone after three hours of treatment. An increasing CO₂ and constant

CO productions are also observed and result from the oxidation of the carbon of the material itself. It is shown that the induced surface modification inhibits the subsequent acetone adsorption.

Another study with consecutive adsorption plasma cycles was also performed and showed the same tendency as that observed during prolonged ozone exposure. It was shown that i) the adsorption capacity of acetone gradually decreased after each plasma cycle, ii) carbon is oxidized leading to an increasing CO₂ and constant CO production independently of acetone surface coverage (figure 2) and iii) ozone dissociation decreases after each plasma cycle.

Fig. 1. Ozone concentration at reactor output during non thermal plasma of air with 50% relative humidity (42.57mW, 14ppm O₃, 5.1J/L) on activated carbon bed.

Fig. 2. Gas phase products observed upon 5 different plasma cycles of one hour (19mW, 24ppm O₃, 2.8J/L) in dry synthetic air.

BREAKING NEWS

Among investigated field emitters - nanocomposite emitters based on the multiwall carbon nanotubes and a polymeric matrix (MWCNT-polymer) are rather promising on the operational properties. For degradation properties examination of the MWCNT-polymer emitters in the large (up to 100 mA) currents modes we suggested to use mass spectrometer methods of main volatile products diagnostics [1].

The further development of our approach consists of the phenomena accompanying FE in various vacuum conditions, current levels and power supply regimes investigation [2]. The examination of the specimens adsorbed on CNT surfaces influence on the FE behavior is of particular interest.

It was offered to use multichannel system of recording current voltage characteristics (IVC) performances and other parameters with simultaneous processing of the incoming information.

The hardware-software complex under control of LabView allows building IVC in Fowler-Nordheim and "slope-intersection" coordinates during FE experiments and also to process spectra TOFMS of reflection type.

The offered technique is universal and can be used not only for MWCNT-polymer, but also for almost any multiple tip field emitters in various longtime FE operating modes for their comparison and certification.

This research is supported by the grant N 12-08-31406 of Russian Foundation for Basic Research and by the grant of “Physics of New Materials and structures” Program of Physics Sciences Department of the Russian Academy of the Sciences.

TF-P3-16a

Control of microstructure and phase formation in sputtering targets by using rapid hot pressing methods.

Breaking News

#TF-P3-16a

E. Neubauer, M. Kitzmantel, W. Kapaun.

RHP-Technology GmbH & Co KG - Seibersdorf (Austria).

Ti-Al-N films are frequently used as wear resistant coatings, e.g. on cutting tools. For the manufacturing of these thin films either two targets (Al and Ti) or compound Ti-Al targets are used. The thin film processing is taking place under a nitrogen gas flow to form the Ti-Al-N coatings with high hardness and wear resistance. In order to improve further the properties of thin films - especially hot hardness - additional elements are introduced in the Ti-Al target materials. When using compound targets for the thin film manufacturing this can be achieved by admixing of third elements and subsequent consolidation by using powder technological processing such as hot pressing or hot isostatic pressing.

Sputtering targets being composed of two or more metals, which tend to form intermetallic phase during the manufacturing process, show some problems during the subsequent processing such as: difficult to machine as a result of formation of brittle intermetallic phases; lower thermal conductivity of the target as a result of the phase formation and more difficulties to obtain full densification during the powder technological processing.

By using a powder metallurgical process based on a direct hot pressing method it is possible to allow a very fast densification (within minutes) of Ti-Al or other materials with tendency to form intermetallic phases. Starting with an appropriate powder mixture followed by hot consolidation it is possible to obtain target materials with a densification > 99%. The result of fast processing is a control of microstructure and reduction of phase formation and therefore minimization of brittle phase formation. Finally the prepared targets have been analysed with respect to their thermal conductivity. In comparison to the target materials which contain intermetallic phases higher thermal conductivities have been measured on these targets

Figure 1:

Left: Microstructure of Ti-Al target processed by rapid hot pressing showing a minimized intermetallic phase formation between the Al matrix and the Ti powders.

QUASI-PERIODIC MATERIALS - CRYSTAL REDefined

Plenary

#PL-1-PI-1

D. Shechtman ¹, D. Shechtman ².

¹Technion - Haifa (Israel), ²Iowa State University - Ames (United States).

Crystallography has been one of the mature sciences. Over the years, the modern science of crystallography that started by experimenting with x-ray diffraction from crystals in 1912, has developed a major paradigm – that all crystals are ordered and periodic. Indeed, this was the basis for the definition of “crystal” in textbooks of crystallography and x-ray diffraction. Based upon a vast number of experimental data, constantly improving research tools, and deepening theoretical understanding of the structure of crystalline materials no revolution was anticipated in our understanding the atomic order of solids.

However, such revolution did happen with the discovery of the Icosahedral phase, the first quasi-periodic crystal (QC) in 1982, and its announcement in 1984 [1, 2]. QCs are ordered materials, but their atomic order is quasiperiodic rather than periodic, enabling formation of crystal symmetries, such as icosahedral symmetry, which cannot exist in periodic materials. The discovery created deep cracks in this paradigm, but the acceptance by the crystallographers' community of the new class of ordered crystals did not happen in one day. In fact it took almost a decade for QC order to be accepted by most crystallographers. The official stamp of approval came in a form of a new definition of “Crystal” by the International Union of Crystallographers. The paradigm that all crystals are periodic has thus been changed. It is clear now that although most crystals are ordered and periodic, a good number of them are ordered and quasi-periodic.

While believers and nonbelievers were debating, a large volume of experimental and theoretical studies was published, a result of a relentless effort of many groups

around the world. Quasi-periodic materials have developed into an exciting interdisciplinary science.

This talk will outline the discovery of QCs and describe the important role of electron microscopy as an enabling discovery tool.

TOPOLOGICAL INSULATORS AND THEIR EDGE AND SURFACE STATES

Plenary

#PL-2-PI-1

S. Zhang.

Stanford University (United states).

Recently, a new class of topological states has been proposed and experimentally observed. These topological insulators have an insulating gap in the bulk, but have topologically protected edge or surface states due to the time reversal symmetry. In two dimensions the edge states give rise to the quantum spin Hall (QSH) effect, in the absence of any external magnetic field. I shall review the theoretical prediction[1] of the QSH state in HgTe/CdTe semiconductor quantum wells, and its experimental observation[2]. Bi₂Te₃, Bi₂Se₃ and Sb₂Te₃ are theoretically predicted to be topological insulators with a single Dirac cone on the surface[3]. I shall discuss experiments which observed these surface states[4,5] and various theoretical proposals for their novel properties. Discovery of topological insulator has the potential to revolutionize surface science, it could also lead to many useful applications.

PL-2-PI-2 NANOWIRES – MY “NARROW- MINDED” APPROACH TO MATERIALS, PHYSICS & DEVICES

Plenary

#PL-2-PI-2

L. Samuelson.

Lund University (Sweden).

In the search for new ways to enable the continued trend towards increasingly smaller and more efficient semiconductor devices, as well as the integration of different kinds of materials with mainstream silicon, nanowires have emerged as key candidates. In this talk I will give an update on the general concepts of self-assembly processes that enable the formation of highly ideal nanowires, also such that incorporate advanced axial and radial hetero-structures by which physically interesting three-dimensional semiconductor systems are created. Of special importance have been the technical implementations by which top-down patterning and processing merges with the bottom-up, self-assembly-based methods of nanowire growth. By this approach it has recently been possible to realize advanced nanowire-based systems of importance for ICT- and energy-applications as well as offering interesting interfaces to life-sciences. I will particularly highlight recent progress in research and development of highly efficient nanowire-based solar cells and light-emitting diodes, in both cases with potential to profoundly influence the future of our society.

PL-2-PI-3

APPLICATIONS OF AES AND XPS TO STUDY PRACTICAL TECHNOLOGICAL PROBLEMS

Plenary

#PL-2-PI-3

J. Grant.

University of Dayton (United states).

Several examples will be given where Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS/ESCA) have been used to study practical technological problems. I will start with some of my historical studies in AES which were very exciting, and also very challenging due to the lack of desktop computers. The lack of desktop computers made early XPS analysis very challenging as well. I will show how experimental parameters chosen for data acquisition in AES and XPS are very important when analyzing samples. I have found that, even today, many operators do not understand how their instruments work and therefore are not taking data using optimal conditions. Obtaining the required data in the shortest time will also reduce any possible effects of beam damage on the sample. It is also easy to misinterpret spectra. Some issues that will be discussed and illustrated include peak identification, detection limits, and quantification.

Ultra fast depth profile measurements of materials: GD OES and Plasma Profiling TOFMS, tools for thin and thick films characterisation

T01 Applied Surface Science

#ASS-5-Or-6

P. Chapon, C. Olivero, A. Tempez, S. Legendre.

Horiba Scientific - Longjumeau (France).

Functional multilayered coatings often feature layers down to the nanometre scale. Reference surface techniques (XPS, AES, SIMS) offer very high surface sensitivity but are limited for depth profiling to thin layers. For embedded nanometre layers or interfaces observation, cross section and SEM EDX or TEM characterisation is generally used.

However there are techniques that could provide a direct measurement of the chemical composition as a function of depth, with a nanometre resolution and the capability to measure both thin and thick layers.

These techniques rely on the fast sputtering of a large area of the material of interest by a high density ($10^{14}/\text{cm}^3$) and low energy plasma. The unique characteristics of this plasma allow very fast erosion (2-10nm/s) with minimum surface damage (as the incident particles have an average energy of about 50eV) and it has been shown that this plasma can be used advantageously for sample preparation in SEM.

When coupled to a high resolution optical system, the resulting technique is called RF GDOES and is well established, when coupled to ToF MS detection, it is named Plasma Profiling Time of Flight Ion Mass Spectrometry. Both instruments feature an advanced pulsed RF source allowing the measurements

of conductive and non conductive layers - the TOFMS offering the additional advantage of isotopic depth profiling.

Various applications taken from different fields from high temperature corrosion in metallurgy to photovoltaic, coatings on glasses to Li batteries will be presented illustrating the capabilities and range of applications of these techniques. A new development will be presented allowing for ultra fast profiling of polymer layers.

ASS-P1-03

Preparation and characterization of supported metal catalysts based on cobalt

T01 Applied Surface Science

#ASS-P1-03

A. Mouna ¹, M. Chater ².

¹Centre de Recherche Scientifique et Technique en Analyses Physico-Chimiques (C.R.A.P.C), ¹Laboratoire d'Etude Physico-Chimique des Matériaux et Application à l'Environnement, USTHB - Alger (Algeria), ²Laboratoire d'Etude Physico-Chimique des Matériaux et Application à l'Environnement, USTHB - Alger (Algeria).

Heterogeneous catalysts are used for a wide variety of reactions, such as hydrogenations, dehydrogenations and oxidations. Selective hydrogenation of multiple unsaturated molecules towards one particular product is a major challenge. For example, the selective hydrogenation of α,β -unsaturated aldehydes towards unsaturated alcohols is important from an industrial point of view. Moreover, it is an attractive test reaction from a fundamental point of view, since C=C hydrogenation is thermodynamically more favored than C=O hydrogenation.

In this work, we studied the preparation and the characterisation of supported Co catalysts. We examined the effect of metal loading (1, 5 and 10 %) on Co dispersion, on the character of metal-support interactions and on the Co particle size. Catalysts are prepared by impregnation from chlorid precursors and characterised by H₂ chemisorption, temperature-programmed reduction (H₂-TPR), scanning electron microscopy (SEM), XRD and cyclohexane dehydrogenation. Results obtained showed that the high hydrogen uptake of the catalysts with 1Wt.% Co reflects the high Co dispersion.

However, chemisorption values decrease with increasing Co amount, reflecting a loss in the number of surface sites, suggesting either the development of a SMSI or sintering of the metal particles. This lower ability for H₂ chemisorption must be attributed to the larger particle formation.

TPR profiles indicate that hydrogen consumption appears from 200 °C. This consumption is attributed to the reduction of Co₃O₄ species. Cyclohexane dehydrogenation results show that the specific activity decreases as the Co content increases. This result indicates that Co dispersion decreases with increasing Co

amount, which is consistent with the formation of large Rh particles as evidenced by H₂ chemisorption experiments.

Fouling is generally defined as the unwanted formation of thermally insulating materials or deposits from process fluids onto heat transfer surfaces, leading to sanitary risks in food-processing industries [1] and forcing them to take expensive cleaning measures [2]. Research teams are intensively working on antifouling coatings development, which is however an issue, as many parameters are involved; however no fundamental study on the fouling growth mechanism at the interface has been carried out yet. The comprehension of these phenomena might help the development of antifouling coatings in an important manner. In this study, the interfacial behaviour of two different model dairy foulings at a stainless steel surface after different times of exposure to dairy solutions in a heat exchanger were investigated using Electron-Probe Micro Analysis, Time-of-Flight Secondary Ion Mass Spectrometry, X-Ray Photoelectron Spectroscopy and Atomic Force Microscopy. Deposits were formed using two model fouling solutions containing 30 ppm (sol.1) and 120 ppm Calcium (sol.2). After two hours fouling, the fouling layer is thin, smooth and homogeneous when sol.1 is used, whereas it is thick, rough, with a growth in arborescence when sol.2 is used.

To better understand the early stages of the fouling growth, samples were submitted to only one minute fouling in both solutions. Fouling was proven to be initiated by unfolded proteins in the first seconds of exposure to both fouling solutions. When sol.1 is used, a smooth homogeneous surface constituted of small clusters of size 60 nm is observed. 3DToF-SIMS reconstructions evidence that calcium is in low amount

and appears at the same places than the protein. It also confirms that the protein is present both on the steel surface and in the steel defects. When sol.2 is used, 3D ToF-SIMS images evidence that the protein appears at the interface with the steel plate earlier than calcium (Fig. 1a). AFM shows the apparition of particles (Fig. 1 b), corresponding to unstable amorphous calcium carbonate nuclei formed in the sol.2 and stabilized by the protein. These protein-coated nuclei are preferentially trapped in the steel roughnesses. The unfolded protein covers again these calcium particles, etc. This explains the arborescence growth structure observed by EPMA (Fig. 1,c).

ZnO nanocrystals annealed in UHV: Surface chemistry and induced band bending

T01 Applied Surface Science

#ASS-P3-01

L. Ericsson, H. Zhang, K.O. Magnusson.

Karlstad University - Karlstad (Sweden).

ZnO nanocrystals distributed by spin-coating on SiO₂/Si surfaces were annealed in UHV and characterized in situ by synchrotron radiation based X-ray Photoelectron Spectroscopy (XPS). Changes in chemical composition and electronic structure on ZnO nanocrystal surfaces were related to increasing annealing temperatures. An annealing temperature of 650 °C drastically reduces the surface contaminant levels without any observed de-composition of ZnO. After annealing at 700 °C an initial de-composition of ZnO together with further reduction of contaminants was observed. As a result, annealing at 650 °C is found to be the optimal temperature for thermal cleaning of ZnO nanocrystals. Chemical changes and induced point defect formation cause changes in the band structure of the ZnO/SiO₂/Si system as observed by XPS. An upward band bending of 0.6 eV on the surfaces of the ZnO nanocrystals was observed after annealing at 300 °C. The bands on the surfaces of ZnO nanocrystals gradually bend downwards with increasing annealing temperatures and finally, annealing at 750 °C for 1 h results in a total downward band bending of 1.5 eV. This large downward band bending is explained as due to the balance between oxygen vacancies and zinc vacancies on the surfaces of ZnO nanocrystals.

Low frictional ZnO thin films synthesized by a combinatorial sputter coating system

T01 Applied Surface Science

#TF/SE-1-Or-9

M. Goto, M. Sasaki, A. Kasahara, M. Tosa.

National Institute for Materials Science - Tsukuba (Japan).

In order to solve the problems of resource depletion and global environment, saving energy have much attention. One of the ways of saving energy is to reduce the friction loss of the moving parts in vehicles and thus save fuel and extend the lifetime of the moving parts. Many low-friction coatings such as transition-metal dichalcogenides, diamond-like carbon, and so forth have been developed so far. However, the friction coefficients of the solid lubricants usually increase upon their reaction with oxygen in air, in oil, in high-temperature and high-humidity, and in space environment. Metal oxide coating is a strong candidate to solve this problem. However, the friction coefficient of the metal oxides known so far is usually too large to be used as low-friction coatings. In this paper, we synthesized the low frictional zinc oxide coating by using a combinatorial sputter coating system.

Abstract

Attempt has been made to join borosilicate glass and cycloolefin(COP) polymer film by using gas adsorption method. Prior to joining, corona plasma treatment in air atmosphere by changing plasma energy was carried out to control surface functional group on both surfaces. An (3-glycidoxypropyl)trimethoxysilane, GPS was adsorbed on glass and an (3-aminopropyl)triethoxysilane, APS on COP both in air atmosphere, resulting in coadsorption of water vapor and organosilane gases (1). Surface characterization of plasma treated and gas adsorbed surfaces was carried out by X-ray photoelectron spectroscopy (XPS) using Mg K α X-ray source. Joining was carried out by a roll laminator after contact of both surfaces at room temperature, followed by annealing at 130 °C for 10 min. Adhesion strength was evaluated by 180 degree peel test based on ASTM D-903 and durability was examined under the conditions of 60 °C and 95 % RH. Surface functional group of OH can be seen on glass surface after plasma treatment. On the other hand, XPS spectra of C1s revealed the existence of complex functional groups of O-H, C-O, C=O, O-C=O and CO₃. In addition, plasma treatment energy gives an influence on the concentration of those functional groups on COP surface. At low energy plasma treatment, dominant functional group of COP surface was C-O and O-H and the surface concentration was estimated to be more than 70%. With increase in applied plasma energy, surface concentration C-O and O-H decreased slightly and C=O increased instead, and then O-C=O emerged on the surface as a result of further increase in energy. CO₃ carbonate functional group appeared clearly on COP surface after plasma energy over 10 KJ/m². Thickness of APS gas adsorption layer on COP was

evaluated by the intensity of XPS Si2p peak. It was found that thickness rapidly increased to reach constant value after several minutes, where saturation thickness was estimated to be 1.1 nm by taking inelastic mean free path (2) of Si2p photoelectron into consideration. Adhesion force by pulling test revealed strong adhesion and was found to be more than 5N/25 mm corresponding to almost equal to COP bulk tensile strength. In addition, durability of this adhesion strength remained unchanged over 2000 hrs even after exposure to the durability test conditions of 60 °C and 95 % RH. The results can be explained in terms of the formation of H-H hydrogen bond and Si-O covalent bond via silanols at the interface as a result of lamination and annealing processes.

In conclusion, direct joining method using gas adsorption was carried out in the system of glass and cycloolefin polymer film at low temperature. Joining thickness was estimated to be 1-5 nm and joining force more than 5N/5mm and long term durability were also confirmed. The results of ultrathin joining can be explained in terms of formation of hydrogen and covalent bondings at the interface by low temperature reaction process.

On-surface polymerization represents a novel bottom-up approach for producing macromolecular structures. To date, however, most of the structures formed using this method are lack of long-range ordering, contain structural defects or exhibit a broad size distribution. To overcome these obstacles, here we demonstrate a strategy of using metal-direct template to control the on-surface polymerization processes. Taking advantages of efficient pre-organization provided by flexible pyridyl-Cu-pyridyl coordination, we have synthesized macromolecular porphyrin systems exhibiting a narrow size distribution and hierarchical organization on a Au(111) surface. We use scanning tunneling microscopy and kinetic Monte Carlo simulation to gain single-molecule level insights of the metal-directed polymerization mechanism. The results reveal that the synthesis profits from the rich chemistry of Cu - as catalyst in covalent coupling, as binding motif for topochemical polymerization and as template for size-selective reactions.

ASS-P1-17

EFFECT OF THE BINARY AND TERNARY EXCHANGES ON CRYSTALLINITY AND TEXTURAL PROPERTIES OF X ZEOLITES

T01 Applied Surface Science

#ASS-P1-17

H. Hammoudi.

**FACULTE DES SCIENCES ET TECHNOLOGIE ,UNIVERSITE DE MOSTAGANEM
BP227 - Mostaganem (Algeria).**

The ionic exchange of the NaX zeolite by Cu^{2+} and/or Zn^{2+} cations is progressively driven while following the development of some of its characteristic: crystallinity by XR diffraction, profile of isotherms, RI criterion, isosteric adsorption heat and microporous volume using both the Dubinin–Radushkevich (DR) equation and the t-plot through the Lippens–de Boer method which also makes it possible to determine the external surface area. Results show that the cationic exchange process, in the case of Cu^{2+} introduced at higher degree, is accompanied by crystalline degradation for $\text{Cu}(x)\text{X}$, in contrast to Zn^{2+} -exchanged zeolite X. This degradation occurs without significant presence of mesopores, because the RI criterion values were found to be much lower than 2.2. A comparison between the binary and ternary exchanges shows that the curves of $\text{CuZn}(x)\text{X}$ are clearly below those of $\text{Zn}(x)\text{X}$ and $\text{Cu}(x)\text{X}$, whatever the examined parameter.

On the other hand, the curves relating to $\text{CuZn}(x)\text{X}$ tend towards those of $\text{Cu}(x)\text{X}$. This would again confirm the sensitivity of the crystalline structure of $\text{CuZn}(x)\text{X}$ with respect to the introduction of Cu^{2+} cations. An original result is the distortion of the zeolitic framework of X zeolites at middle exchange degree, when Cu^{2+} competes with another divalent cation, such as Zn^{2+} , for the occupancy of sites distributed within zeolitic cavities. In other words, the ternary exchange accentuates the crystalline degradation of X zeolites. An unexpected result also is the noncorrelation between crystal damage and the external surface area.

We present a method for efficiently coupling of nucleophilic molecules of choice to a nanostructured gold surface via photo-induced surface chemistry. The method is based on photoactive self-assembled monolayers and it is shown how the method can be used to functionalize localized surface plasmon resonance (LSPR) based biosensors with biorecognition motifs while reducing unspecific binding via introduction of hydrophilic units. The photoactive linker molecule, 5-bromo-7-nitroindoline^[1] couples nucleophilic molecules such as biotin ethylene diamine to a surface when exposed to 365 nm photons. The specific, non-covalent recognition between biotin and streptavidin is used for demonstration of a simple bio-recognition assay based on the LSPR principle. By doing so, the binding of any streptavidin fusion-proteins attached to specific spots at the gold surface by photochemical reaction can be monitored by a LSPR peak shift (**Figure 1**). Since the surface functionalization is based on a photo-induced reaction, this method can be used to functionalize surface in a local and in a site specific way and biomedical applications such as drug screening platforms, microarrays, solid support protein synthesis, and even single molecule experiments can be envisioned.

Surface thermodynamic characteristics of polyaniline complexes with two inorganic and organic acids were investigated using inverse gas chromatography. Thirteen solutes were injected into two separate chromatographic columns packed with polyaniline complexes as stationary phases without any chromatographic support. The retention volumes for these solutes were measured to show a strong retention with the both PANI complexes; particularly the three isomers of xylene, i.e. ortho, meta and para. The free energy of adsorption, consisting of dispersive term and the acid-base interaction term was also determined showing that is mainly based on its dispersive contribution. The dispersive surface energy of hydrochloric acid polyaniline complex ranged from 70.39 mJ/m² at 130°C to 65.75 mJ/m² at 150°C while the surface energy of dodecylbenzenesulfonic acid polyaniline complex has shown slight upper difference ranging from 70.90 mJ/m² to 66.23 mJ/m² in the same temperature's interval, thus reflecting a behavior comparable to that of high surface energy materials. Furthermore, FTIR, Raman spectroscopy, UV-visible XRF, SEM, were used to characterize the PANI complexes powder.

The retention volumes combined with solvation energy relationship (LSER) allowed us to determine the physicochemical parameters describing dispersive, polar and acid-base properties finding out that the surface of both polyaniline complexes is exhibiting a basic nature.

Application of gold nano-particles for silicon solar cells efficiency increasing

T01 Applied Surface Science

#ESD/ASS-2-Or-1

A. Axelevitch, B. Gorenstein, G. Golan.

Holon Institute of Technology (HIT) - Holon (Israel).

The main problems preventing widespreading of solar cells as alternative energy sources are their high cost and low efficiency. Efficiency of solar cells based on semiconductor materials is limited due to high electrical and optical losses and due to recombination processes. It's known several ways to increase the efficiency of solar cells by using multi-junction devices [1] or various low-dimensional structures [2]. In this paper we present one novel way to increase the efficiency of solar cells by using gold island film imbedded in a semiconductor junction.

Fig. 1 presents a side view of the experimental photovoltaic cell. A conventional p-type silicon wafer with a resistivity of $\sim 10 \Omega \cdot \text{cm}$ was used as a substrate-base. Series of thin films: gold island film, p-type silicon emitter film, conductive transparent ITO film, Al rear electrode, and Al pass-bar upper electrode were consequently deposited on the substrate, as shown in figure 1. Thin films of Au and Si were deposited using home-made triode sputtering system working at a pressure of 0.5-2.5 mTorr [3] and ITO film was deposited by magnetron sputtering. Al electrodes were deposited by thermal evaporation in vacuum of $3\text{-}5 \cdot 10^{-5}$ Torr. Prior to the electrode films deposition, the samples were thermally heated in vacuum according to vacuum photothermal process [4].

In order to compare the influence of gold island film on the parameters of the solar cell, we prepared a series of the same pairs samples. In the pair, one of the samples was prepared with the gold island film imbedded between the base and the emitter and the second one was built without a gold film. All the rest parameters of the samples remained the same. Different pairs of samples were varied in thickness of the gold film.

For the made photovoltaic cells, we measured the open circuit voltage and the short circuit current. Measurements were provided in the dark and in the direct sunlight. It was found that imbedded gold film significantly influences on the measured PV cell parameters. The measured open circuit voltage and the short circuit current generated by sunlight in the samples containing the gold island film was higher by about 1.2 and 1.5 times respectively. Also, it was found that the dimensions of gold

ASS-4-Or-4

Surface and interface studies of metal nanoparticles grown on TiO₂ and its oxidation behavior under oxygen environment

T01 Applied Surface Science

#ASS-4-Or-4

J. Pan.

Institute of Materials Research and Engineering, A*Star (Agency for Science, Technology and Research) - Singapore (Singapore).

TiO₂ has attracted remarkable interest as photocatalyst since initial work by Fujishima and Honda on the photolysis of water on TiO₂ electrodes without an external bias. Although TiO₂ itself can be used for the photocatalytic reduction of carbon dioxide, most of time a suitable co-catalyst is needed to obtain a high photocatalytic activity and reasonable reaction rates. In this study, surface science approach was employed to study the growth of Cu, Pt and Co nanoparticles as co-catalysts on rutile TiO₂ (110) single crystal surfaces. Two types of surfaces were used, a sputtered surface and an annealed surface. The co-catalysts were grown through e-beam evaporator in UHV and subsequently characterized by XPS. Only metallic Cu and Pt were observed on TiO₂ surface. Cu and Pt were found to grow in 3D Volmer-Weber growth mode. Interfacial charge transfer on sputtered surface was detected, with electrons transferring from TiO₂ to Cu and Pt resulting in the formation of Schottky interface. Binding energy shift due to cluster effect was observed. Both metallic Co and Co oxides were observed on TiO₂ surface, with more oxide species on sputtered surface as compared to annealed surface. Co was found to grow with higher wetting compared to Pt, with a growth mode that is similar to layer by layer growth. No cluster effect was detected. Co-Ti interactions were found, with electrons transferring from TiO₂ to Co. Oxygen exposure on sputtered TiO₂ surface was found to result in dissociative adsorption that filled oxygen vacancies. The presence of Cu, Pt and Co did not impede this adsorption. Cu and Pt were observed to not be oxidized after exposure to oxygen, while Co was oxidized. The growth of Pt and Co on the same TiO₂ surface was investigated. The initial deposition of Pt followed by the deposition of Co did not alter the growth mode of Co. Nucleation of Co around Pt for 3D growth did not occur. The presence of Pt did not affect the oxidation of Co

when exposed to oxygen. A shift to higher binding energy of Pt was discovered and a possible explanation was put forth involving an induced work function change of Pt due to the oxidation of Co that resulted in the electron transfer of Pt to TiO_2 .

Clusters of boron hydrides have recently been investigated as new building blocks for self-assembled monolayers on surfaces of gold, silver and copper [1–5]. Twelve-vertex dicarba-closo-dodecaboranes (often referred to only as carboranes) are stable molecules with rigid icosahedral molecular architecture, pseudo-aromatic character and, in case of ortho-carborane (1,2-C₂B₁₀H₁₂), also a relatively strong dipole of about 4 Debye. Their thermally robust character and general stability makes them good candidates for effective protection of metal surfaces on a molecular level and their dipolar character can be used to tune the surface potential. In this contribution we will report on a few particular aspects related to: (1) the mechanism and kinetics of formation of SAMs composed of 1,2-dicarba-closo-dodecaborane-1,2-dithiol (A) (the inset of the Figure 1 shows the schematic representation of this isomer on a gold surface) and 1,2-dicarba-closo-dodecaborane-9,12-dithiol (B), (2) the competitive adsorption of both positional isomers A and B, (3) the quantitative analysis of surface potential changes as a result of their immobilization on metal surfaces, and (4) their capacity to protect silver surfaces against corrosive environments. The chemisorption process, electric properties and environmental stability of the SAMs has further been assessed by TOF-SIMS and electrochemical Impedance Spectroscopy. **Acknowledgement:** This work was supported by the SCIEX program (project 11.206) from the Swiss Universities conference within an established cooperation between the Institute of Inorganic Chemistry ASCR, Rež near Prague and EMPA, Dübendorf. We additionally acknowledge the use of facilities of the Laboratory of Nanostructures and Nanomaterials at the Institute of Physics ASCR in Prague.

Surface Structures and Electrochemical Properties for Platinum-enriched Ni/Pt(111) Bimetallic Surfaces Prepared by MBE

T01 Applied Surface Science

#ESD/ASS-1-Or-4

T. Wadayama, N. Todoroki, R. Takahashi, Y. Asakimori.

Graduate School of Environmental Studies, Tohoku University - Sendai (Japan).

Atomic arrangements or compositions of bimetallic alloy surfaces are expected to affect catalytic properties. As for oxygen reduction (ORR) catalysts of polymer-electrolyte fuel cells (PEFC), numerous studies of the Pt-based alloys's nanoparticles have been conducted. However, discussion of the ORR mechanisms is complicated because of uncertainties in topmost surface structures of the nanoparticles. Our experimental approach is well-defined model-catalyst fabrications in UHV by using MBE. In this study, we discuss the relation between topmost surface structures and ORR activity of the MBE-prepared Pt-enriched topmost surfaces (Ni/Pt(111)-skins). The MBE apparatus and the UHV-EC sample transfer system used in this study has been described earlier [1]. The Ni/Pt(111)-skins were prepared through 0.3nm-thick-Ni deposition onto the clean Pt(111) at 823 K by an electron-beam evaporation method. As-prepared surface structure is observed by using STM and XPS in UHV. Then, the sample was transferred to a rotating disk electrode (RDE) apparatus set in a N₂-purged glove box without being exposed to air. Cyclic voltammetric (CV) curves for the surfaces are recorded in N₂-purged 0.1 M HClO₄. After that, linear sweep voltammetry (LSV) measurements were conducted in O₂-saturated 0.1 M HClO₄. A UHV-STM image of the Ni/Pt(111)-skin (Fig. 1) shows 6-fold symmetric honeycomb atomic arrangement that is typical for an fcc(111) topmost surface. However, Atomic-scale disorder with a corrugation of 0.06-0.12nm height is present at the topmost surface. Such corrugations are probably originated from relief of surface-strain derived from lattice mismatch between the topmost Pt layer and subsurface Ni atoms. XPS analysis of the sample showed chemical shift of Pt 4f band (ca. 0.2 eV) relative to clean Pt(111). The LSV curve for the as-prepared Ni/Pt(111)-skin shifts positively relative to the clean Pt(111) and the ORR activity

determined by kinetic controlled current density at 0.9 V was 8 times higher than clean Pt(111). However, the skin surface was degraded rapidly by applying potential cycling between 0.6 V and 1.0 V. The activity enhancement factor estimated after 1000 potential cycles was ca. 2: a UHV-STM image of the sample showed atomically roughened topmost surface caused by dissolution of the under-laid Ni atoms. The results suggest that the ORR activity enhancement of the Pt-skin correlate with surface strains and electronic states of the topmost Pt lattice.

ASS-P3-03

Development of a low energy electron beam source using the photoelectric effect

T01 Applied Surface Science

#ASS-P3-03

T. Hirayama, T. Konishi, T. Tachibana.

Department of Physics, Rikkyo University - Tokyo (Japan).

We have been studying electronic excitation processes in rare gas clusters by electron energy loss spectroscopy. In this study acquisition time for one spectrum was about 50 hours. This is partly due to the low current of incident electron beam (a few nA), which is limited by the use of an electron energy selector. The purpose of this study is to develop an electron beam source which can produce a low energy electron beam of a current ~100 nA with an adequate energy spread (< 0.2 eV) using the photoelectric effect.

Schematic view of the apparatus is shown in fig 1. LaB₆ (100) surface of 1 mm in diameter is used as a photocathode. Visible light from LD (Laser Diode) is focused onto the photocathode surface. A parallel plate electron energy analyzer is used for the measurements of the electron energy distribution. The photocathode is heated to 1800 K for several minutes before the measurements for surface cleaning. Background pressure in the vacuum chamber is about 5×10^{-9} Pa.

Figure 2 shows the results of the electron energy distribution emitted by the irradiation of the photon energy of $E_p = 2.79$ eV. Solid line represents the result of gauss fitting. FWHM of the peak is 0.34 eV. This yields the photoelectron energy spread to be ~ 0.3 eV, which is estimated considering the energy resolution of the analyzer. From this results it is expected that an electron beam with energy spread less than 0.1 eV can be obtained using a LD of $E_p = 2.6$ eV. Quantum yield, defined as the number of photoelectrons per photon, is 1×10^{-5} at $E_p = 2.79$ eV. If we use a LD with a power of about 4 mW, the photoelectron current of 100 nA can be achieved. The lifetime, which is defined as the time when the current of the photoelectrons decreases by half, depends on the pressure of the vacuum chamber.

Lifetimes measured at $P = 2 \times 10^{-8}$ and 5×10^{-7} Pa were 8000 s and 600 s, respectively, while it is shorter than 10 s when the pressure is in the order of 10^{-6} Pa.

Fig. 1. Schematic view of experimental apparatus.

Fig. 2. Electron energy distribution measured using a LD of $E_p = 2.79$ eV. Solid circles are measured points and the solid line is the result of Gauss fitting.

Atomic dipole moment induced variation of local surface potential on Si(111)-(7×7) surface studied by noncontact scanning nonlinear dielectric microscopy

T01 Applied Surface Science

#ASS-10-Or-11

K. Yamasue, Y. Cho.

Research Institute of Electrical Communication, Tohoku University - 2-1-1, Katahira, Aoba, Sendai 980-8577 (Japan).

Noncontact scanning nonlinear dielectric microscopy (NC-SNDM) can resolve atomic dipole moments on cleaned semiconductor surfaces through the frequency modulation based electrical measurement of tip-sample capacitance. So far, NC-

SNDM imaging of a Si(111)-(7 × 7) surface has revealed that the individual adatoms on the surface have upward (outward-pointing normal to the surface) dipole moments [1]. In addition, the simultaneous measurement of tunneling current, which

is induced by ac electric field modulation ($V_p \cos \omega_p t$) in NC-SNDM imaging, has shown

that the dipole moment image ($\epsilon_3(A \cos \theta)$ image) closely resembles the time-averaged

tunneling current ($I(t)$) image. A recently proposed explanation attributes this resemblance in the two different images to the existence of a strong electric field localized on the individual adatoms [2]. Since this localized field, which originates from and is proportional to the dipole moment, causes effective shift of the surface

potential (ΔV_d), it enhances asymmetry of current-voltage ($I-V$) characteristics on

the adatoms. The resulting significant rectified current ($I(t)$) is theoretically derived as

and thus proportional to the dipole moments [2]. In order to experimentally

validate the proposed explanation, simultaneous imaging of $\epsilon_3(A\cos\theta)$ and ΔV_d was here performed as shown in Figs. 1 and 2. The images were acquired under $V_p = 1.2$ V at 30kHz and the ΔV_d image was constructed from $I(t)$ and the 3rd harmonic ($I_{3\omega}$) images. As expected, ΔV_d image resembled $\epsilon_3(A\cos\theta)$ one and ΔV_d was spatially maximized on the adatoms. The spatial average of ΔV_d was about +0.2 V and, reasonably, almost equals to the dc bias that was needed to cancel out $\epsilon_3(A\cos\theta)$ in average. These results thus suggest that the local surface potential is governed by the strong electric field from atomic dipole moments, which can be directly imaged through the measurement of the capacitive component at an atomic scale.

The low density polyethylene (LDPE) films were irradiated with gamma radiation using the ⁶⁰Co source in the dose range varied from 0 to 500 kGy at dose rate of 24.32 Gy/min in air at room temperature. The induced changes in the chemical structure and morphologic properties were investigated. The structure modifications of the LDPE were recognized using Fourier Transform Infrared Spectroscopy (FTIR). The morphologic properties of the non-irradiated and irradiated LDPE were evaluated by the Scanning Electron Microscopy (SEM). Differences in FTIR spectra were observed. SEM studies showed that the surface morphology of LDPE changed.

Omicron NanoTechnology GmbH - Taunusstein (Germany).

A major challenge in the development of novel devices in nano- and molecular electronics is their interconnection with larger scale electrical circuits required to control and characterize their functional properties. Local electrical probing by multiple probes with STM precision can significantly improve efficiency in analyzing individual nano-electronic devices without the need of a full electrical integration. Recently we developed a microscope stage that merges the requirements of a SEM navigated 4-probe STM and at the same time satisfy the needs for high performance SPM at low temperatures.

Besides SEM/STM probe fine navigation and imaging with atomic resolution at temperatures of $T < 5K$, the pm-stability of the LT NANOPROBE expands applications to tunneling spectroscopy and even the creation or modification of nanostructures or single atoms by a sharp and precise SPM probe.

A further milestone in the development of the instrument was the implementation of the QPlus- NC-AFM mode [1, 2] for imaging on insulating surfaces. The QPlus mode becomes important if nanowires/nanostructures are deposited on an insulating substrate for a better electrical decoupling of the nanowire from the substrate. In this case the QPlus sensor can be employed to locate the nanostructures and, after finding the structure, to carry out conductance measurements.

In this contribution we will present first QPlus results obtained with the LT Nanoprobe at low temperatures. Furthermore we will focus on measurements that prove the performance level of the instrument as well as on tunneling spectroscopy and atom manipulation experiments on Ag(111) at temperatures of $T < 5K$.

Cooperative modulation of electronic structures of aromatic molecules coupled to multiple metal contacts

T01 Applied Surface Science

#ASS-5-Or-7

W. Wang¹, X. Shi², S. Wang¹, J. Liu³, M.A. Van Hove², P.N. Liu³, R.Q. Zhang⁴, N. Lin¹.

¹Department of Physics, The Hong Kong University of Science and Technology - Hong Kong (China), ²Institute of Computational and Theoretical Studies and Department of Physics, Hong Kong Baptist University - Hong Kong (China), ³Shanghai Key Laboratory of Functional Materials Chemistry and Institute of Fine Chemicals, East China University of Science and Technology - Shanghai (China), ⁴Department of Physics and Materials Science, City University of Hong Kong - Hong Kong (China).

We use cryogenic scanning tunneling microscopy/spectroscopy and density-functional theory calculations to inspect the modulation of electronic states of aromatic molecules. The molecules are self-assembled on a Cu(111) surface forming molecular networks in which the molecules are in different contact configurations, including laterally-coupled to different numbers of coordination bonds and vertically-adsorbed at different heights above the substrate. We quantitatively analyze the molecular states and find that a delocalized empty molecular state is modulated by these multiple contacts in a cooperative manner: its energy is down-shifted by ~ 0.16 eV for each additional lateral contact and by ~ 0.1 eV as the vertical molecule-surface distance is reduced by 0.1 \AA in the physisorption regime. We also report that in a molecule-metal-molecule system the bridging metal can mediate the electronic states of the two molecules.

ASS-10-Or-10

The modification of ultra thin films and in situ electrical conduction measurements using a four-tip STM combined with FIB

T01 Applied Surface Science

#ASS-10-Or-10

N. Fukui, T. Hirahara, S. Hasegawa.

the University of Tokyo - Tokyo (Japan).

The surface conduction becomes more important as the size of electronic devices become smaller. It has been measured by the conventional four-probe method on a planar and uniform surface. In order to unveil further intriguing surface conduction phenomena related to spin transport, one needs a new type of measurement. A promising candidate is surface processing by focused ion beam (FIB), which is an established method for nanoscale fabrication of bulk systems. When FIB process is applied to surface science studies, a problem occurs that the contamination easily destroys the surface states in many cases. Therefore, conductivity measurements and FIB processing should be done in the same ultra high vacuum chamber without exposing the sample surface to air.

In the present work, we performed simultaneous in situ fabrication/conductivity measurement of Bi and Bi_2Se_3 wires. The experiments were performed with our homemade variable temperature four-tip STM equipped with FIB[1]. In the ideal case, the one-dimensional (1D) conductivity of a fabricated wire should be proportional to the wire width and the gradient will be equal to the two-dimensional (2D) conductivity of the original film. The Bi wire, however, had a lower 2D conductivity than that of the original film (Fig. 1 (a)), which is presumably due to the unintended wire destruction. This indicates that even the tail of a FIB beam can change the electrical property of thin film including surface states. Next, a Bi_2Se_3 thin film was capped with Se to keep the film from unintended ion bombardment and then processed by FIB. After that the Se capping layer was lifted off by annealing and its conductivity was measured. Fig. 1 (b) shows the 1D conductivity against the Bi_2Se_3 wire width with and without Se capping process. Without the capping process, the 2D conductivity was lower than the original film like the case of Bi wires. On the other hand, the 2D conductivity of the Bi_2Se_3 wire fabricated with capping layers coincided with that of the original

film. We conclude that FIB processing gives serious damage to the electrical property of an ultrathin film, which can be avoided by capping process. The details will be given in the presentation.

ASS-3-Or-6

Effect of yttrium thin layers on the structural and optical properties of Co/Mo₂C periodic multilayers

T01 Applied Surface Science

#ASS-3-Or-6

P. Jonnard ¹, Y.Y. Yuan ², K. Le Guen ², J.M. André ¹, C. Meny ³, Z.S. Wang ⁴, J.T. Zhu ⁴.

¹UPMC/CNRS - Paris (France), ²UPMC - Paris (France), ³IPCMS - Strasbourg (France), ⁴IPOE - Shanghai (China).

Periodic multilayers having layers within the nanometer range can efficiently diffract radiation from the extreme UV (EUV, 30-100 eV) and soft x-ray (100-5000 eV) ranges. Thus this kind of structure is nowadays widely used as optical components on synchrotron beamlines or space telescopes and for applications such as photolithography, x-ray microscopy, x-ray spectroscopy. It is important to develop efficient multilayers in terms of reflectance and bandwidth and for this purpose necessary to control their structure and particularly the quality of their interfaces. The Co/Mo₂C periodic multilayer has already been characterized and showed a large difference between the experimental and simulated reflectance values. Moreover, annealing experiments up to 600°C have shown that this multilayer presents a good thermal stability. In this communication, we are interested in investigating the reflectivity changes happening when introducing a third material in the structure. In this case, thin yttrium layers are inserted either at the Co-on-Mo₂C or Mo₂C-on-Co interfaces to obtain multilayers having three layers in a period. We expect the insertion of the third material to improve the optical path within the structure and then improve the reflectivity and possibly to also act as a diffusion barrier to improve thermal stability.

The Co/Mo₂C/Y multilayers are deposited by magnetron sputtering. They are annealed up to 600°C under vacuum. Their reflectance are measured in the hard-ray (8048 eV) and EUV (around 80 eV) ranges and compared to simulations performed for perfect structures, i.e. without roughness or interdiffusion. Preliminary simulations have shown that a reflectance up to 56.5% can be expected for perfect Co/Mo₂C/Y multilayers (see figure below). From the fit of the reflectivity curves, the structural parameters of the stacks are determined: density, thickness and roughness of all the

layers including the interfacial ones if any. Nuclear magnetic resonance spectroscopy is also used to know if the cobalt atoms present in the structure interact with the neighbouring Y or Mo₂C layers, i.e. are involved in some interlayers. The influence of the annealing and order of the layers on the optical and structural properties of the Co/Mo₂C/Y trilayer system will be presented and discussed in comparison to the results previously obtained on the Co/Mo₂C bilayer system.

Acknowledgments: The work is done in the framework of the COBMUL project funded by ANR (#10-INTB-902-01) and NSFC (#11061130549). Colleagues from the BEAR beamline of the Elettra synchrotron facility are thanked for their help during the reflectivity measurements.

Measurement of charge separation by friction between metal and plastic in air and vacuum

T01 Applied Surface Science

#SE/ASS-P2-01

T. Miura, M. Yamaguma.

National Institute of Occupational Safety and Health - Tokyo (Japan).

Electrostatic charges generated by friction between industrial materials induce incendiary electrostatic discharges, such as a spark. In fact, many industrial accidents involving explosions and fires occur due to the electrostatic discharges. In this study, we focus on the elemental process, i.e., charge separation, during friction between metal and plastic. Measurement of the charge separation in a vacuum makes it clear that the real amount of triboelectrification between solid materials because of suppression of charge relaxation through gas discharge in a micro-gap interface of them. In air, we can obtain the relaxation efficiency for the initial charge separation.

Our equipment for measuring the charge separation during friction between metal and plastic, which was constructed on the basis of pin-on-disk technique in a vacuum chamber, is shown in Figure 1. The pin was made of metal and the disk was made of plastic material. Amount of the generated electric charges on the metal pin during friction was measured with an electrometer by connecting to the metal sample electrically.

The experimental results of friction between a stainless steel pin and a poly-ethylene terephthalate (PET) disk in a vacuum and air are shown in Figure 2. It was found that the friction speed were not so significant to the charge separation in a vacuum. The charge density on the rubbed surface of PET was calculated to be about $5 \times 10^{-4} \text{ C/m}^2$ from the generated charge and the width of the friction track. In air, the charge accumulation was, however, one order of magnitude less than the value measured in a vacuum. This should be caused by the charge relaxation as a result of the micro-gap discharge [1].

Box 1000, 02044 VTT - Helsinki (Finland), ⁵Knowledge Department., Autonomous Province of Trento - Trento (Italy).

Results from the JET ITER-like wall, ASDEX Upgrade, and laboratories clearly point to a much lower T retention in metallic (W/Be) plasma facing components (PFC) compared to C-based PFCs. However, ITER metallic walls will face additional effects related to the high particle fluxes, material mixing, and neutron irradiation. For example, polycrystalline self damaged tungsten under 12.3-MeV W⁴⁺ irradiation has been already observed¹ to show large D retention. D retention in C-Based and metallic PFCs has been extensively studied by post mortem analyses like SIMS, RBS, NRA, and TDS. While TDS can give an absolute integral value, SIMS, RBS, NRA can provide depth information of the retention of D but one needs to combine two techniques to obtain absolute concentrations². In order to use only one technique (SIMS), a common procedure consists of preparing reference standards, of the same matrix to be analyzed, by ion implantation at different doses so that an absolute sensitivity curve can be constructed to calibrate the instrument. However, for the specific case of D in W this is not viable. In fact, in order to get a good signal to noise ratio at 100 nm of Rp, one needs a concentration peak of at least 1×10^{18} at/cm³. SRIM simulation showed that, to reach this value, an implanted fluence of 1×10^{14} ions/cm² at 20 keV is needed. It was reported that deuterium implantation carried out with energies above 20-25 keV leads to a nuclear reaction generating a non-negligible amount of gamma rays around the implanter³. To circumvent the problem, D-W standards have been prepared by co-deposition of W by magnetron sputtering in an Ar-D plasma environment. Various D⁺ incident energies ranging from 20 to 200 eV were used. Since the amount of D retained depend also on the microstructure of the W coating⁴, the microstructure of the standards was varied and

was studied by SEM cross section micrography. The D absolute concentration was determined by NRA. Once the calibration curve has been obtained, the absolute D concentration of W samples coming from the ASDEX-Upgrade divertor will be directly measured by SIMS. A comparison with previous NRA measurements on the above samples is also foreseen.

ASS-P1-05

XPS analysis of nano-structured surfaces with GOSSIP software

T01 Applied Surface Science

#ASS-P1-05

O. Eric.

EADS Innovation Works - Suresnes (France).

The software tool GOSSIP (Generation of Survey Spectra In X-ray Photoelectron Spectroscopy) was developed in 2008 at EADS Innovation Works. The objective was to develop a simple tool for better comprehension and faster analysis of complex X-ray survey spectra (200-1500 eV) when applying XPS in an industrial context.

It is entirely and only based on S. Tougaard modelling of continuous inelastic background (ref [1]). The main difference with QUASES™ developed and commercialized by S. Tougaard, is that it deals with survey spectra as a whole instead of individual peaks, leading to faster data reduction.

GOSSIP simulates survey spectra of nano-structured surfaces defined by user, that can be compared to experimental data. Principle of GOSSIP and validation of results with simple real nano-structured surfaces have been published in 2009 (ref [2]).

This paper aims at giving a few examples of simple strategies that can be used to “understand” its own XPS data and acquire an expertise at “reading” shapes of XPS survey spectra.

To avoid un-necessary complexities of real XPS spectra, the examples are based on two imaginary pure elements A and B, with very simple survey spectra which have a doublet peak at 1400eV and 1000eV respectively, and identical sensitivity factors. By following an energy dependence law $A E^p$, with $p=0.75$ and $A = 0.01$, Effective Attenuation Lengths (EAL) are respectively 2.3 nm and 1.8 nm at these kinetic energies.

It is shown that by using atomic percentages determined on experimental data by the standard method of peak area ratios, models generated by GOSSIP with these atomic percentage values and simple operations (spectra subtraction or division), unknown surface nano-structures can be quickly and easily solved.

GaN surface polarity determination by photoelectron diffraction

T01 Applied Surface Science

#ASS-3-Or-4

O. Romanyuk ¹, P. Jiříček ¹, T. Paskova ², I. Bartoš ¹.

¹Institute of Physics, ASCR - Prague (Czech republic), ²North Carolina State University - Raleigh (United states).

Nitride materials with non-polar and semipolar surface orientations have attracted significant attention because of their importance for optoelectronic device applications. The surface properties of the wurtzite nitrides are strongly influenced by their surface polarities (the topmost atomic layer in the crystal bilayer contains cations or anions). Different methods for polarity determination of the GaN crystals have been reported, but they are either destructive or highly demanding. For example, polarity can easily be determined by surface etching [1] or by nondestructive methods such as photoelectron diffraction (PED) [2,3].

In this work, a nondestructive approach, utilizing PED intensity, is presented for polarity determination of the polar GaN(0001), (000-1), and semipolar GaN(20-21), (20-2-1) crystals. Clean surfaces have been prepared by annealing under NH₃ atmosphere [4]. Angular resolved PED measurements have been performed for a photoelectron kinetic energy of 825 eV (MgK α excitation from the N 1s core level) and of 1234 eV (Ga 3d level). Corresponding angle resolved intensities from the N 1s and Ga 3d levels have been calculated taking multiple electron scatterings into account.

Calculated PED patterns of GaN with both surface polarities (000-1) and (0001) are shown in Fig 1. The peak locations mostly correspond to directions connecting the emitting atoms with their neighbours due to a strong forward scattering of the photoemitted electrons [5]. One can see that while the Ga 3d patterns are quite similar for both polarities, the N 1s patterns are quite different. Much stronger electron scattering cross-sections of Ga atoms, found convincingly during numerical modelling, simplifies the structural interpretation of the photoelectron diffraction patterns. It enables us to suggest a simplified method for polarity determination utilizing photoemitted electron intensities in just a few azimuths of the crystal.

Periodic multilayers having layers within the nanometer range can efficiently diffract radiation from the extreme UV (EUV) and soft x-ray ranges. Thus this kind of structure is nowadays widely used as optical components on synchrotron beamlines or space telescopes and for applications such as photolithography, x-ray microscopy, x-ray spectroscopy. The reflectance of the multilayer strongly depends on the quality of the interfaces, particularly roughness and interdiffusion.

X-ray standing wave regime enables probing the interfaces of periodic multilayers. Indeed, when the Bragg condition for diffraction of incident radiation is fulfilled, a strong standing wave develops having the periodicity of the multilayer. Then, by slightly changing the incidence angle of the incoming radiation around a Bragg peak, it is possible to move the nodes (maxima) and anti-nodes (minima) of the electric field either at the centre of a layer or at an interface. Upon the excitation by the electric field, secondary processes can take place, such as emission of photoelectrons or of characteristic fluorescence radiation. Fluorescence is interesting to probe multilayers, stacks having a total thickness of a few hundreds nanometers, as the x-ray emission may originate from a great depth whereas the photoelectron escape depth is limited to a few nanometers.

It is also possible to observe the fluorescence, excited or not by standing waves, in a direction close to the Bragg peak for this secondary radiation. Until now, developed models only deal with standing waves of primary radiation. We present a theoretical approach based on the oscillating dipole model and the coupled-wave theory that

can treat both primary and secondary standing wave regimes. We compare our simulations to experimental data available in the literature and find good agreement. We also present a comparison with some of our experimental results obtained on Co/Mo₂C multilayers having a period of 4.2 nm. The intensity of the Co L α emission, excited with a radiation having an energy close to the Co L3 photoionization threshold, is observed as a function of the angle scanning the first Bragg peak of the incident radiation. Possible discrepancies between the experiment and the simulation are finally discussed.

Acknowledgments: The work is done in the framework of the COBMUL project funded by ANR (#10-INTB-902-01) and NSFC (#11061130549).

Status of scanning Auger microscopy for high spatial chemical resolution

T01 Applied Surface Science

#ASS-10-Or-7

E. Martinez, V. Jousseume, S. Borel, C. Dieppedale, B. Reig, O. Renault.

CEA, LETI - Grenoble (France).

Auger electron spectroscopy (AES) and microscopy (SAM) are gaining interest to investigate nano-structures or thin multilayers stacks currently developed for nanotechnologies [1]. New generation Auger nanoprobes combine high lateral (<10 nm) and energy (0.1 %) resolutions thus offering the possibility to analyze the chemical composition, as well as the chemical environment, at the deca-nanometer scale. Surface sensitivity (5 nm or less) makes it complementary to electron microscopy techniques such as EDX and EELS.

The performances of these nanoprobes in terms of spatial chemical resolution are illustrated with the analysis of CMOS-compatible Si nanowires [2]. The catalyst (Cu) and growth temperature (< 450°C) are made compatible with the devices fabrication. AES and SAM are potential techniques to bring information about the surface chemical composition, in order to optimize their synthesis and final performances. The chemical nature of both the catalyst and the nanowire can be identified (see figure 1). Restrictions due to backscattered electrons will be discussed.

SAM will be combined with state-of-the-art XPS imaging with photoelectron emission spectromicroscopy (XPEEM). A cluster system enabling UHV transfers between both instruments is used to optimize and preserve the surface preparation. Combined surface analyses are made possible from the micro to the deca-nanometer scale with meaningful complementary information. SAM offers higher lateral resolution in elemental imaging and XPEEM can bring more details about the chemical environment. This is used to investigate surface contamination on μ -switch devices after successive ageing cycles.

Observation of atomic dipole moment on hydrogen and oxygen adsorbed Si(111)-7×7 surfaces by using noncontact scanning nonlinear dielectric microscopy

T01 Applied Surface Science

#ASS-10-Or-12

Y. Cho, D. Mizuno, K. Yamasue.

Research Institute of Electrical Communication, Tohoku University - Sendai (Japan).

The adsorption on Si surface has been greatly interested in the discipline of surface science [1]. In particular, passivation of Si surfaces by hydrogen or oxygen has been important for semiconductor industry. Scanning probe microscopy (SPM), such as scanning tunnel microscopy (STM) and noncontact atomic force microscopy (NC-AFM), is one of the techniques to observe the passivated surface in atomic level. The images observed by STM and NC-AFM give information on chemical characteristic of the adsorbed surface. For example, in the case of hydrogen adsorption, the dangling bond of Si surfaces forms a chemical bond with atomic hydrogen and then the Si surfaces becomes insensitive to the chemical interaction with reactive molecules and atoms. On the other hand, there have been few studies from the viewpoint of physisorption. Even if a surface is chemically stable, molecular interaction (such as van der Waal's force) is caused by the difference in electronegativity between a Si and hydrogen (or oxygen) atom (Therefore, the surface has dipole moments.). Noncontact scanning nonlinear dielectric microscopy (NC-SNDM) can simultaneously measure the atomic dipole moment and topography by detecting nonlinear dielectric constants $\epsilon(3)$ and $\epsilon(4)$, respectively [2]. In this report, we apply this NC-SNDM to observe atomic dipole moments on the hydrogen and oxygen adsorbed Si(111)-7×7 surfaces in order to investigate the charge distribution around the adatoms. In the case of hydrogen adsorption, it is expected that the atomic dipole moment of the hydrogen-adsorbed adatom becomes weak because the charge distribution around the adatom is nearly central symmetric such as the tetrahedral structure formed by Si atoms in the bulk. Our experimental results are shown in Fig. 1. It was confirmed that

dipole moments on the hydrogen-adsorbed Si adatoms surely became weaker than those on cleaned Si adatoms (shown by black circle in Fig.1(b)). The observed weakened atomic dipole moments suggest that hydrogen-adsorbed surface is passivated physically as well as chemically. Next we observed oxygen adsorbed Si(111)-7×7 surface and found that, in the initial stage of oxidization, the dipole moment at the oxidized adatom (oxygen is inserted into the back-bond of the adatom) becomes weaker. These results can be explained by our model based on the charge distribution around Si adatom [2].

We show a set-up of poly(4,4'-aminotriphenylene hexafluoroisopropylidenedipthalimide) (6F-TPA PI)/Al sample in which holes are injected by photoelectron emission process instead of direct charge carrier injection via metal electrode. In this process, an irreversible electrical phase transition of 6F-TPA PI is found in contrast to the Al/6F-TPA PI/Al structure, leading to a write-once-read-many behavior. The photoelectron spectroscopy results measured before and after the switching process revealed that the irreversible electrical phase transition of 6F-TPA PI is attributed to the chemical modification of the carbonyl group in phthalimide moiety.

Pd-Ag based membranes supported on porous α -Al₂O₃ (doped with yttria-stabilized zirconia) have been studied for hydrogen selective separation. Magnetron sputtering technique was employed for the synthesis of the thin film membranes. The permeation fluxes can be affected by the membrane columnar structure, which is formed during deposition. From SEM analysis it was observed that different sputtering deposition pressures can lead to distinct columnar structure growth. XRD patterns provided evidence of a Pd-Ag solid solution whose crystalline texture can be altered by the deposition pressure. The average crystallite domain size is 21 nm. The gas-permeation results have shown that the Pd-Ag membrane supported on porous α -Al₂O₃ is selective towards H₂. For optimized conditions, the permeate flow at a pressure feed of 300 kPa of N₂ is 73.1 mL/min-1, which shows that the membrane has a reasonable capacity to hinder the permeation of this gas. The selectivity factor α (H₂/N₂) obtained for the optimized membranes was of the order of 10, revealing its selectivity towards hydrogen.

INTERFACE FORMATION BETWEEN POLYMER-DERIVED CERAMIC SURFACES AND STEEL SUBSTRATES

T01 Applied Surface Science

#ESD/ASS-1-Or-8

A. Schütz, M. Günthner, G. Motz, U. Glatzel.

University - Bayreuth (Germany).

Ceramic coatings synthesised from polysilazane polymers (precursors) are easy to apply and guarantee optimum adhesion even on already oxidised metal surfaces. For some purposes those coatings are too thin or too porous. These shortcomings may be corrected by using filler particles. A coating with excellent surface adhesion to low alloyed steel had to be developed in order to prevent high temperature corrosion in chemically and mechanically aggressive environments.

Novel glass particle filled precursor-based coatings were found to offer excellent corrosion protection for steel substrates. The coating systems properties were analysed with different techniques. Adhesion was determined using scratch tests with different loads. The abrasion resistance was tested at a high temperature with large particle freight. Characterisation was done using scanning electron microscopy with energy dispersive X-ray, surface tests as well as thermal conductivity measurements. Micro-structural investigations were conducted using scanning electron microscopy, transmission electron microscopy, and helium ion microscopy.

A specific interface formation was observed in all cases: metal oxide needles grow from the metal substrate surface into the precursor based coating with glass filler particles. In some cases they induce a crystallisation of the coatings glass fillers.

Due to its ultimate surface sensitivity and the quantitative elemental information, Low Energy Ion Scattering (LEIS) is a valuable tool for samples from many fields of science and technology [1]. The latest generation of instruments has made these properties available for routine analytical work, leading to a wider use of this technique. This has become possible by high sensitivity and high resolution analyzers in dedicated instruments. Main fields of application are heterogeneous catalysis, fuel cells and related areas, but also in thin film (ALD, PVD, CVD, etc.) research and characterization.

In addition to providing the elemental composition of the outermost atomic layer of a solid, the virtually non-destructive "static" depth profiling yields additional information from the same data. It allows access to the composition of the first few atomic layers below the surface, up to a depth of < 10 nm, without the complication of sputtering artefacts which are present in most other depth profiling techniques. Here, ions scattered in layers below the surface are recorded, which undergo an additional depth-proportional energy loss. Therefore, the signal from deeper layers is spread out on the energy scale, showing the distribution of the elements below the surface.

In this presentation we will demonstrate how LEIS evolved into a practical surface analytical technique. Examples from a variety of samples, including an automotive exhaust catalyst system and thin films, will be shown and discussed. The work on the automotive catalyst material shows how the active phase of the catalyst changes by ageing under working conditions. LEIS is capable of picking up these changes at the outermost layer, where the actual catalytic reaction takes place.

Work on thin film samples demonstrates how the thickness and conformity of the film can be characterized quickly and non-destructively. While for thicker films (> 5 - 10

nm) sputter depth profiling similar to SIMS or XPS is used, static depth profiling is applied to ultra-thin films. The signal from the outer layer can be separated from the in-depth signal, so both the quantification of the surface coverage for all elements as well as the thickness distributions within the film can be derived from a single measurement.

ASS-2-Or-7

Structure changes of copper in different supported catalysts

T01 Applied Surface Science

#ASS-2-Or-7

A. Oszkó, K. Markó, G. Merza, G. Pótári, A. Erdőhelyi.

University of Szeged - Szeged (Hungary).

Introduction

The surface changes of copper containing catalysts were characterized by XPS. Cu/CeO₂ samples were prepared by different methods and studied in the steam reforming of ethanol. Copper catalysts supported on activated carbon (AC) and MWCNT were tested in the oxidative carbonylation of methanol to produce dimethyl carbonate (DMC).

Experimental

XP spectra were taken with a SPECS instrument. Sample treatments were carried out in a catalysis cell (HPC) in flowing gases at atmospheric pressure. The HPC was directly connected to the analysis chamber of the XP instrument. The samples were treated the same way as usual in other catalytic reactions, e.g. in gas chromatography.

Results and discussion

Cu/CeO₂ prepared by impregnation showed the typical Cu²⁺ 2p doublet in the as received state. On the co-precipitated sample the satellites were less obvious. In this case the oxidation state was determined with the help of the Auger parameter and found that Cu is in the form of Cu⁺ and Cu²⁺. After oxidation both kinds of samples contained Cu²⁺. Reduction caused copper to reduce to metal on the impregnated sample, while an additional low binding energy component appeared on the co-precipitated sample. The ceria spectra were deconvoluted in all stages of the treatment. The Ce³⁺/Ce⁴⁺ ratio was determined from the Ce(III)/[Ce(III)+Ce(IV)] formula where Ce(III) and Ce(IV) denote the sum of the areas of all synthetic peaks present in the given oxidation state. The reduction degree did not change during

pretreatment. The steam reforming reaction led to the reduction of ceria on the impregnated sample. New peaks on the O 1s and C 1s spectra corresponded to -OH and C-H containing deposits on the catalyst. The reduction degree of ceria was much less on the co-precipitated sample, while an enhanced carbon deposition was observed.

Spectra taken on Cu/MWCNT showed that Cu^{2+} was present on the surface of the starting material. Copper reduced to its metallic state after reduction. The reaction with $\text{MeOH} + \text{O}_2 + \text{CO}$ mixture led to the re-oxidation of copper to mostly Cu^+ with some Cu^{2+} . The amount of the latter increased with reaction time. Only a slight change could be observed on the C 1s spectra. The O 1s spectra showed a complex structure with at least four oxygen components. AC supported copper was also active in DMC production. Several copper forms were identified during the reaction as proved by the Auger parameters and Auger peak positions. Oxygen from X=O, X-OH and -COOR species were present on the catalyst surface. These results contribute to the explanation of the reaction mechanism and to the understanding of the changes in catalytic activity.

Some unsolved problems, such as poor adhesion of coatings, currently limit the use of Mg alloys for orthopedic application. The present article aims to overcome these obstacles and improves the corrosion resistance of Mg alloys via combination between surface treatment and electrodeposition. The surface of Mg-0.8Ca-3Zn alloy was pretreated using micro-arc oxidation (MAO) to form an oxide layer upon which a top layer of fluoridated-hydroxyapatite (FHA) was electrodeposited. The corrosion behavior of both layers was evaluated in simulated body fluid (SBF) using linear polarization (LP), potentiodynamic polarization and electrochemical impedance techniques. Surface characterization of the untreated, MAO treated and FHA coated alloy was performed.

Scanning electron microscopic (SEM) examination shows that the MAO treated surface is completely covered by FHA layers (Figure 1) because the MAO oxide layer with high porosity offered considerable sites where FHA particles are easily incorporated. Combination between MAO and FHA coatings was also proved by XRD analysis which shows both peaks of MgO and FHA.

Electrochemical tests show that MAO of the Mg-Ca-Zn alloy surface significantly improves its corrosion resistance. The polarization resistance (R_p) of the MAO samples is 12000 ohm which is 5 times more than the untreated alloy (1530 ohm). FHA coat of the MAO treated samples further enhances corrosion resistance of the alloy as shown by the increase of R_p to 59000 ohm which is about 38 times higher than the untreated alloy. Pores blocking at MAO layer via FHA as top coat plays a

key role in obvious corrosion resistance enhancement.

Surface Wettability of Macroporous Anodized Aluminum Oxide

T01 Applied Surface Science

#ASS-8-Or-3

I. Buijnsters, R. Zhong, T. Natali, J.P. Celis.

KU Leuven - Leuven (Belgium).

Aluminum and its alloys are important industrial materials due to their low weight and good corrosion resistance. Porous anodized aluminum oxide (AAO) formed by the electrochemical anodization of Al has become a popular and highly versatile material for numerous applications in surface tribology (1), catalysis (2), and template synthesis of 1D nanostructures (3). Aluminum oxide itself is a hydrophilic material, but due to the controllable pore dimension and adjustable surface chemistry the porous AAO structures provide a great potential for producing surfaces with special wettability.

Here, we discuss the correlation between the structural characteristics and the wetting of AAO surfaces with large pore sizes (>100 nm). The roughness-induced wettability is examined for oxide films grown by a 2-step, hard anodization in phosphoric acid of 3 different concentrations using an Al alloy. This is done for as-synthesized AAO layers, after various degrees of pore widening by a wet chemical etching in phosphoric acid solution, and upon surface modification by Lauric acid or a silane. The as-grown AAO films feature structurally disordered pore architectures with average pore openings in the range 140-190 nm but with similar inter-pore distances of about 405 nm. The formation of such AAO structures induces a transition from slightly hydrophilic to moderately hydrophobic surfaces up to film thicknesses of about 5 μm . Increased hydrophobicity is obtained by pore opening and a maximum value of the water contact angle (WCA) of about 128° is measured for AAO arrays with a surface porosity close to 60% (see Figure). Higher surface porosity by prolonged wet chemical etching leads to a rapid decrease in the WCA as a result of the limited pore wall thickness and partial collapse of the dead-end pore structures. Modification of the AAO surfaces by Lauric acid results in 5° - 30° higher WCA's, whereas near-superhydrophobicity (WCA~ 146°) is realized by silane coating. The 'rose petal effect' of strongly hydrophobic wetting with high adhesive force on the produced AAO surfaces is explained by a partial penetration of water through capillary action into the dead-end pore cavities which leads to a wetting state in-between the Wenzel and Cassie states. Moreover, practical guidelines for the

synthesis of rough, highly porous AAO with controlled wettability are provided and the possibility of forming superhydrophobic surfaces is evaluated.

Surfactants are widely used to modify surfaces and interfaces properties. Unique cationic trimeric and tetrameric surfactants (Fig.1) were found to form liposome-like aggregates in solution (1, 2). Atomic force microscope (AFM) scans under the trimeric surfactant solution demonstrate the presence of large aggregates (ca. 100nm in diameter) surrounded by worm-like micelles on mica surface. We have investigated the normal and shear forces between two atomically smooth mica surfaces across this surfactant using the surface force balance (SFB) technique (Fig.2). Shear forces measured across the trimeric surfactant solution demonstrate ultra-low friction coefficient ($\mu=5 \times 10^{-5}$) under pressure of tens of atmospheres. The contribution of the compressed charged spheres to the ultra-low friction measured can be explained by the efficient hydration lubrication mechanism exist between the hydrated surfactant head-groups and the mica surface. A weak dependence of the friction coefficient to the shear rate or amplitude was observed. When the mica surface withdrawn from the surfactant solution a unique bilayer pattern was formed, covering large macroscopic area. A model for this surface pattern formation will be presented.

Compositional changes and formation of nanodroplets on GaN epilayer surfaces induced by normally incident 1 keV argon-ion sputtering

T01 Applied Surface Science

#ASS-8-Or-10

V. Venugopal ¹, K. Kumar ², K. Upadhyaya ², S.M. Shivaprasad ².

¹Division of Physics, School of Advanced Sciences, VIT University Chennai Campus - Chennai (India), ²International Center for Materials Science and Chemistry and Physics of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research - Bangalore (India).

Understanding the effect of low energy Ar⁺-ion bombardment on the structural and compositional changes [1] of GaN surfaces is crucial for controlling ion etching process [2] in order to fabricate GaN-based devices. Here we report the surface compositional changes leading to the formation of nanodots on epilayer of GaN on sapphire induced by normally incident 1 keV argon-ion sputtering at an ion flux of $\sim 2.81 \times 10^{14}$ ions/cm²/s studied by interrupting sputtering at 400 s, 800 s and 1200 s and *in-situ* characterization of the sputtered surfaces using XPS, under ultrahigh vacuum conditions. The core-level Ga 3d and N 1s spectra indicate dissociation of disordered Ga and N atoms and formation of metallic Ga, and surface re-organization beyond sputtering time of 800 s. The valence band spectra also confirm the formation of metallic gallium and disruption of Ga-N bonds of the GaN epilayer. AFM images of the epilayer surfaces sputtered to 1200 s indicate the formation of nanodroplets [Fig. 1] and EDX measurements indicate that these nanodroplets are Ga-rich. These hemispherical features are mainly located at the ion erosion modified steps on the epilayer. The lateral size and height range of these Ga droplets are 133 ± 16 nm and 15 ± 2 nm respectively, with a density of 1.64×10^8 cm⁻². The results indicate that preferential sputtering, which is not very pronounced due to strong bonding in GaN, is dominant till 800 s and the ion erosion modified steps are mainly responsible for the formation of nanodroplets with the possibility of threading dislocations in the epilayer acting as nucleation centers for the diffusing Ga adatoms. It is shown that the nanodroplets observed here can neither be explained by the continuum theory [3] nor its subsequent modifications that were applied to many III-V

semiconductors [4] to account for normally incident low energy ion induced pattern formation. The compositional changes accounts for the observation of the variation of the sheet resistance of the epilayer as a function of sputtering time. The effect of ion erosion modified surfaces on optical properties of GaN is also discussed.

Three dimensional Monte Carlo study of EBIC at metallic tip

T01 Applied Surface Science

#ASS-P2-05

J. Priesol, A. Šatka.

Institute of Electronics and Photonics, Slovak University of Technology, Ilkovičova 3, 812 19 - Bratislava (Slovakia).

Electron beam induced current (EBIC) as a scanning electron microscopy technique is well known method used in defect and failure analysis of semiconductor devices, for identification of buried junctions and determination of minority charge carrier properties [1]. In this contribution we report on the results of EBIC experiments performed using Schottky contact formed by a tungsten needle set onto the intentionally undoped, planar GaN layer coalesced on an etched nanorod array prepared on insulating sapphire substrate. EBIC line profiles extracted from EBIC maps of the vicinity of the contact area were used to determine the effective diffusion length L_{eff} of minority charge carriers. Furthermore, 3-D Monte Carlo (MC) statistical model has been developed to investigate the effect of various parameters to evaluation of EBIC line profiles at Schottky contact. Spatial distribution of generated charge carriers was calculated using well known models described by Joy [2] and others. Consequently, the diffusion of these carriers was simulated by means of random walk algorithm, whilst the surface recombination velocity was supposed to be $v_s = 0$. Carriers were considered to contribute to the EBIC signal after reaching the circularly shaped area defined onto the sample surface representing Schottky contact. Described MC model was used to investigate the influence of the energy of primary electrons E_{pe} , contact diameter d and bulk diffusion length L_{bulk} of minority carriers to the spatial distribution of recombining carriers and shape of EBIC line profiles. The experimental details, explanation of obtained results and their use in determination of diffusion length of minority carriers and interpretation of EBIC measurements will be discussed.

Isotropic and anisotropic dipeptide films through gas phase deposition

T01 Applied Surface Science

#ASS-9-Or-5

G. Demirel.

Gazi University - Ankara (Turkey).

Vertically aligned nanostructures have recently attracted increasing interest due to their unique properties and they have been exploited for a variety of applications including field emission devices, filter media, superhydrophobic surfaces, synthetic membranes, intracellular gene delivery devices, biosensors, composites, logic and memory devices, and numerous others. We demonstrated the fabrication and application of well-ordered and vertically aligned dipeptide nanostructures based on a simple gas phase deposition. Deposited nanostructures exhibited the superhydrophobic property with a very low sliding angle. Highly reproducible SERS data have also been obtained after combining deposited films with a thin layer of gold. In addition to these, directional peptide films were, for the first time, successfully fabricated based on the oblique angle deposition technique. We believe that such bio-inspired materials would have a great impact in several technological applications involving catalysis, tissue engineering and biosensors.

By anisotropic etching, pyramids structured silicon can be prepared using sodium hypochlorite for monocrystalline solar cells. Their influence on the reflectance of the silicon surface was studied to optimize the etching and reduce the optical losses of silicon surface more effectively. However, currently the reflectance of the pyramids structured silicon surface can only be reduced to above 10% in the visible range, which is still too high for high efficiency solar cells. Porous pyramids structured silicon is a promising antireflection coating to solve the problem of high surface reflectance in silicon solar cells. In this paper, a promising method for fabricating porous pyramids compound structure on silicon surface was proposed. The silicon surface was first texturized in NaOCl/C₂H₅OH and then electrochemically etched in HF/C₂H₅OH solution. The average reflectance of the surface in the range of 500-900 nm was as low as 5%. The surfaces prepared under optimized condition were investigated by Scanning Electron Microscopy (SEM) and Spectrophotometry (Fig.1).

²Sincrotrone Trieste, Strada Statale 14, km 163.5 - Basovizza-Trieste (Italy).

The adsorption and subsequent dissociation reaction of methanol on various model catalyst surfaces have attracted wide-spread attention due to the importance of this reaction used in direct methanol fuel cells (DMFCs), especially due to continuing research of new materials for DMFCs. Cerium oxide and tungsten oxide based systems have been a subject of interest due to their technological importance in a wide field of various electronic, optical, catalytic and gas sensing applications. The reactivity of cerium and tungsten oxide can be influenced by impregnation of the base material by any active metal, for example Pd, Pt, Au etc. The investigation of relations between the chemical and structural properties is often performed on so-called model systems. By deposition of a small amount of active metal on the surface of epitaxial cerium or tungsten oxide thin film we can prepare such well-defined model system.

In this work an adsorption of methanol on the surface of bare and metal doped (Pt, Pd, Au) epitaxial cerium or tungsten oxide layers was studied. The epitaxial cerium and tungsten oxide layers having (111) surface plane were prepared on Cu(111) and W(110) single-crystal surfaces. The crystallographic structure and epitaxial orientation of the layers were determined by reflexion high-energy electron diffraction (RHEED). The chemical state of the film and adsorbed species were investigated by photoelectron spectroscopy induced by X-ray source (XPS) and synchrotron radiation (SRPES).

The 30L adsorption was performed at low temperature of 140 K. The temperature of the sample was increased in several steps up to 600 K. At each step SRPES measurement with high surface sensitivity and energy resolution was performed. At low temperature multilayer adsorption of methanol was observed for all samples. With increasing temperature methanol decomposed and the different species

resulted from the decomposition process were observed. The process of methanol decomposition was investigated by measurement of O1s, C1s and valence band spectra. The changes of the structure as well as of electronic state were deduced from the core level spectra.

The decomposition pathway of methanol can be followed mainly by observation of the C1s spectra (see figure 1). The multilayer adsorption of methanol was observed for all samples at the temperature of 110 K. With increasing temperature methoxy was formed on the surface by OH bond scission (200 K). Dehydrogenation of the bonded methoxy species proceeded via formyl to CO. Carbon formation due to the partial decomposition of CO was found on Pt-CeO_x, Pd-CeO_x and Pt-WO_x systems. All traces of residual carbon disappeared at high temperatures (500 K for M-CeO_x, 400 K for Pt-WO_x). Resistance to the carbon poisoning is important for using of these systems in the real catalytic applications. By comparing the results obtained for different substrates we have shown that the clean surface with no adsorbed species was reached at the temperature of 400 K in the case of tungsten oxide based systems and at 600 K for cerium oxide based systems, respectively. Encapsulation of Pt clusters at temperatures above 570 K was deduced from the presence of CO species on the surface. The C 1s spectra from Pd-CeO_x have indicated also low amount of formate and formaldehyde species above 300 K.

ASS-P3-04

Determination and Characterization of Edge Flaws in Laser Diced Thin Silicon Wafers

T01 Applied Surface Science

#ASS-P3-04

G. Hayes, H. Fischer, J.E. Bullema.

TNO - Eindhoven (Netherlands).

As silicon dies become thinner to meet current device demands, residual material damage from laser dicing has a large impact on final die strength. These strength limiting flaws in thin dies need to be characterized and quantified in order to utilize laser dicing in industrial practice. Furthermore, an increase in strength could potentially be realized with the removal and repair of the residual edge damage. The edge flaws and residual material damage associated with laser dicing thin (120 μ m) silicon wafers were characterized via electron backscatter diffraction (EBSD), atomic force microscopy (AFM), scanning thermal microscopy (S μ TM), and scanning electron microscopy (SEM). Additionally, the hardness and Young's modulus of the damaged edge zone was characterized via nanoindentation. The extent of edge flaws in combination with a damaged edge zone is discussed in relation to the experimentally mechanical properties. The reported mechanical properties, and corresponding damaged zone investigation shows the effectiveness and viability of surface science techniques to industrial laser cutting applications. The edge damage was characterized in terms of crystallinity, composition, and thermal and mechanical properties. Finally, the removal of the damaged edge zone, along with edge flaws via chemical etching is presented.

ASS-7-Or-3

Enhancement of surface properties on commercial polymer packaging films using various surface treatment processes (fluorination and plasma)

T01 Applied Surface Science

#ASS-7-Or-3

J. Peyroux ¹, M. Dubois ¹, E. Tomasella ¹, E. Petit ¹, D. Flahaut ².

¹Clermont Université, Université Blaise Pascal, Institut de Chimie de Clermont-Ferrand (UMR 6296) - Clermont Ferrand (France), ²Université de Pau et des Pays de l'Adour, IPREM/ECP (UMR 5254) - Pau (France).

Commonly used polymer packaging films have not only many advantages, such as low cost and processability but exhibit also few drawbacks such as poor adhesion, printability, barrier properties and low chemical resistance. Furthermore, it is also possible to obtain the whole articles from special polymers or with multilayer packaging films but these kinds of process remain limited due to the high cost and a high complexity of synthesis. The present work focuses on the change of the surface properties by both **fluorination and plasma treatments**; their combinations are also under investigations.

Fluorination treatment process is known to improve polymers surface properties. It is a diffusion-controlled process which may be described as a heterogeneous reaction between a gas (F₂ pure or mixed with other gases) with the polymer surface. This method modifies only the upper surface layer in order to reach a hydrophilic/phobic surface depending on the gaseous mixture. Concerning the bulk properties, they remain unchanged. This process, a safe technology, displays a lot of advantages which allow it to be used for industrial applications. Different fluorination conditions as well as two fluorinating agents, F₂ and atomic fluorine, were investigated with various commercial polymers. Modifications of the surface layer have been characterized using various complementary techniques such as Fourier Transform Infrared spectroscopy, high resolution solid state Nuclear Magnetic Resonance (¹⁹F) which are suitable to determine the nature of the C-F bonding and the fluorinated groups. X-ray Photoelectron Spectroscopy was also performed to

extract the surface chemical compositions. The first main objective is to understand the different fluorination mechanisms. The resulting properties were then studied showing that the fluorinated layer reduces the friction coefficient and improves the chemical resistance. To complete our study, measurements of surface energy have been also performed underlining the enhancement of the adhesion and printability properties with a higher polar component.

The second strategy consists in **plasma treatments**. Several experiments were carried out, first, etching treatments using Argon plasma, and then, reactive treatments with gaseous mixture plasma (O_2 , N_2). As after fluorination, surface properties of polymer films treated by plasma have been investigated. Composition and morphology of the films were analyzed by contact angle measurements, and XPS. Measurements of surface energy were realized to define the polarity of the polymer films. The main objective is to improve the surface wettability to obtain a better adhesion property. Plasma treatments result in significant changes of the surfaces both in roughness and in composition. Changes of topography and chemical composition convert the polymer surface into highly hydrophilic character, which mainly depends on the roughness state and the contents of oxygenated or nitrogen containing groups at the surface. The O/N ratios were obtained from XPS analysis and have revealed that CO, CN bonds are the key factor for the enhancement of the polymer surface hydrophilicity. The roughness of the surface was also improved at the micrometric scale that influences the surface hydrophilicity.

A study of porous structure of PEG-mediated silica

T01 Applied Surface Science

#ASS-P1-14

O. Gorbunova, O.N. Baklanova, T.I. Gulyaeva.

Institute of hydrocarbon processing, SB RAS - Omsk (Russian federation).

Over the past few decades, many papers devoted to the preparation and application of various colloidal and micro-heterogeneous forms of silica with a developed surface (sols, gels and powders) had been published [1,2]. According to various estimates, from 60 to 80% of the surface-modified materials are made on the basis of silica due to their very considerable merit. First of all, it is possible to vary its structural characteristics (specific surface area, diameter and pore volume, particle size and shape) in a wide range. It is worth to note their availability and relative cheapness. This work is devoted to the synthesis and characterization of porous silica materials based on tetraethoxysilane (TEOS) and polyethylene glycol (PEG) used as the template agent. We studied the effect of PEG macromolecules length and its concentration on the characteristics of the prepared silica porous structure. The synthesis was performed using the method discussed in detail in [3]. We varied the molecular weight of polyethylene glycol from 1300 to 100000 (at constant polymer concentration 0.005 mol/L) as well as for a fixed PEG molecular weight we changed the concentration from 0.0001 to 0.1 mol/L.

The amount of PEG in the SiO₂-PEG composites was determined by thermogravimetric method with STA-449C device (Netzsch). Adsorption-desorption isotherms of nitrogen at 77 K were obtained with the ASAP-2020 device (Micromeritics). Textural characteristics of the calcined silica material (specific surface area, pore volume and pore size) were obtained using different methods: non-local density functional theory (NL DFT), Barrett - Joyner - Halendy method (BJH) and comparative α_S - method.

It is shown that using PEG as template agent depending on its molecular weight and concentration it is possible to prepare mesoporous ($A_{BET}=620 \text{ m}^2/\text{g}$, $V_{\Sigma}=0.43 \text{ cm}^3/\text{g}$, $V_{\text{micro}}(\alpha_s)=0.038 \text{ cm}^3/\text{g}$) or microporous ($A_{BET}=657 \text{ m}^2/\text{g}$, $V_{\Sigma}=0.27 \text{ cm}^3/\text{g}$, $V_{\text{micro}}(\alpha_s)=0.26 \text{ cm}^3/\text{g}$) silica materials.

TAS - Trieste (Italy), ⁶Departamento de Física Teórica de la Materia Condensada, Universidad Autónoma de Madrid, 28049, - Madrid (Spain).

Self-assembly of organic molecules on surfaces has attracted important attention due to their promising applications in nanotechnology and biotechnology. From these organised molecular units arise the possibility of complex functions like molecular recognition, sensing, electronic properties, conductivity, catalysis, chirality and chemical reactivity that are important in nanoscience.

Amino-acids contain a simple structure and can be used as model to study biomolecule-surface interactions, which can assist in the understanding of more complex systems. Among all the amino-acids, Proline is the only cyclic amino-acid. Therefore, the local adsorption geometry and the two dimensional self-assembly of this molecule is of particular interest because the imino (NH) group is fixed rigidly in the pyrrolidine ring, limiting the conformational mobility of the N-H bond with respect to the COOH group.

Previous studies have been reported by Raval's group on the dense (4x2) overlayer of the amino acid, (S)-proline on Cu(110) surface have proposed one specific structural model in which the juxtaposition of molecules leads to the formation of one-dimensional hydrogen bonded prolate chains directed along the [1-10] direction,

where this (4x2) phase possesses both prolate conformers in a 50:50 distribution [1-3].

Here, We report an original multi-technique experimental approach of (4x2) proline/Cu(110) system based on STM, electron-spectroscopies and diffraction techniques such as XPS, XANES, and XPD [4]. This study includes the first spectroscopy probe for the two different proline conformers orientation on Cu(110) even if the total amount of molecules present the same chemical form, and an accurate molecular model including information of molecular angles respect to the surface. We have confirmed by XPS spectra that S-Proline molecules adsorb on the Cu(110) surface as anionic species, and only one type of chemical species are adsorbed on the surface. Furthermore, this multi-technique study including DFT confirms that prolate anion adsorption adopts two different orientation respects to the surface, nearly flat and upright rings, which flip between the neighbour rows to stabilize molecular network. Two main reasons can drive this unusual adsorption model, first due to steric effect constrains, meaning that the molecules are required to optimize surface space, and second the flat-upright model favours the interaction between molecules by H-bonding which partially drives the self-assembled network of the molecules on the surface. In summary, by the complementary use of several techniques and theoretical calculations we have obtained a molecular-model of (4x2) proline/Cu(110) adsorption, which includes information about self-assembly of biomolecules on surfaces, chemical state of the adsorbates and molecular orientation respect to the surface, meaning models at atomic levels to elucidate the understanding mechanisms for molecular self-organization.

Titanium dioxide is a well-known photocatalytic material with a wide range of applications such as water treatment [1], air purification [2], self-cleaning [3] and anti-microbial hygienic surfaces [4] due to its physical and chemical stability, its ability to degrade a wide range of organic pollutants, low-cost, and non-toxicity [5]. In this study, TiO₂ coatings are deposited by reactive magnetron sputtering on heated quartz glass substrates (1000°C) previously covered by Au thin layer (<100 nm) at different pressures and draw distances. The morphology of the coatings is investigated as a function of deposition parameters in order to increase the film specific area. The obtained coatings were characterized by X-ray diffraction, scanning electron microscopy and by measurement of water angle contact variations. The photocatalytic activity was assessed by using the Orange G decomposition upon the UV illumination. Finally, microstructural and photocatalytic properties of the obtained coatings are compared with those of the films prepared under the same conditions but without Au thin interface layer.

ASS-2-Or-4

Modification of metal films with the aid of atomically thin oxide layers

T01 Applied Surface Science

#ASS-2-Or-4

L. Deak, L. Óvári, I. Szenti, Z. Kónya.

MTA-SZTE Reaction Kinetics and Surface Chemistry Research Group,
Hungarian Academy of Sciences - Szeged (Hungary).

The study of atomically thin metal deposits and metal oxide films is of fundamental interest in relation to heterogeneous catalysis, production of microelectronic devices, corrosion protection of metals, magnetic tunnel junctions, dielectric barriers [1], etc. Although the alteration of electronic properties of metal particles separated from an other metal by atomically thin oxide layer is gaining interest [2], most work apply single crystal for one of the metals. We addressed the modification of rhodium and molybdenum films through formation of ultrathin oxide layers on them in correlation with controlling the work function and catalytic performance of rhodium and preparation of metal-insulator-metal structures. Monometallic and bimetallic layers formed by PVD on moderately O-deficient $\text{TiO}_2(110)$ single crystals were characterized by AES, XPS, ISS, TPD and work function (WF) measurements.

Rh deposition led to electron transfer from the metal towards the $\text{TiO}_2(110)$ surface below 0.1 monolayer (ML) Rh coverage. Annealing of titania supported Rh multilayers at 950 K in UHV resulted in the surface diffusion of titanium and oxygen ions and formation of a few atomic layer thick titania overlayer in a self-limited way with definite, O-deficient stoichiometry and strongly suppressed capability for CO adsorption. The accompanying 0.3-0.6 eV WF increase at $\Theta_{\text{Rh}}=2\text{-}6\text{ML}$ can be attributed to the presence of a TiO_x dipole layer consisting of positive Ti ions at the metal-oxide interface and negative O ions in the topmost position. Deencapsulation, i.e. diffusion of titania overlayer back to the substrate was observed above 800 K on a TiO_2 sample less reduced in its bulk, revealing the role of both the bulk and surface stoichiometry of the substrate in the encapsulation process. Enhancement of the thickness of Rh multilayers supported on the $\text{TiO}_2(110)$ single crystal led to an increase in the temperature characteristic for the completion of decoration by TiO_x layer due to hampered ion diffusion from the $\text{TiO}_2(110)$ surface.

To prepare a metal-oxide-metal structure, the growth and properties of a second Rh layer has also been studied. The deposition of Rh at 300-500 K on the TiO_x layer, covering Rh multilayer resulted in the growth of particles with similar height up to above one monolayer coverage. At 200 K deposition temperature a 2D Rh layer formed up to 1ML metal coverage, indicating that at this temperature the mixing of second Rh layer with the ultrathin oxide is absent.

Mo deposits displayed high reactivity with the titania substrate and were oxidized even at 300 K accompanied by the reduction of titania as revealed by XPS. Annealing the 2.7 ML thick Mo layer to 1000 K promoted further oxidation and gave a substantially modified surface with WF of 5.7 eV. Deposition of Rh on both clean and oxidized Mo films resulted in 2D film growth up to 1ML coverage, corresponding to a remarkable increase in Rh dispersion due to the presence of Mo, being relevant to the enhancement of catalytic performance of Rh particles.

REDUCED PREFERENTIAL SPUTTERING OF TiO₂ AND Ta₂O₅ USING ARGON CLUSTER ION BOMBARDMENT

T01 Applied Surface Science

#ASS-5-Or-4

M. Baker ¹, R. Grilli ¹, R. Simpson ², P. Mack ², R. White ².

¹University of Surrey - Guildford (United kingdom), ²ThermoFisher Scientific - East Grinstead (United kingdom).

TiO₂ and Ta₂O₅ are technologically important thin film materials for various applications. XPS is a widely used technique to investigate chemical state and surface composition and Ar⁺ ion sputtering is employed to remove surface contaminants and to investigate the chemical composition as a function of depth. However, both TiO₂ and Ta₂O₅ are known to suffer from the preferential sputtering of oxygen when etched under typical Ar⁺ ion gun conditions for XPS analysis. Hence, sub-stoichiometric metal oxides are formed and the XPS data is no longer representative of the native material.

In this study, TiO₂ and Ta₂O₅ thin films and a TiO₂ single crystal have been exposed to ion bombardment from a 3 keV Ar⁺ ion beam, 200 eV Ar⁺ ion beam and a novel 4 keV Ar⁺ cluster beam. The surfaces have then been analysed by XPS to determine the resulting chemical composition and changes to the metal oxidation state.

The most substantial preferential sputtering takes place for 3 keV Ar⁺ bombardment. Lowering the Ar⁺ beam voltage to 200 eV slightly reduces the extent of preferential sputtering. However, using the 4 keV Ar⁺ cluster beam results in a substantial reduction in preferential sputtering for TiO₂ and no observable preferential sputtering for Ta₂O₅. The reduced damage obtainable with the cluster beam has significant implications in the accurate compositional analysis of many technologically important metal oxide thin films and the potential for widespread use of this novel Ar⁺ cluster beam source will be discussed.

ESD/ASS-P3-09

PVdF/HFP membranes with nanostructured titania fillers as a matrix for porous polymer electrolyte

T01 Applied Surface Science

#ESD/ASS-P3-09

P. Polrolniczak, M. Walkowiak, L. Horla.

Institute of Non-Ferrous Metals Branch in Poznan Central Laboratory of Batteries and Cells - Poznan (Poland).

Polymer electrolytes have received considerable attention, because of their potential in solid-state batteries, electrochromic devices and fundamental research of ion transport in disordered phases [1]. The use of polymer electrolytes make batteries safer, lighter and more flexible in shape. Amongst the polymer electrolytes, PVdF-HFP films have received attention as promising host matrix for polymer electrolytes because of its excellent mechanical strength and electrochemical stability [2]. Kim et al. [3] found that the addition of nanoscale inorganic fillers, such as alumina (Al_2O_3), silica (SiO_2) or titania (TiO_2) to the polymer electrolyte results in the improvements of ionic conductivity and absorption level of electrolyte solution.

Nanostructured titanium oxide TiO_2 and lithium titanate $\text{Li}_4\text{Ti}_5\text{O}_{12}$ with different morphologies (nanowires, spheres, particles) was obtained using solvothermal synthesis methods. Synthesized nanomaterials were applied as fillers for composite polymer membranes PVdF/HFP. Composite membranes were prepared according to the so-called Bellcore process. By activating in lithium conducting gel electrolytes have been obtained.

Morphology, porosity, thermal stability and electrolyte uptake of prepared composite membranes were evaluated. For determining the electrochemical stability window of the composite polymer electrolytes, a linear sweep voltammetry experiments were performed. Temperature dependence of ionic conductivity by electrochemical impedance spectroscopy was also measured. It was found that when titanium oxide was mixed with PVdF/HFP membrane, the impedance spectroscopy showed that the room temperature conductivity increased from $0,54 \cdot 10^{-3} \text{ S cm}^{-1}$ to $1,43 \cdot 10^{-3} \text{ S cm}^{-1}$.

SE/ASS-1-Or-8

The liquid-phase mass transfer of material in the film-substrate irradiated by intense energy streams

T01 Applied Surface Science

#SE/ASS-1-Or-8

A. Leivi.

Yalovets A. - Chelyabinsk (Russian federation).

Now the treatment by intense energy streams (electron or ion beams, plasma) with power density $\geq 10^6$ W/cm² is widely used for improvement of material properties. The intense charge particle irradiation of systems like support films is used for material adhesion improvement as a result of layer mixing. The mass transfer in the treated material is very important for material property modification.

The main mixing mechanisms are Richtmyer-Meshkov instability (RMI) on the interface, thermoactivated diffusion and thermocapillary convection.

The quantitative depth estimations for mixing zone caused by thermostimulated diffusion for melting lifetime are about 1 mkm. Experimental mixing depths are considerably greater and approach 10-20 mkm. The role of thermostimulated diffusion is essential in thin layers (tens- hundreds nm) [1]. In ref. [2] it has been shown RMI on the interface can cause near-surface mixing only in case of surface perturbations corresponding to the wave number range which is defined by irradiation regime. Therefore for such mixing the special surface treatment is needed.

The irradiation can cause nonuniform target depth heating. If the target temperature increases with depth there is necessary condition for thermocapillary convection. The target microrelief induces the surface temperature perturbation. For simulation mass transfer the mathematical model including the system of continuum mechanics equations, the kinetic equation for high-speed electron, the wide-range state equation has been developed.

To research roles of thermoactivated diffusion and thermocapillary convection in mixing the mathematical model has been developed. It describes medium flow as a result of irradiation taking into account mentioned mechanisms.

The numerical research reveals the main near-surface mixing mechanism of melted medium is thermocapillary convection. But the pulse duration is necessary to be less than characteristic heat conduction time to arise convective flow. The mixing zone is 1-20 mkm depending on the irradiation regime.

The research was supported by research engineering of FSSFEI HPE "SUSU" (NRU), conducted within the limits of the state assignment of the Ministry of Education and Science of the Russian Federation (№ 2012043-GZ04, № 2012060-GZ21).

ASS-7-Or-6

SiC coating layers of nano sizes.

T01 Applied Surface Science

#ASS-7-Or-6

M. Menyhard, A. Barna, S. Gurban, L. Kotis, J.L. Labar, A. Sulyok, A.L. Tóth, A. Pongracz, E. Vazsonyi.

**Research Centre for Natural Sciences, Hungarian Academy of Sciences,
Institute for Technical Physics and Materials Science - Budapest (Hungary).**

In modern technologies one frequently needs coating of small sizes in all dimensions. We will report on the production of amorphous SiC coating meeting such demand. C/Si multilayer was produced by sputtering. The C layer, 20nm, was amorphous, while the Si layer, 22nm, was polycrystalline. This sample was irradiated by Ga⁺ applying various fluences ($10\text{-}120 \times 10^{15}$ ions/cm²) and projectile energies (10- 30 keV). The irradiation produced a mixed layer the size of which (in the range of 2-8 nm) could be tailored by using appropriate fluence and projectile energy. AES analysis based on the C peak shape could show that some of the mixed Si and C formed silicon carbide. TEM studies proved that the SiC was amorphous. The amount and distribution of SiC could be altered by changing the irradiation conditions [1].

For checking the chemical resistance of the coating layer $100 \times 100 \mu\text{m}^2$ areas were irradiated by various fluences ($10, 20, 40, 80 \times 10^{15}$ ions/cm²) of 30 keV Ga⁺ ions, creating various thicknesses (3-8 nm) of SiC rich layers. The thickness of the C cover layer varied accordingly. These regions were imbedded in the unaltered layer system. First the carbon layer was removed by oxidation at 500°C, then the remainder Si or/and SiC covered surface was etched applying various etchants generally used for polysilicon. Because of the lower etching rate of the SiC covered surface, rSiC, columns developed on the surface, Fig.1. Measuring the disappearance of the columns the relative etching rate could be estimated. In the case of a 3 nm thick SiC layer the relative etching rate of $r_{\text{SiC}}/r_{\text{polySi}} < 10^{-3}$ was found.

Proximity effect on the superconductor-normal metal hybrid nanostructures: Scanning tunneling microscopy and spectroscopy

T01 Applied Surface Science

#ASS-10-Or-8

H. Kim, Y. Yoshida, Y. Hasegawa.

The Institute for Solid State Physics, The University of Tokyo - Kashiwa (Japan).

A superconductor (SC) in a good metallic contact with a normal metal (NM) induces superconducting properties in NM within a certain distance from their interface, as well as electronic properties, including the local density of states (DOS). Recently, research of the proximity effect has been extensively studied thanks to technological advances in the fabrication of complex mesoscopic structures. Nevertheless, many of these works, mostly characterized via electrical conductance measurements, addressed macroscopic properties of the samples, thus obtaining average rather than local information.

Here, we investigated proximity effect at the interface between superconducting two-dimensional (2D) Pb islands and a single-atomic-layer surface metal, known as the striped incommensurate (SIC) phase of the Pb formed on Si(111) surfaces by performing local spectroscopy with a low temperature scanning tunneling microscope (STM). We observed tunneling spectra with a fully-developed gap in a normal metal side around superconducting islands and spatial decaying behaviors of the induced gap with the distance from the SC-NM boundary. Additionally, we study influences of the proximity effect by the presence of the external magnetic field, which suppress the superconducting properties in both sides. The experimental results are compared with the predictions of the quasiclassical theory based on the Usadel equation.

SE/ASS-1-Or-4

Investigation of tribochemical interaction between polytetrafluoroethylene and silicon oxide surfaces

T01 Applied Surface Science

#SE/ASS-1-Or-4

M. Copuroglu, A. Ucar, S. Suzer.

Bilkent University - Ankara (Turkey).

Tribochemical interaction between surfaces, and identification of the chemical and physical nature of this interaction are of great academical as well as commercial importance. In addition, hydrophobic surfaces have a wide range of applications in various areas; and therefore there has been a great deal of interest in enhancing the hydrophobicity of surfaces. The aim of this work is thus to investigate the tribochemical interaction between thermally-oxidized silicon and polytetrafluoroethylene (PTFE). A simple rig was designed to actualize a friction motion between the surfaces with an approximate angle of 45° employing also an inclination along the motion in order to bring about a gradual tribochemical interaction. Additionally, some patterns were sketched on the SiO_x surface using the PTFE piece to investigate any potential change in the hydrophobicity of the surface. The nature of the interaction was characterized by X-ray photoelectron spectroscopy (XPS) and scanning electron microscopy (SEM). Contact angle measurements were carried out to characterize and monitor the hydrophobicity of the SiO_x surface. XPS measurements were performed for the associated elements (C, F, O, and Si) and the relative binding energy peak intensities/areas of these elements were monitored and evaluated in a detailed manner. The results revealed that PTFE could indeed be transferred onto SiO_x surfaces even in the case of the application of the friction at relatively small forces. The SEM images taken demonstrated that some morphological changes could be imparted to the SiO_x surface. Contact angle measurement results showed that upon PTFE transfer the hydrophobicity of the SiO_x surface could be significantly enhanced, which might also depend upon the pattern sketched onto the surface. A contact angle value as high as $101 \pm 5^\circ$ was obtained.

The field of biosensors is a very attractive field of research. Indeed, biosensors gather the selectivity and sensitivity of a biological compound with power of detection. Porous silicon (PS) appears as the ideal candidate to be linked with biological molecules through its special features such as the high specific surface area and the luminescence property[1,2]. The work we propose is to detect the presence of organophosphates(OP) pesticides and heavy metals traces in the agricultural environment by an amperometric detection using a PS biosensors based on the immobilization of the Acetylcholinesterase (AChE) because its catalytic activity is inhibited by the traces of OP pesticides[3]. The surfaces was characterized by SEM (scanning electron microscope) as shown in the pictures below and the FTIR (Fourier Transform Infrared spectroscopy) where we have the appearance of the Si-H bonds at 2085 cm⁻¹ (Si-H), 2112 cm⁻¹ (Si-H₂) et 2135 cm⁻¹ (Si-H₃) which allow to form Si-C bonds and then link the enzyme.

In-situ oxidation of Au, Ag and Cu studied with Ambient Pressure Photoelectron Spectroscopy: An attempt to bridge the Pressure-Gap in Heterogeneous Catalysis

T01 Applied Surface Science

#ASS-3-Or-1

K. Roy, C.P. Vinod, C.S. Gopinath.

CSIR-National Chemical Laboratory - Pune (India).

The world of heterogeneous catalysis has been enriched by the development of modern surface science techniques which can actually monitor surface properties under reaction conditions. One of these state-of-the-art *operando* techniques is the Ambient Pressure Photoelectron Spectroscopy (APPEs)¹. We present here the oxidation of coinage metal group (Au, Ag, Cu) elements studied under *in-situ* conditions by a laboratory-APPEs commissioned recently at CSIR-NCL, Pune². Interaction of oxygen with polycrystalline foils of Au, Ag and Cu from UHV to 1 mbar pressure and up to 773 K has been studied. Results show Au is inert, Ag and Cu can be totally oxidized. Diffusion of oxygen into subsurfaces of Ag occurs, which is a precursor for oxidation. A pictorial representation of the abstract is shown in Figure 1. No oxide formation could be observed with Au. Ag behaves mildly; formation of subsurface oxide species at 600 K and 1 mbar O₂ pressure demonstrates this fact. However, Cu is prone to react with oxygen and complete surface oxidation to CuO was observed at 1 mbar O₂ and ≥ 600 K. Indeed there is a systematic oxidation of Cu metal to Cu₂O, Cu₂O + CuO and finally to CuO with increasing temperature at 1 mbar O₂ pressure (Figure 2). This study shows the capability of laboratory-APPEs to understand material surfaces under working conditions or closer to that.

Metal oxides have recently attracted enormous attention due to their applications in a variety of fields such as catalysis, chemical sensors, solar cells, and electronic devices. Vibrational spectroscopy is among the most powerful analytic techniques for understanding adsorption and reactions on catalyst surfaces. In this contribution, the structure and reactivity of TiO₂ and ZnO surfaces are investigated using high-resolution electron energy loss spectroscopy (HREELS) and a novel ultrahigh vacuum (UHV) FTIR spectroscopy.¹

One of the important applications of TiO₂ is the reduction of NO_x released when fossil or other nitrogen containing fuels are burned. We determined the adsorbate structure of NO and its reaction products N₂O₂, N₂O, and NO₂ on rutile TiO₂ by combining UHV-FTIRS with ab initio periodically embedded cluster calculations.² These reactions are important for the photo-catalytic reduction of NO in exhaust gas, but yet little is known about the mechanisms or the intermediates involved. Our consistent experimental and theoretical results made it possible to assign the bands observed in the UHV-FTIR spectra to nine species which are formed upon adsorption and reaction of NO on rutile TiO₂. After adsorption on the TiO₂ surface NO first dimerizes to N₂O₂ which is decomposed to N₂O and an oxygen atom attached to the TiO₂ surface, probably bound to a defect or at a (step) edge. The oxygen atom can later react with another NO molecule to form NO₂.

Hydrogen transfer on metal oxide surfaces is a fundamental process in heterogeneous catalysis and photocatalysis. In general, oxide surfaces expose

unsaturated sites of oxygen and metal ions where serve as Lewis base and acid sites, respectively. The cooperative interplay between these sites plays a crucial role for the activation of surface reactions involving hydrogen transfer. Here, we present a combined experimental and theoretical study of NH₃ adsorption on both ZnO single crystals and powder surfaces. A comprehensive and atomistic picture of the interfacial chemistry of NH₃ on ZnO has been established by the surface science study on well-characterized ZnO single-crystal and powder surfaces by HREELS, UHV-FTIR and thermal desorption spectroscopy (TDS) in conjunction with accurate density function theoretical (DFT) calculations and provide consistent evidence for the unusual partial dissociation of chemisorbed NH₃ on ZnO(10 0) surface, which occurs only at full monolayer via hydrogen transfer to the neighbouring O²⁻ base sites leading to coexistence of NH₃, NH₂ and isolated OH groups in a (2x1) superstructure. The unambiguous fingerprint of this hydrogen transfer is an OH band (3607 cm⁻¹) observed for both single crystal and powder samples and fully corroborated by theoretical calculations. The unexpected hydrogen transfer between adsorbed NH₃ and surface O is a consequence of the complex interplay of multiple factors including H-bonding, steric repulsion and pK_a.³

The surface-assisted synthesis of adsorbed organic nanostructures is a powerful bottom-up approach towards functional surfaces for applications in catalysis, sensor systems, or organic electronics. A major challenge of this approach is that most organic reactions require a solvent and thus cannot be applied to "dry" surfaces in ultra-high vacuum (UHV). An exception is the Ullmann reaction, which achieves C-C coupling between haloarene molecules using metallic Cu and has been employed to prepare one- and two-dimensional (1D/2D) polymers on metal surfaces. Here, we used bromo-terphenyl precursors in a UHV-compatible variant of the Ullmann reaction to synthesize cyclo-octadecaphenylene (hyperbenzene), a novel hexagonal

macrocycle consisting of 18 phenylene units, on a Cu(111) surface. The molecules form close-packed islands with a hexagonal unit cell. Formation and structure of hyperbenzene on Cu(111) were studied with scanning tunneling microscopy, X-ray photoelectron spectroscopy, and first-principles theory. The lack of previous reports on this molecule likely reflects the fact that synthesis in solution, without the stabilizing template effects of the hexagonal Cu(111) substrate, is difficult to achieve. The large inner diameter of the hyperbenzene molecules of 2.13 nm makes them interesting candidates for nanotroughs that can enclose metal particles or organic molecules. Besides these large hydrocarbon molecules, the surface-assisted formation of novel zigzag-shaped 1D organometallic coordination polymers consisting of Cu-bridged terphenylene units will be discussed.

We report a study on treatment of flat glass surfaces by ambient air atmospheric pressure plasma generated by a dielectric barrier discharge (DBD) with coplanar arrangement of electrode system – the so called Diffuse Coplanar Surface Barrier Discharge (DCSBD) [1]. The DCSBD atmospheric plasma system (Roplass, Czech Rep.) is made from multiple parallel stripline molybdenum electrodes embedded in 96% alumina. Dimensions of the alumina ceramic of DCSBD system are $a = 93$ mm in width and $b = 230$ mm in height and the total plasma area is about 80 mm \times 200 mm. The 16 pairs of molybdenum comb-shape electrodes of width and inter-electrode distance $c = 1.5$ mm and $d = 1$ mm, respectively, were printed by green-tape technique on a 0.5 mm thick flat ceramic plate. The plasma is generated on the ceramic surface in thin 0.3 mm layer. We observed an influence of a glass on DCSBD plasma in respect to glass-ceramic distance z . The DCSBD plasma consists of two optically different segments: the diffuse plasma and the streamer plasma. We found that the introduction of a glass into DCSBD plasma led to increase of the diffuse plasma width w . This was explained mainly as a consequence of Meek's breakdown criterion [2]. The study of a water contact angle with respect to glass-ceramic distance z showed that water contact angle depends strictly on z in small interval between 0.1 mm $< z < 0.6$ mm where the most effective treatment occurred. The X-ray Photoelectron Spectroscopy (XPS) technique was used to investigate the changes in surface chemistry before and after the plasma treatment of a glass. The

results are summarized in Table 1. We found that the DCSBD plasma treatment for 3 s led to decrease of carbon concentration and C/Si ratio from 15 at.% to 4 at.% and from 0.69 to 0.15, respectively. The detailed study on high-resolution C1s peak shown that the plasma treatment for 3 s decreased C–C or C–H bonds concentrations while the concentrations of C–O and O–C=O bonds increased. Since the C–C and C–H bonds are related with the initial surface hydrocarbon contaminants this shows that the plasma treatment exhibits the cleaning effect of glass surface. Saturation on total amount of carbon reached after 3 s can be explained by fast accumulation of the carbon contaminants from ambient air during transportation of samples [3].

ESD/ASS-P3-13

Raman characterization of aluminium induced crystallization of hydrogenated amorphous silicon (a-Si:H) deposited by PECVD: Effect of aluminum film thickness.

T01 Applied Surface Science

#ESD/ASS-P3-13

F. Kezzoula.

CRTSE - Algiers (Algeria).

The crystallization of the amorphous silicon (or formation of polycrystalline silicon) deposited on various and inexpensive substrates (glass, ceramics....) is into full today exploration because it offers the advantages of low costs and a great stability. The crystallization induced by aluminum (AlC) was studied during several decades [1]; it seems that this kind of crystallization technique recently gained an attention increased in the field of the devices in thin layers. The thickness of the aluminum layer can influence various parameters in the AlC process as the grains [2], the temperature of crystallization, the homogeneity of the poly-silicon layer.

In this contribution, we have deposited a 100 nm thickness of hydrogenated amorphous silicon layer by PECVD on a glass (Corning) substrate. A aluminum layer was deposited on the a-Si:H layer with various thicknesses (10 nm, 20 nm and 100 nm) in order to form the Al/a-Si:H/Glass structure. The study of the crystallization of this Al/a-Si:H/Glass structure according to the thickness of the aluminum layer was carried out by using Raman spectroscopy and X-rays diffraction.

The Raman spectra show a crystallization of all the layers of amorphous silicon for the various thicknesses and the durations of annealing. These spectra show the presence of the peaks located around 519 cm^{-1} and 520.6 cm^{-1} indiquant thus a crystallization of all the layers, except for the layer of 100nm aluminum thickness annealed during 6 hours (Fig c). Where it is noticed that his spectrum is composed of two distinct peaks, a peak is located at the surrounding of 480 cm^{-1} which represents amorphous silicon and another to 515 cm^{-1} which represents the contribution to the crystalline phase. By increasing the thickness of the layer of aluminum one notices a growth of the crystalline fraction. The same behavior was observed par S.Gupta et al

[3].

In the field of transparent conducting oxides, in addition to the basic properties of electrical conductivity and optical transparency, the possibility to enhance light trapping and harvesting by means of nanoengineered morphologies would be beneficial for a wide variety of solar cells. In particular, novel 3-D architectures can overpass the limits reached by conventional approaches. Al-doped ZnO (AZO) is getting increasing interest as an alternative to ITO while, in parallel, low deposition temperatures are needed to assure compatibility with plastics and organic materials in view of flexible devices. By exploiting nanosecond Pulsed Laser Deposition in the presence of a background gas we developed nanostructured AZO architectures constituted by a 3-D hierarchical assembly of atomic clusters which forms a nano-tree forest with multiscale organization from the nano- to the micron-scale. Tuning the gas type (O₂, Ar) and pressure (0.01–500 Pa), room temperature deposition of AZO films with different morphology, structural and electronic properties was obtained and the structure-property relationship investigated [1]. For conventional compact films, performances competitive with AZO films deposited at high temperatures were obtained at 2 Pa O₂ (see fig.1a, resistivity 4×10^{-4} ohm cm, carrier density up to 7.5×10^{21} cm⁻³, mobility of 18 cm²/V s and 86% transmittance in the visible range) even on polymeric substrates [2]. Hierarchical structures are deposited at pressures above 100 Pa O₂ and show high light scattering capability (see fig.1b). The mean value of the haze factor in the visible range increases up to 80% while assuring an overall transmittance > 85% [3]. A twofold approach was adopted to address the abrupt conductivity decrease

encountered as a result of the decreased connectivity of such hierarchical architectures. One consists in the use of Ar:O₂ gas mixtures to separately control morphology and stoichiometry (i.e. oxygen vacancies). The second is based on a spatial separation of layers with different functionality. By changing the gas pressure during the deposition we realized a graded morphology composed by a hierarchical layer, designed to scatter the light, and a top compact layer designed for electrical conduction. The optimized structure has 80% transparency to the visible light, haze factor higher than 40% and resistivity of 3×10^{-3} ohm cm.

Organic light emitting diode (OLED) is an important device as the next generation light source for illumination. Its low cost, easy fabrication and reasonable efficiency have attracted many research interests. The multilayer device structure emphasizes the significance of understanding the interfacial structure and properties. In most OLEDs, Tris(8-hydroxyquinolinato)aluminium (Alq3) is the activating layer and different metals (Al, Au, et al.) are used as the metal electrical contact. Upon sputtering on Alq3, metal atoms can diffuse into the organic layer, modifying the both morphological and electronic structure, which are directly related to the device performance. The interaction between metal and Alq3 has been discussed by different spectroscopic techniques^{1,2} and theoretical method³ at single molecule level. Nevertheless, the growth mechanism of the metal thin film on Alq3 is scarcely studied. For this purpose, in situ grazing incident small angle X-ray scattering (GISAXS) plays a powerful role to characterize the inorganic/organic interfacial structure during the film growth process^{4,5}. In this work, we have carried out GISAXS characterization to monitor the entire process of diffusion, coarsening and growth of different metal thin film on top of Alq3 layer during the sputtering process. Considering the elemental chemical reactivity, such as, Al and Au, we elucidate different lateral growth process from the out-of-plane scattering cut. Meanwhile, the sputtered metal/Alq3 films demonstrate good correlation to substrate roughness, illustrated by the in-plane scattering cut. The results benefit the comprehension of the development the general metal/organic semiconductor interfacial structure prepared via sputtering process which is widely used in the industry.

XPS depth profiling studies of the high-temperature transformation of InGaN/GaN multi-quantum wells

T01 Applied Surface Science

#ASS-P1-06

J. Sobczak, W. Lisowski, A. Jablonski, E. Grzanka, T. Suski.

Institute of Physical Chemistry - Warsaw (Poland).

InGaN quantum-wells (QW) are widely applied in optical and optical devices like blue/green light-emitting diodes and long lifetime violet and blue laser diodes. One of important parameters is thermal stability of the QW at higher temperature. The question arises what the tendency of the changes of QW parameters will be towards high temperature annealing, necessary in technology processes. In this work we present the results of a study dealing with this question, using a XPS depth profiling technique. The results are compared for four InGaN/GaN QW samples, containing two well separated QW, which were annealed at temperatures from 800 °C to 990 °C for 0.5 hour. The InGaN/GaN quantum well (QW) structures were grown on (0001) sapphire substrates by metal-organic chemical vapor deposition (MOCVD) method. Such two InGaN/GaN quantum wells (QWs) are used in light emitting diodes (LEDs) and laser diodes (LDs) emitting at 460nm. All samples, prior to annealing, were prepared at the same experimental conditions. The XPS depth-profiling analysis were carried out using the a PHI 5000 VersaProbeTM (ULVAC-PHI) spectrometer with monochromatic Al K α radiation. The XPS analysis was combined with Ar⁺ depth profile sputtering (0.5 keV ions at normal angle of incidence rastered over a 2x2 mm² surface area) with the Ar⁺ sputter rate of 0.34 nm min⁻¹. It was found that annealing of the InGaN/GaN QW, performed at temperature range 800-990 °C, leads to distinct QW transformations, which was found to be different at 800 °C, 900 °C and 990 °C, respectively (Fig. 1). After annealing at 800 °C we observed lowering of the QW, which was located close to GaN substrate layer and increase of In concentration in the GaN barrier areas (Fig. 1b). At 900 °C this QW vanished and only one QW, close to surface region, was detected (Fig 1c). Both QW disappeared after annealing at 990 °C and significant increase of In concentration was found at the surface region of annealed QW sample (Fig. 1d). Degradation of both QW is evidently caused by annealing procedure and this process is accompanied by inter-diffusion of In to the surface area of annealed QW samples. The QW remain stable at temperatures lower

than 800 °C.

This research was partially supported by the European Union within European Regional Development Fund, through grant Innovative Economy (POIG.01.01.02-00-008/08), and by the grant no. 2011/01/B/ST4/00959 of the National Science Center of Poland.

Quantitative ToF-SIMS MCs Dual Beam Depth Profiling with Improved Dynamic Range

T01 Applied Surface Science

#ASS-1-Or-7

S. Kayser, A. Sears, R. Möllers, D. Rading, E. Niehuis.

ION-TOF GmbH - Münster (Germany).

In recent years MCs^+ depth profiling has become increasingly popular for the analysis of thin films using Time-of-Flight SIMS (ToF-SIMS). The MCs^+ mode offers quantitative or semi-quantitative SIMS data and allows for the measurement of electropositive and electronegative elements simultaneously by detecting MCs^+ and MCs_2^+ , respectively. In addition, the use of heavy cluster ions like Bi_n^+ or C_{60}^+ allows for a significant increase of the MCs_x^+ yields by a factor of up to 1000 with respect to Ga as primary ion projectile and leads to a remarkable improvement of the achievable detection limits [1].

However, one disadvantage of current TOF-SIMS instruments for the quantification in MCs^+ mode is the limited dynamic range, which restricts the possibility of achieving high sensitivity on the MCs^+ clusters and of using the Cs^+ intensity for normalization. The normalization is especially important for the analysis of layer systems where sputter rates or the cesium surface concentration might change from layer to layer. This requires a registration system which is able to detect more than 100 secondary ions of a specific element per primary ion gun pulse with high linearity.

We have developed a new registration system for TOF-SIMS, which increases the useable dynamic range by a factor of 100 i. e. $1E7$ counts/sec with an excellent linearity. In this paper we will discuss the characteristics of this new experimental setup. We will present examples of the quantitative depth profiling in the MCs^+ mode to demonstrate the benefits of this new detection system.

BI/ASS-1-Or-7

Gold nanoparticles-based system for biosensing: surface functionalization and characterization.

T01 Applied Surface Science

#BI/ASS-1-Or-7

V. Spampinato, M.A. Parracino, D. Gilliland, P. Colpo, G. Ceccone, F. Rossi.

JRC-IHCP - Ispra (va) (Italy).

It is well known that gold nanoparticles show extraordinary optical, electronic and molecular-recognition properties, and for this reason they can be very interesting platform for many different applications in various fields as nanotechnology, materials science, life sciences and biosensors.

Gold nanoparticles can be functionalized using different kind of ligands, polymers, biomolecules, etc. depending on the aim for which they are prepared.

In this work, we describe the preparation of a gold nanoparticles-based system for biosensing purposes, and its physico-chemical characterization for each functionalization step.

In particular, we have used a thiolate as nanoparticles stabilizing agent because the bond between gold and sulfur is easy-to-form and quite strong. Since pristine gold nanoparticles (15nm in diameter) were stabilized with citrate ions, the first step of the functionalization process consisted of a dialysis procedure to remove some citrate and then to replace the residual citrate with the thioglucose, forming a self-assembled monolayer on the gold nanoparticles surface. In this way we have a sugar platform that can interact with biological systems like, in our case, the maltose binding protein.

The investigation of the biological behaviour of the glucose-modified particles in presence of the maltose binding protein was performed by surface characterization methods as ToF-SIMS and XPS and confirmed by optical detection method (iSPR). ToF-SIMS and XPS resulted to be very useful tools for monitoring all the functionalization steps and for obtaining information on the effects of dialysis procedures. In particular, by ToF-SIMS spectra, it was possible to identify some characteristic peaks related to the coordination of thio-glucose with gold as well as with the binding pocket of the protein, while XPS provided complementary

quantitative information of surface composition in each functionalization step. Moreover, from the high resolution spectra, additional information about the bonds formed between the different species involved in the functionalization has been obtained.

The same functionalization procedure and characterization was also applied to flat gold substrate for comparison.

The presented method displays a valid approach for surface analyses of functionalized nanoparticles and the results obtained underline the possibility of using the developed system in biodetection field.

Cu(In,Ga)Se₂ (CIGS) thin films solar cells are the most promising technology for high efficiency conversion energy. Several techniques are used to synthesize CIGS absorbers. The record efficiency of 20.3% is obtained by indium, gallium, copper and selenium co-evaporation. This technique is now standard because it leads to the most efficient cells and the consolidation of the 3 stage process, which allows a controlled distribution through the material absorber composition. On the other hand, the reactive sputtering deposition technique is suitable for large surfaces, thus offering the possibility to perform industrial scale-up. This technique also leads to better use of source materials, and its stability is attributed to the control of a single reactive gas (vapor selenium). In this work the absorber is prepared by reactive sputtering. Several samples of Cu (In,Ga) Se₂ deposited on Mo / glass were pulverized at different pressures and powers values. Each one of these samples was analyzed by X-ray fluorescence in order to measure the composition and also the thickness. Raman spectroscopy and X-ray diffraction were used to know the several phases present in the material. To complete the structural analysis a novel depth profiling technique Plasma-Profiling Time-of-Flight Mass Spectrometry (PP-TOFMS) was employed to determine composition distribution, identify contaminants and study the diffusion mechanisms which can occur during the thin film growth. Finally, optical properties were measured by spectroscopic ellipsometry. The optoelectronics properties analysis of each sample was also performed by I(V) under illumination and dark conditions and also by spectral response.

A new generation of nanoparticle materials has exhibited unique structural, electronic, magnetic, and optical surfaces properties with the potential to develop new technologies in the fields of catalysis, sensors, and devices [1]. In particular, nanoparticles (NPs) of gold and palladium have proved to be effective catalysts for several reactions. In this contribution, we present a study on Au and Pd NPs supported on CeO₂, TiO₂, and Mn₂O₃. The CeO₂, TiO₂, and Mn₂O₃ supports were prepared by a sol-gel method using Ce(NO₃)₂·6H₂O, C₁₂H₂₈O₄Ti, and Mn(NO₃)₂·4H₂O in order to obtain highly dispersed NPs. Then they are dried and calcined at 250°C for 2 hours. Additions of 0.5 at.% of Au and Pd were incorporated by impregnation using HAuCl₄·3H₂O and PdCl₂. The samples were then calcined at 550°C for 4 hours. The synthesized samples were: Au/CeO₂, Au/TiO₂, Au/Mn₂O₃, Pd/CeO₂, Pd/TiO₂, and Pd/Mn₂O₃. The samples were characterized by X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and high-resolution transmission electron microscopy (HRTEM). The XRD diffractograms presented sharp and intense peaks indicating that the samples are highly crystalline, but no peaks corresponding to Au or Pd phases were detected. This indicates that the Au and Pd NPs were incorporated into the structures of the oxides. It was not possible to obtain an Au 4f spectrum for Au/Mn₂O₃ due to an overlap with the Mn 3p spectrum. The XPS Au 4f spectra for Au/CeO₂ and Au/TiO₂ present negative chemical shifts that could be attributed to strong metal-support interactions [2, 3]. The XPS Pd 3d spectra indicate that for both CeO₂ and TiO₂ substrates, the Pd NPs were in the metallic state, while for the Mn₂O₃ substrate, the Pd NPs were oxidized. The HRTEM results show the formation of nanocrystalline oxides having particles sizes between 50 and 200 nm. TEM micrographs show that the Pd NPs were homogeneously distributed throughout the CeO₂, TiO₂, and Mn₂O₃ supports, while the Au NPs formed nanometric agglomerates.

Multitechnique electron spectroscopic characterisation of optoelectronic devices

T01 Applied Surface Science

#ASS-1-Or-3

A. Wright, P. Mack, T. Nunney, A. Bushell.

Thermo Fisher Scientific - East Grinstead (United kingdom).

Optoelectronic devices, used for inter-conversion of light and electricity (e.g. photovoltaics and displays), depend upon careful optimisation of chemical, electronic and structural properties for efficient operation and useful operating lifetime. Characterisation of such a device will typically aim to identify the chemical bonding states, valence band positions, band gap and work function for each component. Lateral and depth resolution may be required to evaluate cell/pixel and multilayer structures.

Electron spectroscopic surface analysis techniques are ideal for the detailed analysis of the electronic structures of optoelectronic devices. Such techniques allow full quantitative characterisation of materials with chemical state and structural information. Surface specificity of spectroscopic information ensures that thin films can be analysed without interference from deeper parts of the sample. Multilayer structures may be studied with depth profiling techniques, and imaging functionality may be used to study cell or pixel structures. Novel cluster ion beam technologies are now available for the profiling of thin, fragile organic layers while preserving chemical state information.

The Thermo Scientific Escalab250Xi offers several such spectroscopic techniques, which have been employed in this study. X-ray Photoelectron Spectroscopy (XPS) offers surface-sensitive, quantified chemical state analysis and imaging capabilities. Ultraviolet Photoelectron Spectroscopy (UPS) allows measurement of valence band positions. Reflected Electron Energy Loss Spectroscopy (REELS) can yield information on the electronic band gap and hydrogen content of a material. In this

study, these techniques are combined for characterisation of the electronic structure of some optoelectronic devices.

ASS-P1-15

Study of structural and electrical properties of nanocomposite films by means of methods of computational physics

T01 Applied Surface Science

#ASS-P1-15

R. Hrach ¹, S. Novak ².

¹Charles University, Faculty of Mathematics and Physics, Department of Surface and Plasma Science - Prague (Czech republic), ²J. E. Purkinje University, Faculty of Science, Department of Physics - Usti Nad Labem (Czech republic).

Composite and nanocomposite metal/dielectric structures consist of metal particles embedded into dielectric matrix. The behaviour of the composite films varies with their filling factor, i.e. with an amount of metal component in the film. For small filling factors the structures contain individual metal particles or nanoparticles completely insulated by dielectric or polymer matrix and the films have dielectric properties. With increasing filling factor the conductivity increases and finally the transition into metallic state occurs. Composite films near a percolation threshold, where the change of charge transport mechanism from the thermally-activated tunnelling between individual metal objects into the ohmic conductivity is observed, are especially interesting.

Morphological analysis of the composite and nanocomposite thin films is important both for the characterisation of the films themselves and for the study of their properties. These properties are given not only by the concentration of metal component but also by a spatial distribution of metal objects. An image analysis of their sections and projections is a valuable source of information (e.g. [1]) for the characterisation of composite films structure. However, standard algorithms based on the theory of mathematical morphology [2], typical in thin film physics, lose their sensitivity when applied to composite films. Therefore, in the first part of our contribution an analysis of various morphological methods will be performed.

There exist a close connection between morphological and electrical properties of composite and nanocomposite films [3]. Therefore the charge transport in composite and nanocomposite films is studied by the kinetic Monte Carlo method in the second part of our contribution. Electrical current paths are concentrated into channels creating so-called fuzzy clusters (see Fig. 1) below the percolation threshold. The technology of nanocomposite films can result in both homogeneous and inhomogeneous systems with various distributions of metal objects. The main aim of our study was to find the correlation between the morphological properties of composites and the structures of fuzzy clusters in the dependence on the technology of the composite structures.

Novel Ion Sources for XPS Sputter Depth Profiling Advanced Materials

T01 Applied Surface Science

#ASS-5-Or-2

A. Roberts, W. Boxford, S. Hutton, C. Blomfield, J. Counsell.

Kratos Analytical Ltd - Manchester (United kingdom).

The recent development of polyatomic and argon gas cluster ion sources for surface cleaning and sputter depth profiling materials using x-ray photoelectron spectroscopy (XPS) has greatly increased the types of samples that may be analysed. In particular successful XPS depth profiles of organic polymer materials are now routinely possible where the chemical information of the material is retained during the sputter profile. Whilst polyatomic projectiles such as $C_{24}H_{12}^+$ and C_{60}^+ have been demonstrated to sputter some organic materials with high etch rates, polymers which degrade under irradiation by cross-linking such as polystyrene and polyimide have very low sputter yield with these projectiles. In contrast to the polyatomic ion sources Ar_n^+ cluster ion sources where the number of atoms in the cluster n is typically 500 – 2000 have not demonstrated the limitations of low sputter yields for any class of organic polymers.

Polyatomic ion sources have also been used to profile inorganic materials such as soda lime glass where the concentration depth profile of mobile ions such as sodium have been compromised when profiling with standard monatomic Ar^+ ions. There is also some evidence that sputtering with polyatomic ion sources causes less preferential sputtering of oxygen in inorganic oxide samples relative to monatomic Ar^+ ions.

In this study we contrast the performance of the traditional monatomic Ar^+ , novel $C_{24}H_{12}^+$ polyatomic and Ar_n^+ cluster ion sources for sputter depth profiling a range of thin film and multilayer samples. It is known that unlike monatomic Ar^+ ions, large cluster ions do not penetrate deeply into the material with the result that the energy of the impact is deposited within the first few nanometres of the surface. With the larger polyatomic and Ar_n^+ clusters the energy of the ion is shared by all the atoms in the cluster so that the energy per projectile atom or partition energy can be as low as a few electron volts. A poly(lactic-co-glycolic) acid (PLGA) thin film has been used to show that the effect of changing partition energy from 2.5eV to 20eV per Ar atom has

a linear relationship to the yield volume of the material, shown in figure 1. Further characterisation of the different ion sources has been undertaken using samples as diverse as organic and inorganic photovoltaic materials, cross-linked plasma polymers and organic multilayers. Analysis conditions were optimised to maximise retention of chemical functionalities and minimise ion induced interlayer broadening and preferential sputtering.

Figure 1: Yield volume of PLGA as a function partition energy for Ar_n^+ clusters where $n=1000$.

Ru-modified Pt(332) surface studied by STM and XPS

T01 Applied Surface Science

#ASS-8-Or-2

E. Carbonio, M.J. Prieto, A. De Siervo, R. Landers.

Instituto de Física 'Gleb Wataghin', Universidade Estadual de Campinas, 13083-859, SP - Campinas (Brazil).

Ru-modified Pt surfaces are interesting model systems for studying functional properties of the Pt-Ru system, which is extensively used for fuel cells applications¹. Systematic studies using UHV techniques have been widely reported in the literature for low Miller index Pt single-crystal surfaces, mostly for Ru-modified Pt(111). However, this is not the case for Ru-modified high Miller index Pt surfaces. These model systems are interesting because of the high density of steps, which brings them closer to nanoparticle systems. In this research, Ru-modified Pt (332) surfaces were prepared by evaporation of Ru in UHV conditions over a previously cleaned Pt(332) surface at room temperature. Cleaning procedure is described elsewhere². The prepared surfaces with different coverage were studied by UHV-STM (6×10^{-11} mbar) and XPS (1×10^{-10} mbar). XPS spectra show that Ru is deposited in metallic form. Figure 1 shows the Pt(332) surface before and after Ru deposition. Due to differences in their electronic properties, Ru atoms appear brighter^{3,4}. For low coverage, Ru deposits preferentially on the step edges forming 1D chain structures (step decorating) and some 2D structures. When Ru coverage is increased, STM shows that the formation of 3D structures is favored (islands). The height of the 3D structures was estimated from the STM images to be of two atomic layers.

Differences of surface reactivity may be observed as a consequence of the different structures (1D and 2D, or 3D) formed for the different coverage of Ru.

High-quality detachable CdTe (111) heteroepitaxial films on Al₂O₃ (0001)

T01 Applied Surface Science

#ESD/ASS-2-Or-4

K. Meinander, G. Devenyi, S. Jovanovic, J. Carvalho, J. Preston.

McMaster University - Hamilton (Canada).

Cadmium telluride is one of the most attractive compound semiconductor materials available for photonics applications. Currently, however, there exist major obstacles limiting its widespread use in new technologies. Most critical among these is the strong tendency for CdTe thin films to grow in multidomain structures, exhibiting both a high defect density and large surface roughness.

Using pulsed laser deposition (PLD) we have developed a novel method for growing nearly single domain CdTe (111) films on sapphire substrates. Through either a modification of the Al₂O₃ (0001) surface prior to deposition, or by an incorporation of impurities, such as Zn, during growth, we can actively control the domain rotation of these single crystal films with respect to the underlying substrate. After growth, using relatively simple lift-off procedures, these films can then be readily detached from their substrates and transferred onto other surfaces without a noticeable degradation of their quality, allowing for both the reuse of the expensive substrates, as well as for the ability to freely choose any desired carrier material.

By combining two-dimensional X-ray diffraction (2D-XRD) and scanning transmission electron microscopy (STEM), together with density functional theory (DFT) structure calculations, we have unraveled the main mechanisms that allow for a controllable alignment of the crystal domains at this unique CdTe-sapphire interface. Additionally, we present an explanation for how these two polar materials can accommodate both the heteroepitaxial growth of CdTe structures, as well as a subsequent easy detachment of the resulting thin films. An in-depth understanding of this complicated interface will also be of great assistance in the future design of similar heteroepitaxial systems for transferable thin film growth.

ASS-2-Or-9

Bismuth Oxide thin films for photocatalytic degradation of textile dyes

T01 Applied Surface Science

#ASS-2-Or-9

S. Rodil, P. Silva-Bermudez, J.C. Medina, M. Bizarro.

Instituto de Investigaciones en Materiales, Universidad Nacional Autonoma de Mexico - Mexico D. F. (Mexico).

Bismuth oxide (Bi_2O_3) thin films were deposited on glass by Magnetron Sputtering technique under different deposition conditions in order to obtain films having different crystalline phases. X-ray diffraction, profilometry, scanning electron microscopy, X-ray photoelectron spectroscopy and optical transmission were used to characterize the films. The results indicated that it was possible to obtain oxide films in the alpha, beta and delta phase or a combination of some phases, depending on the deposition conditions. The photocatalytic activity for each one of the Bi_2O_3 phases was evaluated testing the degradation of methyl orange dye ($\text{C}_{14}\text{H}_4\text{N}_3\text{SO}_3\text{Na}$) under different light energies (ultraviolet, white and solar light). The photocatalytic activity was measured as a function of the irradiation time, light-energy, concentration and pH of the solution. As comparison, micrometer Bi_2O_3 powders presenting the alpha phase were also tested under similar conditions. The colorant degradation and the kinetic of the reaction were estimated using the variation of the corresponding absorption band. The results pointed out that the photocatalytic effect was only activated under acidic conditions for the thin films, for the other pHs, the activity was negligible. Moreover, it was also found that the delta-phase films presented larger photocatalytic efficiency reaching almost 100% of degradation of the dye solution in only 30 minutes, which was an remarkable result considering the photocatalytic performance of other oxides in similar conditions. The effect of surface roughness was also investigated as a method to enhance the active surface in the thin films. For this, the glass substrates were roughened previously to the oxide deposition, increasing the average roughness from 0.015 to 6.3 μm . However, due to the strong light dispersion caused by the roughness, there was not such increment in the photocatalytic activity as expected.

Acknowledgement: The research leading to these results has received funding from the European Community Seven Framework Programme (FP7-NMP-2010-EU-MEXICO) and CONACYT under grant agreements n° 263878 and 125141, respectively.

Plasma electrolytic oxidation technique, that is anodization of valve metals under spark and arc discharges, allows one to obtain oxide layers incorporating electrolyte components into coating compositions. So it is perspective for preparing both secondary supports [1] and catalytic oxide layers [2, 3] on metal substrates. The report considers two possibilities of PEO for obtaining catalytically active oxide layers on aluminum and titanium. The first is one-stage PEO technique when precursors of catalytically active compounds are directly involved in forming electrolyte. The second approach is related with modification of PEO coatings (secondary carriers) using other methods such as impregnation in precursor solutions, extraction-pyrolytic method, and template synthesis. Using these approaches we obtained composites including transition (Mn, Fe, Co, Ni, Cu) and noble metals (Pt, Pd) on aluminum and titanium. The composites were tested in CO oxidation into CO₂. It has been shown that Co-, Cu-containing composites have an activity comparable with that for Pt-containing ones. Optimal result is obtained when catalytically active composition is deposited on supports possessing own catalytic activity, Fig 1.

Atomistic Theory of Ostwald Ripening and Disintegration of Supported Metal Particles Under Reaction Conditions

T01 Applied Surface Science

#ASS-2-Or-5

W. Li, R. Ouyang.

Dalian Institute of Chemical Physics, CAS - Dalian (China).

Understanding Ostwald ripening and disintegration of supported metal particles under operating conditions have been of central importance in the study of sintering and dispersion of heterogeneous catalysts for long term industrial implementation. To achieve a quantitative description of these complicated processes, an atomistic and generic theory taking into account of the reaction environment, particle size and morphology, and metal-support interaction is developed [Ref. 1]. The thermodynamic criteria for the reactant assisted Ostwald ripening and induced disintegration are formulated, and the influence of reactants on sintering kinetics and redispersion are mapped out. The theory is applied to TiO₂(110) supported Rh particles in the presence of carbon monoxide, and reproduces well the broad temperature, pressure, and particle size range over which the sintering and redispersion occurred in such experiments.

Surface activation bonding of cyclo-olefin polymer to an inorganic substrate: Role of Interfacial Chemistry

T01 Applied Surface Science

#ASS-P3-05

T. Tsukamoto, A. Nakamura, T. Ichii, H. Sugimura.

Department of Materials Science and Engineering, Kyoto University - Kyoto (Japan).

Cyclo-olefin polymer (COP) has been used in a wide variety of applications owing to their excellent transparency, high heat resistance and dimensional stability, and low water absorbency. Extensive studies have been conducted so far to improve adhesivity, dyeability, wettability, etc. of COP. In order to obtain better adhesion of COP, it is necessary to provide adhesive chemical properties on polymer surfaces. We have been reported that the surface modification using vacuum ultra-violet (VUV) light is effective and applicable to the low temperature bonding of COP plates [1]. Here we report on a further extension of this surface activation technique to bonding COP to an inorganic substrate. Materials used in this study were COP sheets (ZF14, Zeon Co.) and Cu substrates covered with a SAM prepared from n-octadecyltrimethoxysilane ($\text{CH}_3(\text{CH}_2)_{17}\text{Si}(\text{OCH}_3)_3$, ODS). Prior to forming the ODS-SAM onto Cu substrates, each substrate surface had been irradiated in air with VUV light at 172 nm in wavelength for 20 min in order to form a thin oxide layer. Both a COP sheet and an ODS-Cu substrate were irradiated with VUV (distance 5mm in dry-air). These samples were pressed with facing the VUV-modified surfaces at a temperature 120 °C or lower. Fig.1 shows water contact angles of the COP and ODS-Cu surfaces irradiated with VUV. As the VUV irradiation was prolonged, both the surfaces became hydrophilic. These chemical changes were further studied by XPS as shown in a graph of the O/C atomic ratio (Fig.2). Both the surfaces are confirmed to be oxidized mainly due to atomic oxygen species generated by the dissociative excitation of atmospheric oxygen molecules with VUV. The ODS-Cu substrates show a more marked increase in the O/C ratio because of the smaller carbon amount of ODS than COP. We have confirmed that the VUV-modified COP and ODS-SAM surfaces became adhesive.

Fabrication and Characterization of Distributed Bragg Reflector like Structured Thin Film Passivation Films for Top Emission Flexible OLEDs Display

T01 Applied Surface Science

#ASS-P2-4a

J. An, C. Park, B.H. Choi, J.H. Lee.

Korea Institute of Industrial Technology - Gwangju-Si (Korea, republic of).

One of issue in flexible top emission display is high transmittance in passivation layer. Therefore, optical properties in passivation layer should be considered. In this study, we have studied optical properties of DBR structured multi-layered passivation layer. DBR passivation structure consist of 50 nm thick Al₂O₃ and 500 nm thick polymer. Al₂O₃ and polymer layer were prepared by sputtering and evaporation. To prevent water and oxygen permeation into layer, DBR structure was repeated 3 and 5 times, respectively. To enhance passivation effect, the top of layer was capped by 50 nm thick Al₂O₃ layer. Figure 1 shows FE-SEM images of DBR structure like thin film encapsulation structures of (a) 3.5 and (b) 5.5 dyads. The transmittance spectra of multi-layered passivation layer exhibited periodic interference patterns, which is similar to that of DBR structure. The sharp dips were observed in transmittance spectra in DBR like multi-layered passivation structures due to interference of incident light. It was also observed that interference patterns were sharp and deeper as the number of layer was increased. Furthermore, the number of interference patterns was also increased as the total thickness of passivation layer increased as shown in Fig. 2. It is observed that transmittance dips are appears more within the same wavelength range in thicker thin film passivation layer. Therefore, to increase the transmittance in top layer, the thickness of polymer layer should be reduced in flexible OLEDs devices. By Fig. 1 and 2, it can be concluded that the number of dyads and thickness of each layer should be reduced with comparable passivation properties to obtain high transmittance in top emission flexible OLEDs display.

Figure 1. FE-SEM image of DBR structured passivation films (A) 3.5 dyads, (B) 5.5 dyads

Frictional property of BN doped ZnO coating films on 440C stainless steel substrates fabricated by a combinatorial sputter coating method

T01 Applied Surface Science

#SE/ASS-P2-02

M. Sasaki, M. Goto, A. Kasahara, M. Tosa.

National Institute for Materials Science - Tsukuba (Japan).

Zinc oxide sputter coating films are prospected candidate as low friction material for their piezoelectric property [1-3]. The frictional property of ZnO was not satisfied the Amonton-Coulombs' law because of the piezoelectric effect. If the effect will be amplified by changing the coating materials, the friction force can be decreased. In this paper, in order to change the frictional property of the coating, we fabricated the BN doped ZnO coating films by a combinatorial sputter coating system (COSCOS). It was found that the frictional property was drastically changed by changing the materials of counter balls. <Acknowledgement> The present work was supported by a Grant-in-Aid for Scientific Research (A) (21246030) from the Ministry of Education, Culture, Sports, Science and Technology, Japan. It also was supported by Japan MEXT's GRENE Program.

ESD/ASS-P3-11

Pyrite thin films (FeS₂) by chemical bath deposition and thermal treatment post-deposit

T01 Applied Surface Science

#ESD/ASS-P3-11

D. Mazon Montijo, M.T.S. Nair, P.K. Nair.

CIE - Temixco (Mexico).

Iron pyrite (FeS₂) thin films, with a band gap of ~ 1 eV, absorption coefficient (α) of ~ 10^5 cm^{-1} in vis-NIR region and *p*-type conductivity have potential for application as solar cell absorbers of abundant elements [1-2]. Methods reported for obtaining these films include spray pyrolysis, molecular beam epitaxy, magnetron sputtering, electrodeposition, and chemical vapor deposition- in most cases accompanied by thermal treatment in sulfur atmosphere [3-5]. This work presents a simple route for obtaining thin films of FeS₂ by chemical bath deposition (CBD) followed by thermal treatment in a sulfur atmosphere under a “sandwich-like configuration”, without the presence of H₂S. First, uniform, homogeneous and yellow-orange colored thin films of amorphous iron sulfur-oxide (α -FeO/S) with around 314 nm in thickness were obtained directly from a chemical bath containing Fe(NO₃)₃, Na₂S₂O₃, (HOC₂H₄)₃N and HCl after 2.5 h of deposition at 40 °C. After heating at 400 °C for different time (from 3 h to 10 h) in N₂/S ambient (~ 10₄ mTorr) in a vacuum oven, the films turned dark-gray, showing X-ray diffraction peaks that match those reported for the cubic phase of the mineral FeS₂ (JCDPS #42-1340). The optical band gap of the films is ~ 0.8 eV due to an indirect transition, and the absorption coefficient of the order of 10^5 cm^{-1} ($\lambda \leq 1127 \text{ nm}$). The morphological characteristics exhibited by these films are typical for films of iron compounds. Moreover, the effect caused by moisture in the films is also showed. The films are photosensitive, present *p*-type conductivity and electrical conductivity from 0.7 to 1.6 ($\Omega \text{ cm}$)⁻¹, depending on the electrode material.

Lattice deformation caused by hydrogen- and oxygen- termination of diamond surface

T01 Applied Surface Science

#ASS-P3-06

K. Nose, M. Kamiko, Y. Mitsuda.

The University of Tokyo - Tokyo (Japan).

Attention has been paid to surface termination of diamond because of its unique physical properties. For example, hole conduction on hydrogen-terminated surface[1] has been studied as a potential candidate of electronic devices. In this study, we studied lattice deformation caused by the terminated elements on the surface. Deformed crystal lattice often affects strongly on carrier transport in semiconductor, however, much less is known how termination effects on the surface lattice deformation. Raman spectroscopy with a confocal microscope was performed to analyze the lattice deformation in the vicinity of diamond surface.

(111)-oriented single-crystalline diamond wafers ($2.5 \times 2.5 \times 0.5 \text{ mm}^3$, Sumitomo Electrical Hardmetal) were used in this study. Hydrogen termination was achieved by an exposure of the sample to hydrogen plasma at 6 KPa. Wafer temperature was greater than 1070 K, evaluated by a radiation pyrometer. Chemical bonding states of the treated surface was analyzed by X-ray photoelectron spectroscopy (XPS, Quantera, ULVAC-PHI) by analyzing C 1s and O 1s peaks. Horiba T-64000 with a confocal microscope and a green laser (514.5 nm, Ar) was used to obtain Raman spectra. The spot diameter at a focal point was 1 μm . The dispersion of the spectrometer was $22 \text{ cm}^{-1}/\text{mm}$. The resolution of the wavenumber was around 0.7 cm^{-1} , and the reproducibility of the measured wavenumber of phonon in diamond was enhanced to be 0.01 cm^{-1} on the basis of the reference measurement of a strong Gaussian emission spectrum of Hg.

Surface of as-received diamond wafer was oxygen-terminated. Atomic ratio on the surface was evaluated roughly to be O/C = 10.0 at. % in XPS, suggesting a termination ratio is relatively high if we assume the length of electron penetration and monolayer thickness to be 2 and 0.15 nm, respectively. Confocality of the

spectrometer in the direction normal to the sample surface was evaluated to be 10 μm . Intensity and center wavenumber of Raman spectra of diamond surface are shown in Fig. 1. At the surface of the O-terminated diamond wafer, we detected a negative shift of phonon energy approximately by 0.04 cm^{-1} , indicating a relaxation of lattice at the surface. On the basis of strain parameters of diamond [2], this shift gives us a tensile deformation greater than 2×10^{-5} on the surface compared to the bulk, i.e., inside of the wafer.

Investigation of carrier life time in third generation solar cells by XPS and KFM

T01 Applied Surface Science

#ESD/ASS-2-Or-5

L. Borowik, H. Lepage, N. Chevalier, D. Mariolle, O. Renault.

CEA, LETI, MINATEC Campus - Grenoble (France).

To sustain the progress in photovoltaic field, a development of novel characterization methods field is essential. The most important solar cells parameters which provide good efficiency are: carrier mobility, lifetime of carrier, absorption coefficient, and band gap of the materials. In this paper we are proposing steady method to measure lifetime of carrier by Kelvin force microscopy (KFM) and X-ray photoemission spectroscopy (XPS). Both methods are applicable on the all kind of solar cells (including indirect gap and organic solar cells), additionally KFM method gives possibility to provide a spatially resolved measurement of lifetime. We will present original method based on modulated illumination, the results are measured on third generation solar cells. Here, we are using hydrogenated and non-hydrogenated bonds Si nanocrystals (NC) [1] (diameter ~5 nm) embedded in 30 nm film of SiO₂. In the case of illuminated solar cell samples, the transfer of charge appears due to the generation of electron hole pairs and followed by electron hole separation in the region of the solar cell junction. This transfer has impact on the sample surface potential and can be measured by KFM [2] or XPS [3] method. We noticed that this phenomenon is reversible in the case of on/off light switching. Moreover, the surface potential can be: measured during modulated illumination and averaged in time. Averaged value of potential is dependent on the modulation frequency. To quantify the carrier lifetime, we calculate potential differences from measured V_{\max} (for continuous light) and V_{av} (for modulated light) under the dark and the illuminated conditions. These differences are notified ΔV_{av} and ΔV_{\max} and the ratio $\Delta V_{\text{av}} / \Delta V_{\max}$ is plotted in the function of the modulated frequency light. Furthermore, experimental points can be fitted by this model (not presented here) where fit parameter is directly lifetime of carrier. By KFM we find that $\tau = 7 \times 10^{-5}$ s and $\tau = 3.5 \times 10^{-5}$ s with $\pm 10\%$ accuracy for the hydrogenated and non-hydrogenated NC (Fig. 1), respectively. The longer carrier lifetime for the case of hydrogenated NC, can be explained by the smaller quantity of defaults defects on the NC surface. This work was supported by the French "RTB"

Program. The measurements were performed on the CEA Minatec Nanocharacterization Platform (PFNC).

Fig. 1 $\Delta V_{av}/\Delta V_{max}$ as the function of light modulation frequency. We present XPS and KFM measurements on the hydrogen passivated sample and KFM data from the sample before hydrogen passivation. The fitting curves to KFM data are made by the model.

ASS-P2-06

Low-noise deflection detection system of AFM with quartz tuning fork sensor for imaging in viscous liquid

T01 Applied Surface Science

#ASS-P2-06

H. Shitazaki.

Kyoto Univ - Kyoto (Japan).

Frequency modulation atomic force microscopy (FM-AFM) has been widely used for high-resolution surface structural analysis on various materials such as metals, semiconductors, insulators, and organic materials. It was significantly improved and it is also applicable for investigating liquid/solid interfacial structures. A Si cantilever is mainly used as its force sensor in liquid as well as in vacuum and in air. However, its quality factor (Q) is heavily suppressed in viscous liquid and thus, the force sensitivity and the stability are expected to be decreased. To solve this problem, we have developed an FM-AFM with a quartz tuning fork (QTF) sensor for imaging in viscous liquids. A QTF sensor shows a high Q even in the liquid and atomic-resolution imaging was successfully achieved [1]. In that study, the deflection of the QTF sensor was electrically detected by using its piezoelectric effect. The deflection noise density was $125 \text{ fm Hz}^{-1/2}$, which was much larger than that of an improved cantilever-based FM-AFM. The reduction of the deflection noise density would be effective for improvement of force sensitivity, resolution and data acquisition time. Optical beam deflection system, which is commonly used for cantilever-based AFM, is not considered to be suitable for a QTF sensor because a QTF sensor is generally much longer than a Si cantilever. Recently, Morita et al. indicated that the deflection noise density of a QTF sensor was significantly reduced by optical interferometric detection system and atomic-resolution imaging was achieved in ultrahigh vacuum [2]. We considered that this technique is also promising for imaging in viscous liquid using a QTF sensor and developed an optical interferometric detection system for liquid environment as shown in Fig. 1.

SE/ASS-P2-03

Adhesion Promotion in Aluminium Polypropylene Composites Measured by Peel test and Centrifuge technology

T01 Applied Surface Science

#SE/ASS-P2-03

R. Mix, S. Hielscher, J. Friedrich, U. Beck.

Federal Institute of Material Research and Testing - Berlin (Germany).

The measurement of the adhesive strength of coated polymers is an important issue for the evaluation of the quality of surface treatments and performance characteristics of laminated polymer foils. Normally, the peel test is used to retrieve information about the effectiveness of the applied polymer treatment. However, the peel test primarily refers to tear propagation strength (in N/m) with respect to the width of the tape (or sample) and not to the adhesive strength (in N/mm²) of a given polymer-metal system. Problems are associated with well adherent coatings where the delamination may start at the 'wrong' layer or interface which may be the polymer itself or "undesirable" interfaces in multi-layer composites. For this reason, the practicability of the centrifuge technology [1] was investigated. The determination of adhesive strength between aluminium and surface-treated polypropylene (PP) foils was realized by on-line detection of rupture events of modular Cu-V2A stamps of known mass (glued on the Al layer by means of adhesive) due to the effect of centrifugal force at certain rotational speed (see Fig. 1).

Fig. 1

Principle of the centrifuge technology (TS-test stamp, GS-guiding sleeve of the stamp, S+C-sample with coating, A-adhesive, F_c – centrifugal force, r – radius of the rotational motion)

The surface treatment of the PP was accomplished in two ways: 1) by the introduction of nebulized aqueous solutions (1% w/w) of functionalized monomers (acetic acid) and polymers (vinylalcohol (co)polymers, poly acrylic acid) into a DBD discharge and 2) by deposition of plasma polymers followed by reaction with functionalized substances to create special interface structures concerning the position of the functional group related to the topmost surface. All modified surfaces

were characterized by XPS in dependence on the plasma conditions. The functionality of the surfaces was estimated by derivatization and subsequent XPS characterization.

Adhesive strength of aluminium-coated PP foils was measured for both testing methods. The XPS inspection of the tested samples proved the location of the failure in the PP laminates.

Ni₃Al intermetallic compound is known as a promising high-temperature structural material because of its excellent high temperature strength and corrosion/oxidation resistance. Recently, we found that Ni₃Al, in the form of both powder and foil, shows high catalytic activity for methanol decomposition [1,2] and methane steam reforming [3,4], indicating a possibility to develop Ni₃Al as catalysts for hydrogen production. More recently, we found that it is possible to enhance catalytic activity by modifying the surface structure of Ni₃Al foil simply by a pre-treatment which includes a steam treatment at proper temperatures followed by a H₂ reduction. In this study, in order to understand the mechanism of the enhancement by the pre-treatment, we investigated the effect of the steam treatment and H₂ reduction on the surface morphology of Ni₃Al foil using a FE-SEM with an EDS system, and synchrotron radiation X-ray photoemission spectroscopy (XPS) at beamline BL23SU of Spring-8. SEM and EDS analysis showed that two surface layers were formed by the steam treatment: the outmost layer consisted of fine particles of Ni oxides, and the layer beneath the outmost layer consisted of Al oxides. The Ni oxides were reduced to metallic Ni by the subsequent hydrogen reduction. XPS analysis revealed the detail chemical state change of Ni and Al in the surface during the pre-treatment process. Figure 1 shows the Ni 2p core level measured before and after the steam treatment and H₂ reduction. Before the steam treatment, the Ni 2p peaks corresponded to the metallic Ni were detected, indicating that the Ni in the surface layer was mainly in the metallic state. After the steam treatment, the relative intensity of the metallic Ni 2p peaks was significantly decreased, and the strong Ni 2p peaks corresponded to NiO appeared, suggesting that most of the metallic Ni in the surface layer were oxidized by the steam treatment. After the H₂ reduction, the relative intensity of the metallic Ni 2p peaks increased again, indicating that NiO was reduced to metallic Ni. These fine

metallic Ni particles formed on the foil surface were considered to enhance the catalytic activity of Ni₃Al foil.

Surface supramolecular chemistry has produced a large variety of atomically controlled systems, but practical applications are seriously restricted by the use of weakly cohesive non-covalent bonds and by the confinement to (mainly) metal surfaces^[1]. In order to create systems usable in real devices it is necessary to covalently stabilize the supramolecular structures obtained by molecular self-assembly^[2-4]. In this direction we report the formation of a new surface covalent organic framework (SCOF) based on the photo-polymerization reaction of a bi-functional compound. A well-ordered polymeric organic sheet was obtained by depositing 5,15-bis(4-aminophenyl)-10,20-diphenylporphyrin (TPP(NH₂)₂) on a Ag(110) surface in ultra-high-vacuum conditions. Covalent stabilization of the units was activated by irradiation of TPP(NH₂)₂ at 405 nm for several hours, which resulted in the formation of azo-bridges (RN = NR) between monomers along the \hat{e} [1-10] direction of the substrate. Two distinct procedures have been optimized for the growth of the polymeric structure. The first one is based on the anisotropy of TPP(NH₂)₂ diffusion coefficients along the substrate [1-10] and [001] directions below room temperature (RT). The second method is based on the topological control that C₆₀ - co-organized with TPP(NH₂)₂ on the substrate surface in a bicomponent supramolecular array^[5] - exerts over the TPP(NH₂)₂ units by directing and organizing them in an ideal geometry for the photo-assisted reaction at RT. DFT calculations have been used in order to confirm the nature of the chemical bonds within the polymeric chains.

ASS-P3-07

Modification of c-Si and its oxides using atmospheric-pressure plasma

T01 Applied Surface Science

#ASS-P3-07

D. Skácelová ¹, D. Hegemann ², M. Černák ¹.

¹Department of Physical Electronics, Faculty of Science, Masaryk University, Kotlářská 2, 611 37 - Brno (Czech republic), ²Swiss Federal Laboratories for Materials Science and Technology, Empa, Lerchenfeldstrasse 5, CH-9014 - St.gallen (Switzerland).

Silicon and silicon dioxide surfaces play an important role in nowadays technologies, especially photovoltaics, integrated circuits and microelectronics. In all these various applications different surface properties are required. Nevertheless, the process of cleaning, oxidating, etching etc. typically includes a complicated wet chemical process or required low pressure systems. Recently it became a tendency to replace such process steps by plasma-based technologies that could provide an environmentally much more friendly alternative.

In this paper we present the surface modification of c-Si by the atmospheric-pressure highly-nonequilibrium plasmas generated using the Diffuse Coplanar Surface Barrier Discharge (DCSBD)

[1-3]. DCSBD generates macroscopically-homogeneous plasma with an extremely high power density of the order of 100 W/cm³ in any working gas including strongly electronegative gases. DCSBD plasma operated in air is able to oxidize c-Si (metalloids) surfaces and creates a distinct silicon dioxide layer with the thickness of several nanometres [4].

In this study c-Si was modified in various working gases (air, oxygen, argon and nitrogen) and optimal conditions of oxidation were specified. In general, oxidation rate depends on the humidity and temperature of the sample. Therefore influence of ambient humidity on the oxidation process was studied and also the effect of the sample temperature was controlled. The influence of native oxide film on Si surface has been investigated. The modification of the surface was studied by various surface analysis including XPS, SIMS, AFM, SEM, UPS and surface energy measurement. Also plasma diagnostics by optical emission spectroscopy during plasma oxidation was studied.

The oxidation by DCSBD seems to be in the future a promising and cheap oxidation process applicable in the field of photovoltaics, microelectronics etc.

SXPS study of photoelectrochemical processes at the GaAs(100)/HCl aqueous solution interface

T01 Applied Surface Science

#ASS-4-Or-3

M. Lebedev ¹, W. Calvet ², T. Mayer ², W. Jaegermann ².

¹Ioffe Physical-Technical Institute, Russian Academy of Sciences - St. Petersburg (Russian federation), ²Darmstadt University of Technology, Institute of Material Science - Darmstadt (Germany).

Chemical reactions and accompanying charge transfer processes under applied voltages at n-GaAs(100)/1M HCl_{aq} solution interface are analyzed by means of highly surface-sensitive synchrotron-radiation photoemission spectroscopy. Experiments were carried out using a conventional three-electrode scheme in the electrochemistry chamber being part of the integrated system SoLiAS permanently operated at BESSY. This glass chamber is purged with Ar gas and is directly attached to a special buffer chamber to allow for the sample transfer into UHV for subsequent photoemission analysis without contact to ambient air. The GaAs(100) surface composition was analyzed after 30 min contact with the HCl solution under different bias voltages with respect to the Ag/AgCl reference electrode. **Results:** After contact to the 1M HCl_{aq} solution at zero bias for 3–4 min the native oxide layer is effectively removed from n-GaAs(100) surface. The core-level spectra indicate components assigned to bulk species, elemental arsenic, As–H₂, As–OH, and Ga–Cl bonds, as well as gallium suboxide. Once the anodic bias voltage is applied to n-GaAs(100)/1M HCl_{aq} solution interface the As-to-Ga ratio increases due to enrichment of the elemental arsenic component at the surface (Fig. 1). The elemental As formation is enhanced when the GaAs/solution interface is irradiated by visible light (Fig. 1). After exposure of the n-GaAs(100) surface to 1M HCl_{aq} solution under cathodic voltage, the chemical composition changes very little. Under these conditions hydrogen is evolved and the As–H₂ component decreases with increasing cathodic voltage. On the other hand, the valence band spectra change strongly (Fig. 2). In particular, the feature with the binding energy of about 5.5 eV increases with cathodic voltage. This feature is related to combinations of the hydrogen orbital with Ga-derived s-like states localized in the second atomic plane from the surface.

The paper demonstrates that synchrotron-radiation photoemission spectroscopy can be successfully used for studying the photoelectrochemical processes at semiconductor/electrolyte interfaces in great detail.

Work function investigation of SiGe heterostructures using Kelvin force microscopy and electron spectroscopy

T01 Applied Surface Science

#ASS-5-Or-11

S. Pouch¹, N. Chevalier¹, D. Mariolle¹, E. Martinez¹, P. Kumar¹, O. Renault¹, J. Morin¹, J.M. Hartmann¹, T. Mélin², L. Borowik³.

¹CEA, LETI, MINATEC Campus - Grenoble (France), ²IEMN, CNRS-UMR - Villeneuve D'ascq (France), ³CEA, LETI, MINATEC - Grenoble (France).

We present here the experimental setup used to perform work function analysis on SiGe/Si heterostructures. These epitaxial heterostructures are consisting in stacks of 500 nm thick SiGe layers with increasing Ge concentration from 6% to 50% [1]. Kelvin force microscopy (KFM) and electronic microscopy like: X-ray photo emission electron microscopy (XPEEM) or scanning Auger microscopy (SAM), provide coupled information on local work function together with surface topography or chemical composition.

The KFM measurements have been performed with Bruker Dimension 3100 and Omicron VT-XA UHV AFM instruments, using a NanoSensors PPP EFM tip ($k \sim 2$ N/m). KFM is one of the techniques used to detect the contact potential difference (CPD), which is directly related to work function [2]. The XPEEM measurements were made using an Omicron NanoESCA [3].

The absolute work function map is obtained from spectromicroscopic image series [4] at the photoemission threshold (secondary electrons) recorded with He I or AlK α 1 radiations.

Electron spectroscopy analysis has been performed using a PHI-700 Xi Auger nanoprobe system, using an electron beam voltage from 10 to 20 keV and current from 5 to 10 nA [\sim (8-22) nm spot size]. This technique is based on the acquisition of the emission threshold of secondary electrons which is directly related to the work function [5].

We will present an improved protocol of the former SAM work function measurement [5]. A stack of emission curves is obtained by analyzing each SiGe layer successively. Then, the difference of threshold energy is extracted for each step to obtain the work function difference between these layers.

Furthermore, we will show comparative results of KFM, XPEEM and SAM, and discuss about the capabilities of each technique. Moreover, KFM and XPEEM characterizations (Fig. 1) are combined by using a UHV suitcase to transfer the sample and prevent oxidation and contamination under air exposure.

This work was supported by the French “Recherche Technologique de Base” Program. The measurements were performed on the CEA Minatec Nanocharacterization Platform (PFNC).

Aluminum alloys (AA) like AA6061 are widely used in automotive, aircrafts and packaging industries because of their good mechanical properties and their remarkable surface stability due to the presence of native oxide (alumina). However, under common environmental conditions, formation of an uncontrolled oxyhydroxide layer can occur on their surfaces.¹ Yet, for industrial applications like production of exhaust pipe made of aluminum or exposure of aluminum structures to reactive environments containing nitric oxide (NO), the aluminum surface need to be controlled and improved. A common way to improve aluminum surfaces is to deposit self-assembled layers from silane or silicon-based molecules like trichlorosilane (HSiCl₃), mainly by immersion in a solution, chemical vapor deposition or plasma techniques.² However, to our knowledge, no studies have been conducted to understand the evolution of AA surfaces pretreated with silicon-based molecules; immediately after pretreatment and in presence of reactive molecule like NO. In the present work, we implemented a controlled and reproducible pretreatment procedure consisting in direct exposure of AA 6061 samples to gaseous HSiCl₃. We show that HSiCl₃ forms discrete nodules (50-500 nm) of silicon oxide on merely polished surfaces, whereas it reacts with OH-rich surface of pseudoboehmite needles formed on hydroxylated (in boiling water) surfaces. We have combined analyses in static (AFM, SEM, XPS) and dynamic (*in-situ* PM-IRRAS) conditions. Then, in line with

former studies on pure aluminum,³ we put in evidence the poor reactivities of polished metal surfaces toward NO, be they HSiCl₃-pretreated or not. In contrast, nitrites, and nitrates are clearly evidenced by *in-situ* PM-IRRAS on hydroxylated AA6061 (HSiCl₃-pretreated or not), with the HSiCl₃-pretreated hydroxylated AA6061 being less reactive (Fig. 1).

³IRTES-LERMPS / LRC CEA - Belfort (France).

P-type transparent conducting oxides (p-TCOs) have attracted increasing attention while the photovoltaic industry is being focused upon them [1]. Within the numerous p-TCOs, the delafossite structure ABO₂ is considered to be one of the most potential p-TCOs because of its special layer structure [2]. However, a compromise has to be found between the transparency and the conductivity in all the p-TCOs. Some p-type delafossites have a relative high transmittance, such as CuAlO₂, but have a very impractical conductivity [3]. In order to obtain p-TCOs with good optoelectronic properties, the presence of different elements at B sites in ABO₂ delafossite has been studied [4]. It should be noted that, in recent years, the conductivity of CuCrO₂ based materials has reached to about 10² S·cm⁻¹, while their transmittance is just under 50% [5]. In this study, we prepare CuCrO₂ thin films by reactive magnetron sputtering. Hence, after a short description of the deposition reactor, we present the chemical evolution of the coatings versus deposition parameters. The coatings morphologies and structures will be characterized by scanning electron microscopy and X-ray diffraction and finally the electrical conductivity and the transmittance of the films will be measured.

CNRS-UVSQ - Versailles (France).

For III-V optoelectronic devices, the knowledge and the engineering of the surface oxide layers are often key parameters for the success of a technology. Its instability is related to the high density of states in the band gap generated by the oxide capping and its relevant interface with the compound. The film thickness can vary from ultra thin layer to micron thick. The spatial homogeneity is also a subject of variation. The global properties of the oxide (chemical composition, texture, morphology, etc.) strongly influence the global electrical responses of the structures and particularly the kinetic of the electron transfers through the interface. Among the III-V semiconductors, Indium Antimonide is an important material in infrared photodetectors and light emitters. InSb has the highest electron mobility, the smallest electron effective mass and the largest electron magnetic moment making it a promising candidate for high speed, low power field effect transistors and spintronics. In order to gain control of this material, surface chemistry has to be better understood. For many applications, it is important first to know how the wet etching of the upper layer occurs and how this etching affect the surface chemistry.

In this work, we propose an original and detailed study where the etching is followed by the dosage of metallic ions (In and Sb) released in the aqueous solution and the obtained surface characterized by XPS for its chemical composition and AFM for its morphology. The importance of the work presented in this manuscript is precisely to address the issue of a total overview of the processes involved in the etching bath. The methodology followed suggest that the formulation and the concentrations used in the bath strongly affect the final surface.

Figure 1 shows the 10-41 eV region of the XPS spectrum on a particular InSb surface after HBr/Br₂ etching. In this region, both Indium and Antimonide exhibit particular peaks (In4d and Sb4d). A linescan with 5 points has been realized to highlight the utility of local XPS on this non-homogeneous particular oxide. The matrix peaks are seen at the same position when the oxides are shifted. Three different energies, named ox1, ox2, and ox3, are observed for the five points made. This same shift on both elements is associated to a particular charging effect, confirmed by the C1s peaks related to contaminants (inset in figure 1). Two components are seen. At 285 eV, the regular carbon peak is seen when another one

is at higher energy. The shift between the two main carbon peaks is the same than the energy shift between InOx and Inmatrix or SbOx and Sbmatrix confirming a general shift of the peaks related to the oxide. Furthermore, quantitative analysis will be shown and recipes to obtain reproducible low quantity of mixed or Indium-rich oxide will be given.

Figure 1: XPS spectra in the 10-41 eV region (linescan on 5 points) of InSb surfaces after HBr/Br₂ etching. Inset: C1s region.

SRSOs grown by PECVD: Controlled structural and optical properties and formation of nanocrystals

T01 Applied Surface Science

#ASS-P2-01

P. Calta, P. Sutta, M. Netrvalová.

University of West Bohemia - Pilsen (Czech republic).

The silicon-rich silicon oxide films (SiO_x , $x \leq 1$) were deposited by a rf (13.56 MHz) plasma enhanced chemical vapor deposition on different substrates (Corning glass, Cu and Si(100)) at the low substrate temperature (250°C) in N_2O - SiH_4 -Ar discharges. The films obtained at different deposition conditions, varying the gas flow ratio of the precursor gases ($R = \text{N}_2\text{O}/\text{SiH}_4$), were heat treated to different temperatures up to 1100°C (in air and vacuum). The effect of the gas flow ratio R and thermal annealing on the compositional (EDS), microstructural (XRD), chemical bonding configuration (FT-IR and Raman microscope), optical (spectroscopic ellipsometry and UV-VIS spectrophotometer) and mechanical (by nanoindentation) properties of films and Si nanocrystals formation (TEM) were studied and results are presented and discussed.

Variable elemental composition Si/O, high deposition rate (60 nm/min), good hardness (around 7 GPa), low residual compressive stress (to 0.3 GPa), refractive indices of 1.6-1.8 and optical band-gap values 2 - 3 eV of as-deposited silicon oxide based films were obtained by varying the $\text{N}_2\text{O}/\text{SiH}_4$ flow ratio. Over 1000°C, annealed SRSO samples showed the c-Si diffraction peaks (Fig. 1), which became narrower with increasing temperature. From the width of the Si (111) peaks, the mean size of Si-ncs and their dependence on temperature was determined and compared to those values from TEM measurements. The size of Si-ncs increases with increasing Si concentration in the films and increasing annealing temperature [1]. FTIR spectroscopy shows the chemical composition of as-deposited films, which was dominated by silicon suboxide containing silicon-nitride and silicon-hydrogen bonds. During annealing, the shift of the Si-O-Si stretching vibration to higher wavenumbers indicates phase separation. The disappearance of the hydrogen related bonds indicates the hydrogen effusion. For the as-deposited films and for the annealed films, Raman spectra show a band approximately at 480 cm^{-1} , related to

amorphous silicon and a band at 517 cm^{-1} , related to nanocrystallite silicon, respectively. The optical band gap and refractive index decreases during annealing.

Beta-iron disilicide (β -FeSi₂) is a promising compound semiconductor for application to optoelectronic devices.¹⁾ For Si-based device fabrication, epitaxial growth of films on Si substrates is one of the techniques employed to achieve better device performance. β -FeSi₂ films can be epitaxially grown on Si single crystals, because the lattice mismatch between β -FeSi₂ and Si is within ca. 5% for all orientations. Control of the interface structure of the films and substrates is necessary to obtain highly oriented thin β -FeSi₂ films that have good optoelectronic properties.

The formation of β -FeSi₂ has been achieved using several growth techniques.²⁾ In our previous studies, ion beam sputter deposition (IBSD) of β -FeSi₂ on Si(100) resulted in the fabrication of highly oriented films.^{3, 4)} After subsequent annealing, the obtained films were found to exhibit strong photoluminescence (PL).⁵⁾ In the present study, β -FeSi₂ films were deposited on two different substrates, namely, Si(100) and silicon on insulator (SOI). Nanostructural and compositional changes at the interface take place during subsequent annealing and it was expected that these would be dependent on the substrates used. The structural changes at the interface, crystallinity of the β -FeSi₂ film and substrates, and the elemental composition, chemical states were investigated using cross-sectional transmission electron microscopy (TEM) and energy dispersive X-ray mapping. The annealed films on these substrates were found to exhibit quite different structures. The β -FeSi₂ films on Si(100) were aggregated, forming β -FeSi₂ particles with sizes of 20-200 nm. No dislocations or stacking faults were observed in the interface region. Aggregation also occurred to form β -FeSi₂ particles with sizes of 20-30 nm on the SOI substrate; however, no β -FeSi₂/Si interface was present because the buried SiO₂ layer significantly swelled during annealing and the surface Si layer disappeared. Based

on these observations, the effect of the interface structure and chemical states on the PL properties, which are important for optoelectronic devices, is discussed with atomic scale TEM observation.

Surface Spectrometry and Depth Profiling using Argon Cluster Ions

T01 Applied Surface Science

#ASS-5-Or-3

A. Sears, S. Kayser, E. Niehuis, R. Möllers, F. Kollmer, D. Rading.

IONTOF GmbH - Muenster (Germany).

Organic multi-layers have recently become of increasing importance in a number of technological fields. One of these areas is organic electronics which include OLED displays/lighting and power production photovoltaics. The optimization of the performance of these devices in terms of lifetime and efficiency requires a detailed knowledge of layer structure and interface composition.

The depth profiling/3D analysis of organic multi-layers with SIMS is only possible if molecular structural information can be preserved under high dose sputtering conditions. High energy cluster ions such as SF₅ [1] and C₆₀ [2] have received interest as their overall energy is large enough to sputter material whilst, at the same time, the energy per atom, of around several hundred eV, is low enough to minimize sample damage. However, there are a variety of organic compounds that cannot be profiled satisfactorily using these ions without the loss of ion signals [3]. Recent studies have shown that massive argon cluster ions have been successfully used for the SIMS depth profiling of a wide range of organic materials without loss of characteristic molecular ion signals [4].

Adequate mass filtering and short pulsing of the argon cluster ions enable them to be used as an analytical beam with high secondary ion yield efficiency on organic materials. In addition, mass spectra generated by these ions exhibit far less fragmentation in characteristic molecular secondary ions in comparison to those obtained using other ion species [5]. This overall simplification of the mass spectrum assists in data interpretation for determining sample composition.

In this paper we shall present the results of dual beam TOF-SIMS depth profiling of bulk and multilayer organic materials using Ar₁₀₀₀₋₂₅₀₀ and C₆₀ sputtering. The analytical potential of these ions in terms of their influence on mass spectra is also investigated with respect to the dependence of molecular fragment abundance as a function of argon ion energy and cluster size.

Optical characterization of semiconductors: photoluminescence measurements

T01 Applied Surface Science

#ASS-P1-18

M. Berouaken ¹, H. Menari ¹, N. Gabouze ¹, T. Kerdja ².

¹CRTSE - Algiers (Algeria), ²CDTA - Algiers (Algeria).

In this work, we carried out a photoluminescence (PL) test bench for the study of different optical properties of semiconductors. Its operating principle consists to illuminate the sample by means of an intense light beam from a laser. The light emitted by the sample is focused by a collimator on the entrance slit of a monochromator. The optical signal is then detected by means of a webcam and sent to a data acquisition system interfaced to a PC, where it is processed by software. This later allows the control of the monochromator, the acquisition and the processing of image from the webcam for the determination of the light intensity, and the plot of the PL spectrum. The excitation of a porous silicon sample with a laser at 405 nm showed a good correlation with other measurement benches.

Morphological methods suitable for image analysis of thin metal films and composite films: Application of methods of modern computational physics

T01 Applied Surface Science

#ASS-P1-10

D. Novotny ¹, R. Hrach ², M. Maly ¹.

¹J. E. Purkinje University, Faculty of Science, Department of Physics, Ceske mladeze 8, 400 96 Usti nad Labem - Usti Nad Labem (Czech republic), ²Charles University in Prague, Faculty of Mathematics and Physics, Department of Surface and Plasma Science, V Holesovickach 2, 180 00 Prague 8 - Prague (Czech republic).

In thin film physics as well as in some other fields of science as solid-state physics, astronomy, metallurgy, biology etc. the complex systems consisting of large number of objects are being studied. An important source of information is the image analysis of micrographs of these systems - discontinuous metal films, sections and projections of composite films, surfaces of solids, etc. Image analysis of such structures provides information about both size and spatial distributions of individual objects and these distributions influence fundamentally most of physical properties of the studied films. Standard methods based on the theory of mathematical morphology [1] are often used for a description of the spatial distribution of objects. The recognition ability of these methods for various types of physical systems differs and has some limits. From this point of view it is necessary to analyse existing methods and create new ways for the study of such image structures.

The contribution deals with a new approach to the image analysis of complex systems consisting of a large number of objects based on algorithms of modern computational physics - on neural networks and advanced integral transforms, i.e. Fourier/Hartley transform, Gabor transform and wavelet transform. It was found that both these techniques represent new powerful tools, which allow us to obtain the desired information hidden in the classical morphological characteristics. However, the application areas of both techniques differ, while the neural networks are better

suitable for the analysis of films in the initial stages of growth, the integral transforms bring the best results when analysing semicontinuous films and composite films near the percolation threshold.

The contribution consists of four parts: preparation of simulated structures with given properties (e.g. [2], [3]), detailed analysis of classical morphological algorithms, analysis of novel algorithms based on advanced methods of modern computational physics [4], [5] and application of both types of algorithms on simulated structures as well as on selected experimental data. For the preparation of simulated structures various types of models with different complexity were used - ranging from simplified hard-disk and soft-disk models to advanced atomistic models. In atomistic modelling two approaches were combined, the molecular dynamics for the description of nucleation process and the kinetic Monte Carlo method for the simulation of further growth stages. The main source of experimental data used for the comparison with model structures were the TEM micrographs of discontinuous and semicontinuous metal films prepared in our laboratory.

Quantitative Auger analysis of polarity-dependent GaN(0001)/ZnO(0001) wurtzite structures

T01 Applied Surface Science

#ASS-P1-07

C. Su.

Department of Electrophysics, National Chiayi University - Chiayi (Taiwan, republic of china).

Gallium nitride (III-V) and zinc oxide (II-VI) wide band gap semiconductor materials are promising in optoelectronics applications. Due to low lattice mismatch, ZnO substrate is suitable for grow GaN films. In this studies, quantitative Auger analysis of an ideal interface/surface such as Ga/N/ZnO(0001) or N/Ga/ZnO(0001) stacking is simulated. We calculate the Auger emission intensity ratio between interfaces and surfaces by inelastic-mean-free-path and transport-mean-free-path models. Interestingly, recent published report has demonstrated that the surface sensitivity of Auger electron spectroscopy can be effective to recognize the surface polarities such as O-ZnO(0001) or Zn-ZnO(0001) [1]. Thus, we progressively calculate the similar structure GaN(0001) in order to make a P-N junction structure in the further experiment. Different surface treatment, e.g. ion sputtering and annealing, on a clean crystal surface may damage and vary the surface composition. However, through the quantitative analysis the Auger signal measurement can be more effective to predict the surface polarity in the initial growth. Important issues focus on the surface bonding and interface stacking to affect greatly the optoelectronic transport and related physical properties are discussed and presented.

ASS-6-Or-2

Initial oxidation process of hydrogen-terminated Si(110)-(1x1) surface

T01 Applied Surface Science

#ASS-6-Or-2

S. Suto¹, H. Niimura¹, E. Kawamoto¹, S.Y. Matsushita¹, K. Haga¹, T. Yamada².

¹Department of Physics, Graduate School of Science, Tohoku University - Sendai 980-8578 (Japan), ²RIKEN - 2-1 Hirosawa, Wako, Saitama 351-0198 (Japan).

Recently, hydrogen-terminated Si(110)-(1x1) [H:Si(110)] surfaces are attracted much attention because the two methods using the Si(110) surface have been intensively studied in order to improve the silicon device, in particular the CMOS circuits. One is the 3D device like Tri-Gate FET proposed by the intel company. The other is the attempt to change substrate from standard Si(100) to Si(110) wafers. However, there is almost no investigations on the initial oxidation process of Si(110) surface. We report here the preparation and oxidation processes of an ultraclean and well-ordered Si(110) surface using the high-resolution electron energy-loss spectroscopy(HREELS).

First, we successfully prepared a well-ordered and ultra-clean H:Si(110) surface by etching a Si(110) wafer in 40% aqueous solution of NH₄F [1,2]. The surface order was verified by LEED and the cleanliness was measured by HREELS. Second, we oxidized the Si(110) surface by atomic oxygen produced by a hot tungsten filament, because the surface is too stable to oxidize by oxygen molecules. Third, we observed the HREELS spectra with increasing the time of exposure in atomic oxygen at room temperature. Fourth, the oxygen coverage was estimated from the peak shift of the Si-H stretching mode; the peak energies are 258.5, 266.5, 273.0 and 280.7 meV for clean surface (H-Si), one oxygen atom adsorption (H-SiO), two (H-SiO₂), and three oxygen atoms (H-SiO₃) adsorption at the first layer Si back bond, respectively. Finally, we carried out Monte Carlo simulations to clarify the adsorption processes.

In the HREELS spectra of the clean Si(110) surface, we observed surface phonon mode at 58.7 meV, Si-H bending mode at 77.5 meV and Si-H stretching mode at 258.7 meV. After the oxidation, new peaks of Si-O-Si symmetric and asymmetric stretching modes appeared at 97.3 and 126.9 meV, respectively, and then, the two

peaks shifted higher energy side with increasing the coverage. Furthermore, the peak and the spectral shape of Si-H stretching mode varied with the oxygen coverage depending on how many oxygen atoms exist at the Si back bonds. We determined the relation between the amount of oxygen adsorption and exposure time, and between the amount of oxygen adsorption and the coverage for each oxidation stage, i.e., Si-H, Si-HO, Si-HO₂ and SiHO₃.

We successfully simulated above results with Monte Carlo method. On the Si(110) surface, first layer Si-Si bonds form the zigzag chain along [1-10] direction (A bond) and there are another Si-Si bonds between first layer and second layer Si bonds (B bond) [2]. At the coverage lower than 1 monolayer (ML), the oxygen atoms prefer to adsorb to form H-SiO₃ where two oxygen atoms exist at A bonds and one oxygen atom at B bonds. The full surface coverage is 3 ML. With increasing the coverage, the oxidation proceeds along the zigzag chain. The present understanding may lead to future possibilities of application of Si(110) surface.

Due to the high solar energy conversion efficiency, dye-sensitized solar cells (DSCs) represent one of the most promising new generation devices [1]. A DSC consists of 3 main components: (i) photo-anode sensitized with dye molecules, (ii) hole-conducting material and (iii) counter electrode. The whole structure is sealed using hot-melt sealants to avoid electrolyte leakages and protect cell elements from environment. To better understand the behavior of different DSC components, an in-situ analysis should give a help, but it results difficult to be performed without compromising cell integrity. Our novel microfluidic approach for DSCs fabrication [2] is based on a reversible electrodes sealing and allows cell easy assembling and disassembling, making possible a non-destructive components analysis over time [3]. In this study we focused on the counter electrode, which is made by TCO-covered glass coated with a thin (few nm) Pt layer, deposited by 2 different methods: thermal decomposition of a printable transparent Pt catalyst and thermal deposition. Our goal has been to establish which method produces the most reliable Pt film, which can withstand the time-dependent degradation, due to the DSC inner harsh environment. So detailed morphological (FESEM) (fig.1), optical (UV-Visible spectroscopy) (fig. 2), electrical (EIS) and surface (XPS) characterizations [4] have been performed on the counter electrodes over a period longer than 3 months. The obtained results confirmed that degradation has occurred, leading to a strong decrease of the counter electrode photovoltaic performances.

Structural and electronic characterization of transition metal nanostructures on vicinal Au(332)

T01 Applied Surface Science

#ASS-8-Or-1

M. Prieto, E. Carbonio, R. Landers, A. De Siervo.

Instituto de Física 'Gleb Wataghin', Universidade Estadual de Campinas, 13083-859 - Campinas (Brazil).

Transition metal nanostructures have been extensively studied for several applications in several areas of research [1,2]. Single crystalline surfaces of high Miller index offer the possibility to model materials of technological interest and study the correlations between electronic and geometrical factors with the role of defects. In this presentation we show the results obtained in the study of the morphology of Co and Pt nanostructures deposited on Au(332) surface, as well as their electronic properties.

Figure 1 shows representative STM images of clean and Co-modified Au(332) surface for the lowest θ_{Co} . From UHV-STM images, θ_{Co} values were estimated as lying in the 0.15-0.6 ML range. In all cases, terraces present on clean Au surface seem to remain unchanged, i.e. do not seem to break-up due to the presence of Co nanostructures. Additionally, it is determined from image analysis that Co structures have a height of an atomic bilayer.

On the other hand, no reconstruction of the substrate is detected after deposition or even after thermal annealing (TA) of the sample, where a break up of steps on the substrate due to an apparent diffusion of Co atoms into the Au lattice. XPS measurements reveal that Co deposited is metallic, as suggested by Co2p_{3/2} binding energy (BE = 778 eV) and the absence of the well-known satellites of Co oxides. Additionally, XPS data confirm Co diffusion into Au crystal after thermal treatment and the extent of Co incorporation into Au matrix is expected to be high. Co-Au alloy formation is discarded at all θ_{Co} investigated, since BE of Co core lines remain unchanged as θ increases. In the case of Pt, XPS reveals the formation of an Au-Pt alloy is detected at all θ_{Pt} explored, even at low values. When Pt/Au(332) surface is investigated by STM, break up of steps by Pt atom deposition is observed and surface morphology after

deposition is different from that observed in Co/Au(332). XPS data reveals that TA of Pt/Au(332) enhances alloy formation and, in contrast to the Co/Au(332) system, alloying seems to be favored over atom diffusion.

Thus, experimental results obtained indicate that Co and Pt nanostructures have different structure as well as electronic properties, reflecting the chemical differences between both transition metals. Provided that substrate used is the same, potential differences on reactivity could be explained with our results.

Nano-FTIR: infrared spectroscopic chemical identification of materials at the nanoscale.

T01 Applied Surface Science

#ASS-10-Or-6

M. Böhmler ¹, F. Huth ¹, S. Amarie ¹, F. Keilmann ², R. Hillenbrand ³.

¹Neaspec GmbH - Munich (Germany), ²MPQ - Garching (Germany),

³IKERBASQUE - Bilbao (Spain).

Fourier-transform infrared (FTIR) spectroscopy is an established technique for characterization and recognition of inorganic, organic and biological materials by their far-field absorption spectra in the infrared fingerprint region. However, due to the diffraction limit conventional FTIR spectroscopy is unsuitable for measurements with nanoscale spatial resolution.

We recently applied the principles of FTIR to scattering-type Scanning Near-field Optical Microscopy (s-SNOM) [1-4]. s-SNOM employs an externally illuminated sharp metallic tip to create a nanoscale hot-spot at its apex which greatly enhances the near-field interaction between the probing tip and the sample. The light backscattered from the tip transmits the information about this near-field interaction to the far zone where the FTIR spectra can be recorded. The result is a novel nano-FTIR technique, which is able to perform near-field spectroscopy and imaging with nanoscale resolution.

Here we demonstrate nano-FTIR with a coherent-continuum infrared light source. We show that the method can straightforwardly determine the infrared absorption spectrum of organic samples with a spatial resolution of 20 nm. Corroborated by theory, the nano-FTIR absorption spectra correlate well with conventional FTIR absorption spectra, as experimentally demonstrated with PMMA samples. Nano-FTIR can thus make use of standard infrared databases of molecular vibrations to identify organic materials in ultra-small quantity and at ultra-high spatial resolution.

As an application example we demonstrate the identification of a nanoscale PDMS contamination on a PMMA sample [4]. In figure 1 the topography image (left) reveals a small sample contaminant (B) next to a thin film of PMMA (A) on a Si substrate (dark region). Comparing the nano-FTIR absorption spectra at the positions A and B with standard IR databases reveals the chemical identity of the film and the particle.

We envision that nano-FTIR will become a powerful tool for chemical identification of nanostructures, for investigation of local structural properties (i.e. defects, strain) of crystalline and amorphous nanostructures, as well as for non-invasive measurement of the local free-carrier concentration and mobility in doped nanostructures.

Central Laboratory of Solar Energy and New Energy Sources,

Bulgarian Academy of Sciences, blvd. Tzarigradsko chaussee 72, Sofia, Bulgaria

The rapidly increasing use of transparent and conductive oxide (TCO) films for photovoltaics has promoted the development of inexpensive materials and low cost technological processes. Most of the TCO films are binary or ternary compounds containing one or two metallic elements. The combination of conductivity and transparency is impossible to obtain in intrinsic or undoped stoichiometric oxides. For obtaining high conductivity in these materials, either they have to be nonstoichiometric in composition or should be doped with appropriate element. The aim in this study is formation of a conductive area in nanolaminate dielectric structure. Physical base is the idea is to use an electronic conductivity in granular materials. The granules are arrays of metallic particles of sizes ranging from a few to hundred of nanometers embedded into an insulating matrix.

The nanolayer structure is formed using one or two dielectrics. The electrical conductivity is modified with planar located metal granules. The advantages are reproducibility of technological parameters, effective methods for process control and a selective formation of conductive areas in dielectric structure. It must be noted that the conductivity area of the nanolaminate structure is transparent. The optical transmittance and the sheet resistance are function of the density of the metal nanoparticle in the middle layers.

A transition from an insulating to a metallic conductivity can be explained by the increase in carrier concentration and formation of a degenerate band. Usually TCOs

have semiconductor behaviour as negative temperature coefficient of receptivity (TCR). The nanolaminate structure with metal granulate demonstrate the metallic conductivity as it has a positive TCR. Therefore the carriers are delocalized due to thermal activation and conductivity is dominated by phonon scattering.

The electrical conductivity can be obtained of the nanolaminate structures with dielectrics such as TiO_2 , Al_2O_3 and $(\text{Al}_2\text{O}_3)_x(\text{B}_2\text{O}_3)_{1-x}$, deposited as a first layer on substrate. The electrical conductivity depends on dielectric type and on its thickness. The contact of the nanolaminate structures with p-Si is ohmic.

Surface morphology of nanolaminate structure with $(\text{Al}_2\text{O}_3)_x(\text{B}_2\text{O}_3)_{1-x}$ as “bottom” layer and selective formed conductive area are studied by AFM microscopy. The conductive area is average 5 nm higher than the non conductive one as it can be observed from the section analysis. The reason for this is the effect of the metal granules. The electrical properties of the “conductive” and “dielectric” areas are investigated.

Chemical liquid deposited $(\text{Al}_2\text{O}_3)_x(\text{B}_2\text{O}_3)_{1-x}$ has been included as “bottom” layer of the nanolaminate structure, where selective conductive areas are formed. The good passivation properties of $(\text{Al}_2\text{O}_3)_x(\text{B}_2\text{O}_3)_{1-x}$ can be used and the possibility to form local contacts without etching or laser ablation. The proposed technological approach is perspective for rear passivation and metallization of high efficiency silicon solar cells.

Surface characterization of Pt thin films on Si substrates during ion bombardment

T01 Applied Surface Science

#ASS-8-Or-9

A. Hervier, D. Aureau, A. Etcheberry.

Institut Lavoisier de Versailles - Versailles (France).

Ion bombardment techniques have become common tools in a wide variety of applications, from tribology to microelectronics or materials toughening. The common feature of these techniques is that they all produce surface effects, which can be readily characterized.

We present the results of an extensive investigation into the effects of ion bombardment on Pt thin films on Si, at energies high enough to induce phase mixing.

Figure 1 shows the Pt/(Pt+Si) ratio, determined by XPS, of Pt/Si films subjected to different doses of ion bombardment, starting from a fresh, completely covered film, to a mixed surface with no elemental platinum left. A transition is visible at which point the film breaks up and the silicon becomes detectable. AFM measurements show that this transition coincides with a maximum in the roughness of the film and, according to XPS measurements, with the formation of a platinum silicide phase at the surface, as explained in Figure 2.

Features of the platinum film disappear in SEM images with increasing dose. Auger nanoprobe analysis shows that no silicon or silicon oxide is exposed at the surface at the doses used here. Instead, the entire surface consists of platinum silicide.

Previous work has shown that the electronic structure of silicon can vary depending on the type of surface preparation. Effective dopant concentrations, flat-band potentials, or reverse dark currents for example, strongly depend on whether the surface has been mechanically or mechanochemically polished, or chemically etched. Ion bombardment can be thought of as another pre-treatment process, the effects of which can be observed with a combination of surface characterization techniques.

Fig.1 – Pt/(Pt+Si) surface ratio determined by XPS measurements of Pt/Si surfaces subjected to nitrogen ion bombardment

Fig. 2 – XPS Pt4f spectra of samples subjected to increasing doses of helium ion bombardment. The dashed arrow shows the transition from Pt/Si on an as-deposited sample to Pt_xSi as the ion dose increases. The +1 eV energy shift under ion bombardment is characteristic of the formation of a mixed Pt_xSi phase.

Iron oxide surface engineering: synthesis of magnetically retrievable nano-organocatalysts.

T01 Applied Surface Science

#ASS-2-Or-10

E. Nehlig ¹, L. Motte ², E. Guénin ².

¹Université Paris 13, Sorbonne Paris Cité, Laboratoire CSPBAT, - Bobigny (France), ²Université Paris 13, Sorbonne Paris Cité, Laboratoire CSPBAT - Bobigny (France).

In the past decades, interest for new catalysts and new catalytic reactions increases greatly due to their large applications in several domains such as pharmaceutical and chemical industries. New catalysts were described for an increasing number of organics reactions. Nevertheless, most of the homogenous catalysts are difficult to adapt to industrial process due to separation and regeneration problems. Moreover, though highly efficient, most of the catalysts are containing noble or toxic metals and so new protocols more economically and environmentally friendly need to be developed. The use of magnetic nanoparticles [1] as a catalysts support in organic synthesis has become a subject of intense investigation because they appear as an ideal solution for solving these catalytic problems. The present project purpose is to mix two new approaches: nano-catalysis and organocatalysis [2] in order to develop new greener nano-organocatalysts. The hybrids are obtained from the grafting of well known organocatalysts (Amino acids, peptides, alkaloids) at the surface of superparamagnetic iron oxide nanoparticles. The 10 nm nanoparticles synthesized by mild conditions [3] in water are stabilized by bidentate coating agent (e.g. bisphosphonates) with a terminal function which enable the post functionalization (grafting from approach) of the particles with organocatalysts. The functionalization is done in aqueous media using microwave-assisted and or click chemistry protocols [4]. A grafting to methodology was also tested in order to modulate the number of catalysts per nanoparticles, using a pre-synthesized organocatalyst bearing a bisphosphonate moiety. These new hybrids are then characterized (TGA, EDX, TEM, IR, UV-visible, MIAplex, MIAtek) and tested for their ability to catalyzed known organic reactions (e.g. enantioselective aldolisation, Michael additions). A Proline loading between 0.12 and 0.15 mM.g⁻¹ was determined

for the different kind of grafting. First results with these new nano-organocatalysts [5] are promising as in some cases yield >95% are obtained with >0.2% mol.

Development of Fe₃O₄-SiO₂ films by sol-gel dip-coating method onto pretreated glass surface

T01 Applied Surface Science

#BI/ASS/NST-P1-07

J. Setina, G. Mezinskis, A. Gabrene, A. Pludons, I. Juhneva.

Riga Technical University - Riga (Latvia).

Obtaining thin films of SiO₂/Fe₃O₄ nanoparticles by sol-gel dip-coating method on the glass involve several stages: preparation of glass surface, preparatory period by creation of substrate for thin films, choice of coating technology.

The soda-lime-silicate glass microscope slides were etched in different solution such as NaOH, H₂SO₄, HF. Etching methods enlarge surface area and generate a new surface by removing material from original glass. Surface property and morphology of glass are changed by all methods of etching. Hydrothermal treatment with NaOH caused hydroxyl ion attack to silica network, converting bridging oxygen into a non-bridging one, thus disrupting the network. Gel-like layer formed during etching by NaOH solution typically provided smoothing effect of surface. Topography and measurements of surface roughness obtained by AFM channel like structure showed. Structured glass surface with holes and cavities could be obtained by combinations of etching media (H₂SO₄ or HF). The atomic percentage of sodium on surface decreases by treatment with H₂SO₄. Morphology of glass surface treated by H₂SO₄ changed dependently on treatment time: R_q-8,558 nm (1h); R_q-3,313 nm (2h); R_q-2,500 nm (20h).

Second step was – preparation of magnetic nanoparticles Fe₃O₄ using coprecipitation method. A coprecipitation in alkaline media starting a mixed FeSO₄·7H₂O/FeCl₃·6H₂O solution with a molar ratio of Fe²⁺/Fe³⁺ = 0.5.

Two sol-gel dip-coating methods of production multilayer films of SiO₂/Fe₃O₄ nanoparticles were used: adding of prepared magnetite direct to SiO₂ sol and encapsulation magnetite between two SiO₂ sol-gel layers. Better quality was for sandwich type films obtained by encapsulation magnetite.

The films consisted three layers on a glass substrate. The first and third layers were a SiO₂ prepared by dip-coating from tetraethylortosilicate solutions and subsequent calcination at 500°C temperature in air. The second layer was prepared by dip-coating from the aqueous colloidal dispersion of previously synthesized magnetite.

The average size of synthesized magnetite nanoparticles was estimated to be c.a. 15 nm. The calcined films reported here exhibit crack-free morphology, consisting of aggregated silica/magnetite nanoparticles. Future controlled advancement of this method could provide a low cost solution for mechanically stable composite thin films with various, technologically useful, properties.

Acknowledgment:

This work has received a financial support of the ERDF “Development of solar heat absorbing materials by means of sol-gel and vacuum technologies” (Project No 2DP/2.1.1.1.0/10/APIA/VIAA/156).

ASS-9-Or-1

Templated substrate; New approach to modify self-assembled molecular structures

T01 Applied Surface Science

#ASS-9-Or-1

M. S. Babiloniaei ¹, D. Lei ², N. Lin ², L. Diekhöner ¹.

¹Department of Physics and Nanotechnology, Aalborg University - Aalborg (Denmark), ²Department of Physics, Hong Kong University of Science and Technology - Hong Kong (Hong Kong).

The design and fabrication of nanostructures at the molecular scale is a key to develop devices with nano-scale precision and ultrahigh efficiency [1]. One of the promising techniques at this point is Self-assembly which gives a very good opportunity to play with molecules and atoms in the bulk and on the surface. By understanding and predicting the possible interactions (molecules-molecule, surface-molecule) existing in the system it is possible to design and create the desired pattern [2]. Molecules with aromatic ring to enhance the interaction with the metal surfaces and functional groups to form multiple H-bondings or metal-organic coordinations are ideal for the supramolecular self-assembly [2,3].

Here we have studied the role of a modulated surface on the self-assembly of organic molecules promoted via either H-bonding or metal-organic coordination. As a substrate we used one monolayer of Ag on Cu(111), which grows in step-flow mode allowing us to fabricate large islands or even cover the entire surface [4,5]. Due to a lattice mismatch, the Ag layer makes a (9x9) reconstruction leading to a Moiré pattern structure with nanometric modulation.

Trimesic acid (TMA) molecule with three functional group for H-bonding, were studied with STM on the Ag/Cu(111) surface and the results were compared with structures formed on flat Ag(111) and Cu(111) surfaces. TMA formed honey-comb pattern on Ag(111) and Cu(111) at room temperature but after annealing to 420K it converted to quartet and close-packed structures, respectively. The experiments on modulated Ag/Cu(111) surface showed an irregular structure at room temperature which indicated that the surface disturbed the self-assembly. Upon annealing it was possible to recover a long range order (quartet structure) on the surface. This quartet structure could be distinguished from the structure formed on Ag(111) by the alignment of the pattern and density of molecules.

We have also studied 1,3,5-trispyridylbenzene (TPyB), which is capable of forming metal-organic network with Cu atoms. The intermolecular interactions are stronger than those of the H-bonded TMA and we therefore expect less influence of the modulated substrate. TPyB/Cu forms a honey-comb structure on Au(111), Cu(111) as well as on the Ag/Cu(111) surfaces. STM images revealed two distinguished phases of honey-comb pattern on the modulated surface. We observed that the molecular structure either undergoes a small structural distortion of the individual hexagons in the honey-comb layer or preserves the undistorted honey-comb shape while rotating slightly from the Moiré pattern alignment. These experiments indicate that the use of templated substrates like Ag/Cu(111) could be a new approach to manipulate self-assembled structures to modify them for the possible applications.

ESD/ASS-2-Or-6

Multi-technique approach on thin photovoltaic films characterization: demonstration on CIGSe absorbers

T01 Applied Surface Science

#ESD/ASS-2-Or-6

D. Mercier¹, M. Bouttemy¹, J. Vigneron¹, I. Gerard¹, P. Chapon², N. Naghavi³, J.F. Guillemoles³, J.L. Pelouard⁴, D. Lincot³, A. Etcheberry¹.

¹Institut Lavoisier de Versailles - Versailles (France), ²Horiba - Longjumeau (France), ³Institut de Recherche et Developpement sur l'Energie Photovoltaïque - Chatou (France), ⁴Laboratoire de Photonique et de Nanostructure - Marcoussis (France).

Absorbers based on thin films technology and in particular CIGSe (Cu(In,Ga)Se₂) are a good alternative to Silicon wafers for highly efficient photovoltaic cells. Currently, CIGSe record efficiencies reach a 20.3% value in laboratory and 13% at the industrial scale. Performances of photovoltaic cells mainly rely on the absorber properties. In the context of understanding and improving cells performances, it is therefore important to control the chemistry (composition, impurities...) in the bulk, at the surface and at the interface of absorbers. This work suggests a multi-technique approach based on ICP-OES (Inductively Coupled Plasma- Optical Emission Spectroscopy), GD-OES (Glow discharge- Optical Emission Spectroscopy) and XPS depth profiling methods to characterize CIGSe absorbers.

The first approach consists in probing the CIGSe absorber depth composition using real time ICP-OES dosage of the absorber constituents during a chemical etching based on acidic bromide solution (HBr/Br₂)... In parallel, XPS analyses are carried out on CIGSe samples having undergone a chemical etching for different durations giving a direct access to the absorber depth composition at specific depth location. A good agreement is found by those both techniques indicating the absence of chemical modifications of the absorbers surface.

Secondly, a plasma etching is realized by GD-OES. Chemical composition and impurities are measured. XPS analyses (probe size 400µm) are also performed in the GD crater (2-8 mm) after different etching time in order to calibrate GD-OES depth composition profiles and evaluate surface modifications (roughness effect).

Finally, a direct XPS depth profile using Ar sputtering is carried out on a CIGSe sample for which the thickness has been reduced by chemical treatment from 2.5 μm to 0.5 μm to characterize the Cu/Mo interface. Optimization of the fitting procedure of the main elements Cu, Ga, In and Se permits to precisely determine the chemical environments. . The MoSe₂ interface is clearly observed between the CIGSe back-side interface and the molybdenum substrate.

To conclude, a multi-techniques depth profiling approach (ICP-OES/XPS, GD-OES/XPS, XPS) is developed whose aim is to get complementary information on the whole absorber material (surface, bulk and interface) and allow a better understanding of the relation between the absorber composition and photovoltaic cell performances.

Effect of Surface Modification of crystalline and amorphous SiC thin films : optical and structural properties

T01 Applied Surface Science

#ASS-P3-16

A. Keffous.

C.R.T.S.E - Algiers (Algeria).

In this work, we study the effect of surface modification (ESM) on optical and structural properties of porous and unporosified hydrogenated amorphous silicon carbide (PASiC) and porous crystalline silicon carbide (PSiC) thin films deposited onto p-Si(100). The thin films are elaborated by a d.c. magnetron sputtering and laser ablation system and electrochemical etching to perform a porification, compared to irradiated laser (KrF) of unporosified same thin films forming pillars structure. The porous structure of the SiC layer deposited was developed by an electrochemical (anodization) method.

For unhydrogenated films, an early birth of nano and micro pillars was observed after irradiation with 1 to 80 laser shots. However, a large number of shots is needed, from 2400 to 7200, to form micropillars on 6H-SiC bulk. It is shown that the dimension and density of pillars depend on the sample nature, shots number and irradiation energy. Finally, it is demonstrated that the luminescence intensity increases with number of laser shots for the thin films. The films were investigated by UV-visible spectrophotometry, infrared spectroscopy (FTIR), secondary ion mass spectroscopy (SIMS), Scanning electron microscopy (SEM), Raman spectroscopy and photoluminescence spectrophotometry (PL).

Electroless nickel deposition on silicon: nucleation and annealing study

T01 Applied Surface Science

#ESD/ASS-1-Or-1

H. El Belghiti ¹, D. Aureau ², E. Delbos ¹, M. Bouttemy ², A. Etcheberry ².

¹Institut Lavoisier de Versailles - OMG UPC - Versailles (France), ²Institut Lavoisier de Versailles - Versailles (France).

One of the major challenges in the photovoltaic field today, and particularly for the silicon solar cells, is to replace the contact lines made by silver past. Indeed, the contact lines must be optimized in order to both increase the solar cells efficiency and reduce the cost of manufacturing.

Several materials and processes are considered. Electrodeposited copper lines are one of these ways. However, the copper diffusion throughout the silicon substrate, leading to the degradation of the solar cell efficiency, must be avoided. In order to overcome that, one solution is to deposit a nickel layer between the silicon substrate and the copper lines (1,2). In this research works, an electroless nickel process has been chosen.

The main goal is the deposition of a thin, homogeneous, continuous and adherent nickel layer. For that, it is necessary to precisely control the nickel layer growth. Consequently, the first stages of the nickel nucleation on the silicon and the final layer composition, after the annealing, are especially studied.

Therefore, thanks to SEM imaging (figure 1), XPS (figure2) and nano-Auger analyses, a specific work dedicated to the study of the nickel nucleation on silicon substrate is proposed. In a second part, the influence of the annealing temperature on the composition, crystallinity and adhesion of this nickel layer was studied and monitored by EDX, EBSD and XPS analyses.

Surface Oxidation and Reduction in Titanium Metal Injection Molding

T01 Applied Surface Science

#ASS-P2-02

W. Lee, J.M. Jang, H.J. Lee, S.H. Ko.

Korea Institute of Industrial Technology - Incheon (Korea, republic of).

Metal Injection Molding (MIM) is a near net shape manufacturing method and a cost-effective and flexible manufacturing technique that provides a large innovative potential over existing methods for the industry[1]. Recently, considerable progress in powder injection molding of titanium and its alloys has been accomplished. However, cost of raw materials, especially for gas atomized powders, is still a limiting factor for a number of applications[2-4]. In this work, the formation and dissolution of titanium oxide layer in metal injection molding process were investigated using TiH_2 feedstock (a mixture of about 300 nm-sized TiH_2 powder and binder such as wax and polymer). The TiH_2 powder was produced by ball milling of titanium turning chips in room temperature under hydrogen atmosphere titanium turning chip. After injection molding using the feedstock, subsequent debinding process to remove binder was performed through heating up to 600°C under flowing high purity hydrogen gas containing 1.8 ppm O_2 and 1.03 ppm H_2O . During debinding, thin Ti_2O and/or Ti_3O oxide layer was formed on surface of the molded part in spite of use of high purity gases and the surface appeared dark-blue. However, after sintering of the debound part at 1250°C in high vacuum of 6.7×10^{-3} Pa, the oxide layer disappeared and any oxide peaks were not observed in XRD analysis, showing bright grey color. The reduction mechanism of the Ti_2O and/or Ti_3O oxide layer is considered as two kinds: one is a reduction due to reaction of titanium oxide and residual carbon after debinding. An amount of residual carbon in samples after debinding was measured to 0.57 wt% and thus, during sintering, titanium oxide is reduced by reaction with residual carbon, releasing CO gas. The other is decomposition of metastable Ti_2O and/or Ti_3O phase. The metastable oxide is decomposed at high temperature in high vacuum and then, oxygen atoms diffuse inside titanium part.

Microstructure of $\mu\text{c-Si:H}$ films prepared by PECVD when used different substrates

T01 Applied Surface Science

#ESD/ASS-P3-07

M. Netrvalova ¹, P. Sutta ¹, P. Calta ¹, L. Prusakova ¹, V. Vavrunkova ¹, I. Novotny ², V. Tvarozek ².

¹University of West Bohemia - Pilsen (Czech republic), ²Slovak University of Technology - Bratislava (Slovakia).

Tandem solar cell is a one of the concepts well established as a way how to improve solar cell performance beyond that of a single cell. Taking into consideration the thin-film silicon solar cell technology, microcrystalline silicon ($\mu\text{c-Si:H}$) is very important for this purpose [1]. The $\mu\text{c-Si:H}$ is usually prepared from silane diluted with hydrogen or from silane mixed with argon and diluted with hydrogen by using PECVD [2]. In order to obtain $\mu\text{c-Si:H}$ films of a good quality, their structural and optical properties have to be carefully monitored by X-ray diffraction, Raman and FTIR spectroscopies as well as by UV Vis spectrophotometry and spectroscopic ellipsometry [3]. Developing microcrystalline silicon thin films on glass is usually used as a substrate for detailed observation its physical properties. Nevertheless, in thin films solar cell configuration the silicon film is deposited on transparent conductive oxide. The aim of this work was to evaluate whether the substrate used influence the microstructure of the film when using the same deposition conditions.

Microcrystalline Si films near the same thicknesses (360 – 410 nm) were deposited on the Corning glass and aluminium doped zinc oxide substrates from silane mixed with argon (90% Ar / 10% SiH₄) and diluted with hydrogen using PECVD. Silane diluted with hydrogen ($R = \text{H}_2/\text{SiH}_4$) was applied at levels from $R = 20$ to 70. In order to ascertain the physical properties of the films the experimental methods mentioned above were used.

X-ray diffraction indicated that regardless of substrate used the films with dilution $R = 20$ are amorphous, whereas the films with higher dilution $R \geq 40$ are microcrystalline (mixture of amorphous and crystalline phases). Average crystallite size of crystalline phase is in the range of 10 to 20 nm. These results were confirmed also by Raman

and FTIR spectroscopies. Substrates used in this work do not influence too much the microstructure of the films.

The result was developed within the CENTEM project, reg. no. CZ.1.05/2.1.00/03.0088, co-funded by the ERDF as part of the Ministry of Education, Youth and Sports' OP RDI programme.

Non-contact electrical characterization of selected inner domains and interfaces in solar cell devices

T01 Applied Surface Science

#ESD/ASS-1-Or-5

H. Cohen.

Weizmann - Rehovot (Israel).

The inability of existing electrical tools to probe selected inner domains is a critical problem in device characterization and nanoscale fundamental studies. In particular, measuring internal junction fields is essential for realistic construction of band diagrams and device optimization. An answer to this problem is provided by chemically resolved electrical measurements (CREM) [1,2], an essentially non-contact technique that extracts electrical information from x-ray ejected photoelectrons. Applied to multi-interfacial solar cells, key features of the CREM methodology are introduced, including detailed evaluation of the internal fields and band offsets and, furthermore, the quantification of internal dynamic distortions under external stimuli. Problem solving gained by this improved feed-back tool is demonstrated.

Interfacial toughness determined from periodic buckling patterns

T01 Applied Surface Science

#SE/ASS-1-Or-1

S. Grachev ¹, J.Y. Faou ¹, G. Parry ², E. Barthel ¹.

¹Surface du Verre et Interfaces, UMR 125 CNRS/Saint-Gobain - Paris (France),
²SIMaP-Laboratoire de Thermodynamique et Physico-Chimie Métallurgiques - Grenoble (France).

Thin films spontaneously buckle under compression forming blisters of various shapes. When attached to a substrate, the buckling phenomenon is restricted by adhesion to the substrate. On one hand, the film buckling is described by the non-linear Föppl–von Kármán equations and has been well reproduced by finite element method (FEM) simulations. On the other hand, the delamination process involves the fracture of the interface under a mixed mode loading (both with normal and shear forces), which influences the energy needed to crack the interface, that is the interfacial toughness. The interplay between the biaxial stress relaxation and the interfacial toughness often results in formation of periodic patterns, as telephone-cord-like blisters. Recently we have shown the importance of taking into account both phenomena [1]. In the current work we make a step further and study the critical conditions for the blisters to branch and to form periodic two-dimensional networks. The parameter's space was thoroughly studied by FEM simulations. We show that the period of a blister rather than its width is defined by the parameters of the system (stress, thickness, materials properties and the interfacial toughness). This relationship provides practical means to estimate the interfacial toughness. Branching and blister networks can form in a certain area of the parameter space, and their period can be predicted. The results of simulations are confirmed by experimental observations of buckling of the sputter-deposited films. In particular, the self-organized hexagonal network was both simulated and observed experimentally with the period of features of $\sim 10 \mu\text{m}$.

ASS-4-Or-2

From sea urchin to catalyst for CO₂ hydration reaction

T01 Applied Surface Science

#ASS-4-Or-2

L. Šiller, G. Bhaduri.

Newcastle University - Newcastle Upon Tyne (United kingdom).

The biomineralisation process occurs at room temperature, at atmospheric pressure and is relatively fast. It is commonly accepted that the biomineral growth is assisted by the Carbonic anhydrase (CA) enzyme, however it is also been suggested that the bioaccumulated metal elements may also play some role, perhaps more than just the nucleation sites for calcification. Mimicking the biomineralisation process is important in many areas, such as medical implants or carbon capture. The two major parts in mineralization of carbon dioxide include conversion of carbon dioxide to carbonic acid followed by neutralization of the acid; the rate limiting step being the hydration of carbon dioxide to carbonic acid. The storage of CO₂ as a mineral salt has been identified as one of the safest method of carbon capture and storage (CCS). In this study, we report the use of novel catalyst (discovered from biomimicking mineralisation in sea urchins) to catalyse the reversible hydration of CO₂ at room temperature and atmospheric pressure [1,2]. We observe that the catalyst increase the CO₂ uptake capacity of water. The catalytic activity is pH independent (of the starting value of pH of water 6.2-5.5) and catalysts are water insoluble and can be easily separated from the reaction mixture. The reaction steps are characterised using X-ray photoemission spectroscopy and a possible reaction mechanism has been discussed. We also observe an enhancement in the activity of the catalyst as a function of the increase in temperature.

In recent years, Auger spectroscopy has been neglected on benefit of X-Ray photoelectron spectroscopy giving an easier access to the surface composition and chemical shift. Indeed, thanks to new generation electron sources, developed for high resolution microscopy, ultimate probe size of 10 nm are achieved^{1,2} with the new generation Auger nano-probes. Such equipments are therefore promising tools to address the need of localized chemical characterization of cutting edge structures whose dimension are reaching the nanometric scale on which "classical" XPS (X-Ray source) is not well adapted. In addition, with energy resolution of 0.1 % (at 2000 eV), nano-Auger electron spectroscopy is not only able to give information about the composition but also, when the chemical shift is high enough, on the chemical environment.

The present work is dedicated to the determination of ultimate performances of nano-Auger spectroscopy. The lateral resolution is evaluated on a certified reference sample, BAM-L200 (« Bundesanstalt für Materialforschung und prüfung »), constituted of a stack of alternated lines of Al_{0.7}Ga_{0.3}As/GaAs with variable intervals ranging from 700 to 7 nm. Results obtained with the different acquisition modes (point, line profile or mapping) will be presented (figure 1). Complementary AFM and XPS measurements will permit to extend the discussion about the impact of topography or surface oxidation state on the spatial resolution and on the detection limit. The capabilities of nano-Auger on practical cases are also presented. The question of the origin of the Auger signal with the topography of the sample and the

geometry of electrons collection is approached on a textured Si wafer presenting Ni nuclei. The accuracy of Auger quantification is tested on a SiGe multilayer sample³ with Ge concentration varying within the cross section from 6 to 30% (X-Ray diffraction calibration) by 300-500 nm steps.

MnCl porphyrins on the Ag(111) surface: axial ligand transformation

T01 Applied Surface Science

#ASS-2-Or-12

B. Murphy¹, **S. Krasnikov**², **N.N. Sergeeva**³, **A.A. Cafolla**², **A. Preobrajenski**⁴, **O. Lübben**¹, **A. Chaika**¹, **M.O. Senge**³, **I. Shvets**¹.

¹Centre for Research on Adaptive Nanostructures and Nanodevices (CRANN), Trinity College Dublin - Dublin 2 (Ireland), ²School of Physical Sciences, Dublin City University, Glasnevin - Dublin 9 (Ireland), ³SFI Tetrapyrrole Laboratory, School of Chemistry, Trinity College Dublin - Dublin 2 (Ireland), ⁴MAX-lab, Lund University, Box 118, S-22100 - Lund (Sweden).

The 3d transition metal porphyrins are very stable planar complexes with extensive applications in catalysis, nonlinear optics, enzyme models, sensors and molecular electronics. Since the practical application of metalloporphyrins is closely related to their underlying unique electronic structures, their investigation has remained a subject of intense research for several decades.

In the present work, scanning tunnelling microscopy (STM), x-ray absorption (XAS) and core-level x-ray photoemission spectroscopy (XPS) were used to study the self-assembly and the central ligand transformation of the surface-supported monolayer of {5,10,15,20-tetraphenylporphyrinato}Mn(III)Cl (MnCITPP).

When deposited onto the Ag(111) surface at room temperature, the MnCITPP molecules self-assemble into large well-ordered molecular domains with a close-packed square structure. In the MnCITPP overlayer, each molecule has a flat orientation on the surface with the molecular plane lying parallel to the substrate. Depending on the applied bias voltage, the axial Cl-ligand can be resolved by STM, and is observed to point out of the plane of the molecule into the vacuum.

Annealing the MnCITPP layer on the Ag(111) surface up to 510 K leads to changes in the molecular structure, keeping the monolayer intact. At this temperature, the chlorine ligand desorbs from the porphyrin, leaving the oxidation state of the central Mn(III) unchanged. The Mn(III)TPP is stabilised through interaction with the substrate, and the Ag(111) surface acts as a fifth ligand for the metal centre.

When the MnTPP molecules are exposed to molecular oxygen, the oxidation state of the central Mn is observed to change from Mn(III) to Mn(IV), as confirmed by XAS, and O₂ is bound to the central Mn ion in peroxide form. The presence of oxygen in the centre of the porphyrins is confirmed by STM, and this oxygen ligand can be manipulated by the STM tip.

This oxidation is reversible. Further annealing at 445 K reduces the O₂-Mn(IV)TPP complex back to Mn(III)TPP/Ag(111), removing the peroxide ligand, and allowing the process to be cycled. However, exposure of the MnCITPP layer to O₂ exhibits no direct substitution of the Cl ligand by O₂.

The activation energies for Cl and O₂ removal, derived from the Arrhenius equation using Cl 2p and O 1s XPS data, were found to be 0.35 eV ± 0.02 eV and 0.26 eV ± 0.03 eV, respectively.

Schematic model of axial ligand transformation. When MnCITPP is annealed to 510 K, the Cl ligand is removed. This MnTPP complex is stabilised by the Ag(111) surface (not shown). Mn(III)TPP can then be oxidised to form O₂-Mn(IV)TPP. Finally, the O₂ ligand can be removed by annealing to 445 K.

The secondary electron emission yield (SEY) of technical materials is of crucial importance in the appearance of impeding effects like multipaction or electron cloud in high-power RF space equipment or in high-energy particle accelerators. The diminishment of electron emission by electron bombardment (electron conditioning or scrubbing) is a known effect and made a good use in technological applications. The growth of a surface carbon layer induced by low-energy electron irradiation on silver has been studied by quantitative X-ray photoelectron spectroscopy (XPS) and SEY measurements. Silver plating on aluminium alloy prepared by a standard technique of space industry was compared to pure silver (Goodfellow); both in technical as-received conditions. 500-eV-electron fluences up to 10^{18} e/cm² were used in a vacuum of 5×10^{-9} mbar. Quantitative analysis of XPS signals of carbon and oxygen chemical species as well as Ag, allows characterizing the surface contamination over layer along with its growth.

Both total surface carbon, graphitic (sp² bonded) carbon, and contamination over layer thickness increases steadily during electron irradiation; while sp³ carbon, carbon bonded to oxygen species, and total surface oxygen decrease during treatment. Silver plating in as-received conditions has more surface carbon bonded to oxygen species. The treatment produces the reaction of sp³ bonded carbon into graphitic species but this is not sufficient to explain the growth of this last species. The growth of the surface contamination over layer can amount to a total of about 14

monolayers, thus doubling initial thickness. This is very difficult to understand as having the residual gas interacting with the impacting electrons as the only source of carbon atoms. The grown surface carbon over layer is stable in ultra high vacuum. SEY was measured for normal incidence. First cross-over energy increases from 25-50 to 90-100 eV during electron irradiation; while maximum value decreases from 1.9-2.2 to 1.1.

The secondary electron emission from materials used in high power RF devices in space is the main trigger and sustaining mechanism of the resonant avalanche electron discharge known as Multipactor effect. It limits the attainable power of these devices and also affects the normal operation of particle accelerators. During decades, research was focused on bulk material properties for obtaining anti-multipactor coatings of low secondary emission yield (SEY). This approach has shown its limitations in space applications where strong requirements on stability in atmospheric environment and surface electrical conductivity are set. ESA is leading technological research on a new approach based on surface roughness which might work as black body or Faraday cup effect. Appropriate surface morphology can reduce effective SEY of any material below one and thus certainly suppress Multipactor effect; however, it might increase RF surface resistance and consequently insertion loss of the device. This can be avoided because of a different dependence on surface morphology.

Anti-multipactor coatings are being developed for the 10 GHz range of frequencies by etching submicron high aspect ratio, high density surface roughness of silver standard plating in space industry by the combined effect of a noble gas ion beam and a hard metal atom beam. The resulting surface roughness growth dynamics is complex and different scales of roughness might overlap but appropriate surface morphologies are possible. The deposited amount of the hard metal and its influence on surface resistance are negligible.

That silver rough surface should be further coated for improving intrinsic SEY and stability in air. As long as the last coating is much thinner than RF skin depth, it does not affect either surface morphology or RF surface resistance.

Devices with resulting anti-multipactor coatings are tested for SEY, RF insertion loss, Multipactor power threshold, SEM and AFM microscopies, EDX and XPS analysis.

Zinc sulfide (ZnS) is one of the most important II-VI group semiconductors, with a wide direct band gap of 3.8 eV has been extensively investigated and used in electroluminescent devices, flat panel displays, infrared windows, sensors, and lasers [1]. To explore the possibility of using it in electroluminescent devices, a study of the structural and optical properties of the host material is an important step. Based on the above criterion, the structural and optical properties of ZnS films have been studied in the present work. ZnS thin films were grown on (001) GaAs substrates at different temperatures by RF magnetron sputtering. The x-ray diffraction (XRD) analysis and Raman scattering reveals that deposited films showed hexagonal wurtzite phase. The crystallite size range of the films was determined by Scherrer equation, which was from 11.15 to 45.83 nm. The stoichiometry chemical was determined by Energy-dispersive X-ray spectroscopy (EDS). Besides it made an experimental study on first- and second-order Raman scattering of wurtzite. The 300K photoluminescence presents a visible radiative band associates to vacancies of zinc and sulfide [2]. In addition was carried out energy dispersive spectroscopy (EDS) measurements on the films to determine their stoichiometry chemical which allows relating the intensity of radiative bands associated to oxygen and zinc vacancies.

Amazing nanoparticles properties, as magnetic ones, are mainly governed by their size and structure. Thus, the growing interest of scientists in nanoalloys structural study requires the development of characterization methods providing not only morphology and spatial atomic arrangement, but also chemical order. Therefore, chemical selectivity characterization techniques are essential to determine the nanometric size influence on the alloy state [1,2].

Specially, the anomalous X-ray scattering is promising. This method, based on the atomic scattering factor variations with wavelength next to an X-ray absorption edge, implies to modify one element contribution to the scattering spectrum in function of energy. Thus, the signal obtained is chemically selective. Combining anomalous small [3] and wide angle [4,5] X-ray scattering in grazing incidence (A-GISAXS and A-WAXS), which provides morphological and structural information, the mixing or segregation state of metallic elements in supported nanoalloys is revealed. Firstly, this experimental work exhibits the anomalous scattering implementation thanks to synchrotron beam (SixS beam line – SOLEIL synchrotron). Then, the chemical order evolution during in-situ annealing of supported AgCo bimetallic nanoparticles smaller than 3nm, elaborated by UHV evaporation on an amorphous substrate, is studied. Finally, the annealing conditions role, and the influence of the deposition mode (sequential deposition and co-deposition) on the nanoalloy state are investigated.

Ultrathin cobalt films studied by angle-resolved XPS

T01 Applied Surface Science

#ASS-P3-09

J. Polčák ¹, J. Čechal ², M. Urbánek ¹, T. Šikola ².

¹Institute of Physical Engineering, Brno University of Technology, Technická 2, 616 69 - Brno (Czech republic), ²CEITEC BUT - Brno University of Technology, Technická 10, 616 69 - Brno (Czech republic).

Depth profiling by angle-resolved XPS is a useful method for studying chemical composition of surfaces and ultrathin films. However, the calculation of depth profiles is not an easy task contrary to the theoretical calculations of XPS intensities from the known compositional depth profiles (reversed methods). We have made some improvements in our calculations based on implementation of a genetic algorithm method in finding proper depth profiles. Our calculation algorithm has been successfully tested on modeled samples even when some noise was added to the input data [1]. However, the real samples are influenced by other effects i.e. geometric inaccuracies, real noise, surface contaminations. Another problem is that investigated films are not often sufficiently smooth and the method is very sensitive to the top-most surface composition and morphology. Therefore, we studied ultrathin cobalt films made in situ by UHV atomic-beam evaporation of cobalt on a silicon oxide surface which leads to the formation of smooth uniform layers if deposited under room temperature [2]. To obtain not so smooth films we also deposited cobalt under higher temperatures and made comparison of both cases. In this way, it was possible to observe surface morphology influence to the depth profile calculations and to check the accuracy of the depth profiling method more precisely.

ASS-P2-03

Interaction of gold with native SiO₂ layers: Au diffusion and SiO₂ decomposition

T01 Applied Surface Science

#ASS-P2-03

J. Cechal, J. Polcák, P. Procházka, T. Šíkola.

CEITEC BUT, Brno University of Technology - Brno (Czech republic).

The interaction of gold layers prepared by thermal evaporation under UHV conditions was studied in-situ by X-ray photoelectron spectroscopy and ex-situ by scanning electron microscopy and atomic force microscopy. On thermally cleaned silicon sample with a native silicon dioxide layer, gold forms islands above the room temperature. The annealing to higher temperatures leads to diffusion of gold atoms through the oxide layer and subsequent gold silicide formation. The thermal stability of SiO₂ layer is significantly reduced partially due to inducing defect sites during the gold transport through the oxide layer and partially due to a catalytic effect of gold islands. The effects taking place at native oxide layers are compared with samples with thermal oxide layers of various thicknesses and modified samples (e.g. annealed in presence of oxygen or with BN layers on top), and the mechanisms of gold interaction with SiO₂ layers are discussed in detail.

Preferential oxidation of CO on Ir(111) and Pt(111) surfaces studied with ambient pressure X-ray photoelectron spectroscopy.

T01 Applied Surface Science

#ASS-2-Or-3

J. Knudsen ¹, N. Johansson ², E. Grånäs ², M.A. Arman ², J.N. Andersen ¹, J. Schnadt ².

¹Division of Synchrotron Radiation Research and the MAX IV Laboratory - Lund (Sweden), ²Division of Synchrotron Radiation Research - Lund (Sweden).

Preferential oxidation of CO (PROX) is an efficient way to remove CO impurities from hydrogen rich streams used for low temperature fuel cell applications. In contrast to CO oxidation that has been studied extensively on single crystal surfaces [1,2] the amount of published literature reporting PROX-studies on single crystal surfaces is very limited [3]. Here, we used the new ambient pressure X-ray photoelectron spectroscopy (AP-XPS) setup at the MAX IV laboratory to study the PROX reaction over Ir(111) and Pt(111) surfaces at total pressures around 1 mbar. In agreement with ref. [3], that only characterized the reactivity of different metal surfaces, we found that Ir(111) is a better PROX catalyst as compared to Pt(111). In contrast to ref. [3] and since the AP-XPS setup both probe free and adsorbed molecules this talk focus on correlating the atomic scale structure on the surface with the reactivity. For Pt(111) we find that the surface is blocked by adsorbed CO at sample temperatures below ~ 450 K and no CO₂ or H₂O are, therefore, produced. At higher temperatures, where CO start to desorb from the surface, both CO₂ and H₂O production start and around ~ 550 K the mass transfer limit for CO₂ and H₂O production is reached simultaneously. Thus, the Pt(111) surface is not really able to preferentially oxidize CO at our experimental conditions. In contrast, we find that Ir(111) is able to selectively oxidize CO at temperatures around ~ 550 K. At this temperature the CO₂ production reached the mass transfer limit, but no water is produced. At higher temperatures (550 – 650 K) we observe an increased water production when the temperature is increased. Similar to our results on Pt(111) we find that both CO₂ and H₂O production are absent below ~ 450 K

because of adsorbed CO that block the surface. By comparing with known structures that is formed in pure oxygen and CO atmospheres we plan to develop atomic models for the inactive phase (< 450 K), the phase present when CO is preferentially oxidized (~ 550 K), and the phase present when both water and CO_2 is produced ($550 - 650$ K).

Finally, we studied H_2O production on Ir(111) with different amounts CO mixed into the H_2/O_2 feed gas. Interestingly, we found that a small amount of CO promotes the production of H_2O . Too much CO in the feed gas will, however, lead to CO blocking of the entire Ir(111) surface and as a result no CO_2 or H_2O will be produced. Different models explaining CO promoted water production will be discussed at the end of the talk.

The growth of ultrathin epitaxial oxide films on metal supports is attracting considerable scientific interest both on a fundamental level and for potential technological applications. Growth techniques such as reactive deposition (i.e., metal deposition in oxygen atmosphere) and/or post-oxidation are typically applied, leading to ordered phases and well defined oxide-metal interfaces on noble metal substrates. On the contrary, when a more reactive metal, such as Fe, is used as a substrate for the nano-oxide growth, these procedures fail to produce sharp metal/oxide interfaces. Indeed, during the metal deposition in oxygen atmosphere, extensive and uncontrolled oxidation of Fe occurs, preventing the stabilization of long-range ordered oxide monolayers. An alternative route to obtain a sharp interface between a single layer of transition metal oxide and a reactive substrate may be to exploit the oxygen adsorbed on the surface before metal deposition since, in this case, the amount of oxygen available is well defined. The well ordered and defect-free Fe(001)-p(1×1)O surface is an ideal template to implement this strategy. The surface is characterized by one oxygen atom per surface unit cell, which can be used as a reservoir for the stabilization of two-dimensional transition metal oxides. In this contribution, by means of a combination of high resolution Scanning Tunneling Microscopy images, Auger Electron Spectroscopy, and Density Functional Theory calculations, we show how the Fe(001)-p(1 × 1)O surface can be used as a template for the self assembly of two dimensional Cr oxides. Cr deposition on this surface leads to two different phases, depending on the amount of deposited Cr. At 0.75

monolayers coverage a $c(4 \times 2)$ overlayer with Cr_3O_4 formal stoichiometry is stabilized, while an overlayer with $(\sqrt{5} \times \sqrt{5})R^{27}$ symmetry and Cr_4O_5 stoichiometry is obtained at slightly higher coverages [1].

Furthermore, the magnetic properties of these oxide monolayers are investigated by means of X-ray magnetic circular dichroism.

#ASS-10-Or-3

J. Hieulle, F. Silly.

CEA - Saclay (France).

Controlling the formation of organized structure at the nanometer scale is essential to develop the new generation of electronic components. Perylene imides are promising organic building blocks for photovoltaic application due to their semiconducting nature, and their thermal and photo-stability.

Difficulties associated with organic photovoltaic devices include their low quantum efficiency.

One origin is usually attributed to organic film defects.

Highly ordered organic structure can be tailored taking advantage of molecular self-assembly. To engineer the supramolecular assembly we can use different types of molecular bonds, like covalent bond, hydrogen bond and metal-ligand bond. In our case we selected hydrogen bond, which offers more flexibility for controlling the final arrangement of the supramolecular network, than covalent bond. This enhanced flexibility is due to the physical nature of the hydrogen bond. Finally the choice of the hydrogen bond is a good compromise, because it's relatively weak compared to covalent bond but it's really strong compared to Van-der-Waals bond.

We investigated PTCDI [1,2] thin film on a Au(111) surface, using a scanning tunneling microscope in ultrahigh vacuum. We observed the formation of well organized PTCDI monolayer. At room temperature the PTCDI molecule formed a brick-wall structure. By annealing the surface we were able to form a double and triple-row PTCDI structure. We observed that molecular contrast was depending of tunneling parameters in that case.

In addition we used XPS [3] to investigate the PTCDI thin film growth. We observed that PTCDI molecules adopt a flat lying configuration in the monolayer regime as well as in the multilayer regime. We also able to measure the energy of the valence-band and conduction-band states of the PTCDI film depending the film thickness.

Thin films technology is a good alternative to silicon wafers for highly efficient photovoltaic cells. For example, cells based on CIGSe (Cu(In,Ga)Se₂) absorbers reach at present about 21% efficiency (in laboratory measurements). To replace indium, a rare and expensive element, CZTS (for Cu₂ZnSnSe₄) is a promising candidate material for low cost absorber layer.

Electrochemical deposition is an attractive technique for CZTS preparation, one of the possible synthetic paths consists in the precursor layers electrodeposition followed by a thermal annealing. In this synthesis method, the growth of each layer is important and must be absolutely controlled. In this work, we have studied the first growth step of electrodeposited copper on molybdenum substrate by surface analysis (XPS/SEM-FEG and nano-AES). A specific chemistry based on CuSO₄ and H₂SO₄ bath - OMniCu™ High Copper - from OM Group Ultra Pure Chemicals (OMG UPC) enhanced by organic additives - OMniCu™ additives series - has been used. First, SEM-FEG observations have evidenced a three steps copper deposition mechanism: (1) nucleation, (2) coalescence and finally (3) a growing stage. Then, combining XPS and nano-AES (figure 1) surface analyses methods, global (micrometric scale) and localized (nanometric scale) characterizations of the Cu/Mo surface have been jointly performed. More specifically, a thin layer of Cu₂O at the surface of copper nuclei has been observed.

To conclude, by combining different characterization methods (XPS, nano-AES and SEM-FEG), complementary information about the different steps of copper electrodeposition on molybdenum substrate have been determined. Using specific chemistry, a dense and thin layer of electrodeposited copper (100 nm) has been

obtained.

Self organization of thin solid films under an external melting agent has received a great attention both experimentally and theoretically since the work of Bischof et al. [1]. This process indicates a new route for nanofabrication with a strong potentiality for improving the throughput and the resolution capabilities of traditional top down techniques. The pattern characteristics phenomenology has extensively been studied in laser induced melting of thin metal films on substrates like fused silica and a strong analogy with spinodal dewetting of thin liquid films has been found: the concurrent action of surface tension and van der Waals forces can amplify capillary waves in the molten metal film up to its rupture. Recently also ion irradiation has been indicated as a melting agent which can induce spinodal dewetting [2]. However, during ion irradiation, capillary waves of proper wavelength cannot exist due to the reduced size of the molten volume and to its short lifetime which prevents the superposition of molten zones produced by several impacts. In this case initial perturbations for the amplification process are provided by the substrate roughness which produces a background of thickness fluctuations in the film flattened by its surface tension. Here we investigate both experimentally and with simulations the dependence of the spinodal process on the amplitude and on the Fourier spectrum of the roughness with particular attention to the rupture fluence and the possibility to modify the thickness dependence of the characteristic wavelength by modifying the roughness spectrum.

Interlayer Formation of Diamond-Like Carbon (DLC) Coatings on Plastic Material

T01 Applied Surface Science

#ASS-8-Or-6

C. Fischer ¹, M. Rohrbeck ¹, S. Wehner ¹, M. Richter ², D. Schmeißer ².

¹University Koblenz-Landau, Institute of Integrated Natural Science - Department of Physics - Koblenz (Germany), ²Brandenburg University of Technology Cottbus, Department of Applied Physics and Sensors - Cottbus (Germany).

The engineering of plastic materials and their popular application in industry and daily life is accompanied by essential requirements. Besides the basic performance of these materials such as flexibility, elasticity, fracture strength and chemical resistance, further determinants are long term stability, durability or biocompatibility. Concerning materials features according to its specified exposure especially the surface is in charge of intensive interaction touching the environment. To avoid incompatibilities in surface characteristics of the optimal parent plastic these materials can be customized for their intended use by coating. The main limiting factor for such modifications is the preservation of basic material performance in addition to benefits like changed adhesive, improved repellent or antibacterial behavior.

Protective coatings with the objective to preserve main characteristics of selected plastic materials have been realized by a few layers of diamond-like carbon (DLC). The assembly of soft plastic material and robust carbon layers is important for the resulting material characteristics. The detailed understanding of the interlayer formation between these unequal materials and the connection of carbon centers in a chemically different neighborhood is the perspective of the presented work. The composition of DLC layer is a network consisting of sp^2 - and sp^3 -carbon centers. Depending on the allocation and fraction of each carbon state the material exhibits different properties ranging from medium-hard to stiff. Two types of nanometer-scaled DLC films forming more flexible and hard coatings are investigated. Different DLC compositions and increasing layer thickness have been examined by the use of synchrotron radiation and multiscale microscopic analysis. Results will help to provide an enhanced understanding of layer formation at the interface between the

basic plastic material and the DLC coating and will help to optimize parameters for the surface coating to achieve improved product characteristics. Collected information will be transferable to other plastic materials with diverse needs, e.g. energy storage devices, water treatments and coatings for everyday commodities or industrial parts.

ASS-1-In-2

PROBING ELECTRONIC STRUCTURE IN MATERIALS SCIENCE WITH HARD X-RAY PHOTOELECTRON SPECTROSCOPY

T01 Applied Surface Science

#ASS-1-In-2

W. Drube.

Deutsches Elektronen-Synchrotron DESY - 22607 Hamburg (Germany).

Photoelectron spectroscopy is a well-known, very effective method for electronic structure investigation at solid surfaces. When using hard X-ray excitation in the multi keV range, the energetic photoelectrons emerge from deeper inside the material because their inelastic mean free path significantly increases. It then becomes possible to also study complex bulk materials and/or buried interfaces. Because photoelectric cross sections rapidly decrease with photon energy above ionization thresholds, brilliant undulator radiation at synchrotron sources is generally needed to effectively use the technique which is rapidly emerging at storage ring facilities worldwide.

X-rays in the range 2 to 10 keV are typically used allowing to probe electronic and chemical structure down to a depth of about 10-20 nm. This bulk sensitivity not only is essential in the study of complex correlated materials, which often exhibit a modified surface electronic structure, but also indispensable for technologically relevant multi-layered materials with buried interfaces. Most interesting for materials science applications is the ability to study "as-grown" materials without any need for prior in-situ surface treatment or sensitive structures covered by protective layers. An overview will be given on the current state of the technique at instruments worldwide, highlighting its great potential by recent scientific results.

ASS-P3-10

Raman surface characterization of cadmium telluride using 325 nm and visible laser lines

T01 Applied Surface Science

#ASS-P3-10

M. Soares, A.J. Neves, T. Monteiro.

Department of Physics and I3N, University of Aveiro - Aveiro (Portugal).

Telluride compounds have been extensively studied by micro Raman spectroscopy during the last years. Vibrational modes observed in the range of 90 – 130 cm^{-1} are associated with tellurium inclusions or aggregates due to the lack of stoichiometry. In previous works we showed Raman peaks of the crystalline tellurium phase and the intensity enhancement behavior with the energy density of the laser spot with energies above the CdTe bandgap. This behavior suggests the formation of crystalline tellurium aggregations on the CdTe surface due to laser irradiation during the acquisition of the spectra.

In this work, the changes on surface morphology and surface composition of Cadmium Telluride (CdTe) single crystals grown by vertical Bridgman process and CdTe thin films surface grown by metalorganic chemical vapor deposition (MOCVD) on GaAs substrate, are studied by Raman Spectroscopy and complemented by Atomic Force Microscopy (AFM) and Energy Dispersive x-ray Spectroscopy (EDS) techniques.

The goal of this work is the study of the appearance of two Raman peaks at around 600-800 cm^{-1} in CdTe surface when the samples are excited with 325 nm HeCd laser at the room temperature and to clarify the origin of those peaks

ASS-4-Or-5

Interaction of Oxygen with Palladium at O₂ Pressures from 10⁻⁶ to 10⁵ Pa and temperatures 500 - 1400 K

T01 Applied Surface Science

#ASS-4-Or-5

A. Salanov, E. Suprun, V. Nikulin.

Boreskov Institute of Catalysis SB RAS - Novosibirsk (Russian federation).

Platinum group metals (PGM) are widely used as catalysts in chemical industry and in neutralizers of the automobile exhausts due to their unique properties [1]. Palladium is the most active catalyst for CO and C_xH_y oxidation with oxygen, and, for this reason, it is most commonly used in the neutralizers and in the catalytic combustion of methane. Therefore, it is necessary to study the interaction of oxygen with palladium in the wide temperature and pressure ranges. In order to understand the mechanism of the interaction of oxygen with palladium, we analyzed the dependences of the amount of oxygen absorbed by polycrystalline palladium foil (Pd(poly)) on exposure to O₂, on oxygen pressure and the surface microstructure and composition of Pd(poly). The samples were treated with O₂ in wide ranges of pressure 10⁻⁶–10⁵ Pa and temperatures 500–1400 K. The amount of absorbed oxygen by palladium was determined by temperature-programmed desorption (TPD). The surface microstructure was studied using a scanning electron microscope (SEM) JSM-6460 LV (Jeol). The surface chemical composition of the studied samples was determined by Energy Dispersive X-ray Microanalysis (EDS) using INCA Energy-350 instrument (Oxford Inst.).

At low P_{O₂} values ($\leq 1.3 \times 10^{-5}$ Pa) and exposure (ϵ) ≤ 200 L the dissociative chemisorption of oxygen on the Pd(poly) surface is observed. The chemisorbed oxygen coverage of the surface reaches ~ 0.5 ML. At P_{O₂} $\geq 10^{-5}$ Pa and $\epsilon \geq 200$ L, after the saturation of the O_{ads} layer to $\theta \approx 0.5$, O_{ads} atoms begin to insert under the surface layer of the metal. This is a consequence of the decrease in the energy of binding of the chemisorbed oxygen atoms to the palladium surface due to the repulsive interactions between O_{ads} atoms. The insertion of O_{ads} atoms under the surface layer of the metal gradually yields surface palladium oxide, and this accompanied by the absorption of up to ~ 1 ML of oxygen. O₂ chemisorption and the formation of the surface oxide on Pd(poly) are almost temperature-independent at T=500-600 K. At P_{O₂} = 0.1– 10.0 Pa and $\epsilon \geq 10^7$ L, oxygen dissolves in the palladium

bulk. The oxygen atoms penetrate deep in the subsurface layers of palladium, diffuse, and accumulate progressively in the metal bulk. Oxygen dissolution in palladium depends strongly on temperature. At $\epsilon \geq 10^7$ L and $T = 500$ K, palladium absorbs 1–2 ML of oxygen, while at 600 K it absorbs up to ~20 ML of oxygen. A possible reason why oxygen absorption accelerates with an increasing temperature is that the rate of O atom diffusion in the palladium lattice increases. In addition, at $\epsilon \geq 10^7$ L an increase in the O_2 pressure (≥ 0.1 Pa) appreciably accelerates oxygen absorption. As the pressure is raised from 0.1 to 10 Pa, the amount of oxygen absorbed by Pd(poly) at 600 K increases from ~1 to ~20 ML. Detailed analysis of the microstructures observed on the surface of Pd(poly) after treatment in the oxygen atmosphere at $P_{O_2} = 10^5$ Pa and at temperatures increasing from 500 to 1400 K indicates that the palladium surface microstructure is determined by the formation and decomposition of palladium oxide PdO. At $T < 900$ K palladium is intensely oxidized to form PdO particles with dimensions 25-50 nm. At 900-1100 K PdO microcrystals with dimensions 250-500 nm are formed.

ASS-P1-11

Work Function Measurement of Non-Uniform Surfaces Based on Electron Emission

T01 Applied Surface Science

#ASS-P1-11

J. Trigueiro, N. Bundaleski, A.G. Silva, A.M.C. Moutinho, O. Teodoro.

Departamento de Física da Faculdade de Ciências e Tecnologia Universidade Nova de Lisboa - Caparica (Portugal).

A Work function study based on the onset shift (i.e. following low energy cut-off) of secondary electron spectra has been used for the last four decades to monitor the deposition and adsorption in real time, measure the dipole momentum and polarizability of the surface layer and determine the lateral distribution of the work function [1,2]. Nowadays, it is also known as photoemission measurement of the work function because the secondary electrons are usually produced by photon irradiation (particularly with UV light). In this work we show that the onset shift depends on both, the coverage of species that change the work function and the size of low work function patches. The later dependence on WF using the low energy cut-off, which is due to the so-called patch field effect [3.4], has never been considered in details so far. Neglecting this effect may contribute to different kinds of misinterpretations related to determination of the dipole moment and polarizability of adsorbed dipoles, but also to work function mapping results using a rastered beam to produce secondary electrons.

The influence of the patch size on the onset shift is analyzed in detail. Numerical calculations of the potential distributions above different non-uniform surfaces were performed in order to quantitatively determine this influence. Depending on the patch size, we define three measurement regimes in which the onset position is related to either the surface average of the work function (small patches), the minimum local work function (large patches), or a value in-between (intermediate size patches). It is also shown that the extraction field, which is always present in these measurements due to sample biasing, plays a significant role in these measurements. Therefore, its influence has to be considered for correct interpretation of obtained results.

The conclusions obtained from numerical simulations were tested by performing work

function study of a sample consisting of a low work function material (In) surrounded with a high work function metal (Ni). Experimental data has corroborated the findings of numerical simulations and demonstrated that manipulating with the extraction field intensity enables transition between the measurement regimes. Typical misinterpretations due to the neglecting of the patch size contribution to the onset shift are analyzed.

Energy loss structures in hard X-ray photoelectron spectra

T01 Applied Surface Science

#ASS-1-Or-1

L. Kövér.

Institute of Nuclear Research of the Hungarian Academy of Sciences - Debrecen (Hungary).

Hard X-ray induced photoelectron spectra of solids are significantly influenced by energy loss processes of the excited high kinetic energy electrons. Obtaining accurate information on electronic structure or chemical composition of surface, subsurface, interface or bulk regions of materials from these spectra assumes the fundamental understanding of the processes leading to electron energy losses in solids. In the first part of the contribution the specific features of interactions yielding energy loss of photoelectrons induced by hard X-rays are discussed. Then the models describing these interactions are compared, including the basic assumptions used by them, their limitations and the areas of applications (e. g. inelastic background correction, concentration depth profiling, extraction of electronic structure information, 3D analysis of surface or - even deeply buried - interface nanostructures). Illustrative examples are presented for the different applications

In situ surface analytical characterization of electronic devices: thin film solar cells and lithium ion batteries as examples

T01 Applied Surface Science

#ASS-1-Or-8

T. Kampen, S. Bahr, A. Thissen, M. Meyer.

SPECS Surface Nano Analysis GmbH - Berlin (Germany).

Electronic devices have revolutionized everyday life in industrial countries over the last decades. Especially devices for energy conversion and storage like thin film solar cells and lithium ion batteries are of importance for the future. Recently two main tasks for research and development are dominant: miniaturization for sophisticated applications targetting at the nanoscale, and designing low cost large scale devices. In both fields the device performance is strongly determined by materials quality, composition, combination and last but not least by processes at materials interfaces. Nanostructures, minimization of material consumption and the need to improve device efficiencies consequently leads to the widespread focussing on thin film preparation. For thin film devices surface and interface analysis like photoelectron spectroscopy and surface (spectro-)microscopies are an important tools for material and device characterization. Classical well defined model experiments already reveal important insights using highly integrated vacuum systems for analysis and preparation. But analysis of materials and devices under near ambient conditions and even in situ during operation is an inevitable future development to improve the significance of data for development and quality management. In this respect the application of techniques like Near Ambient Pressure XPS, XPS from liquids and solid liquid interfaces, hard x-ray PES (HAXPS), Near Ambient Pressure SPM on solar cell and lithium ion battery materials is the challenging tasks for manufacturing companies of surface analytical equipment.

Versatile Molecular Surface and Interface for High-Performance Organic Electronics

T01 Applied Surface Science

#ASS-10-Or-2

H. Ma.

University of Washington - Seattle (United states).

Versatile surface and interface tailoring has been realized through molecular monolayers. (1) Exquisite control of molecules is reached by monolayer assembly/confinement, and monitored by photon-STM for molecular motions, reactions and conductance in ground state and excited state (Fig. 1).¹ (2) Insulating and semiconducting molecular phosphonic acid (PA) self-assembled monolayers (SAMs) have been developed for applications in organic field-effect transistors (OFETs) for low-power, low-cost flexible electronics. Multifunctional SAMs on ultrathin metal oxides, such as hafnium oxide and aluminum oxide, are shown to enable (a) low-voltage (sub 2V) OFETs through dielectric and interface engineering on rigid and plastic substrates (Fig. 2), (b) simultaneous one-component modification of source/drain and dielectric surfaces in bottom-contact OFETs, and (c) SAM-FETs based on molecular monolayer semiconductors. (3) High-performance inverted polymer bulk-heterojunction (BHJ) solar cells have been realized by modifying the interface of electron selective ZnO or TiO₂ with a series of fullerene-based SAMs (C₆₀-SAMs) containing different anchoring groups, linkage location, and functionalization. These SAMs serve multiple functions to affect the photoinduced charge transfer at the interface to reduce the recombination of charges, passivate inorganic surface trap states, improve the exciton dissociation efficiency at the polymer/ZnO or TiO₂ interface as well as a template to influence the overlayer BHJ distribution of phases, morphology and crystalline domains leading to better charge selectivity.

Chromium carbides have remarkable properties such as high melting points, good strength and a good corrosion resistance. Therefore, these compounds have been widely used in a variety of industrial applications, such as shaft bearings, seals, high-temperature furnaces, nozzles and metal machining molds.

In this study, we developed an easy and thermodynamically coherent method to synthesize successively the 3 stoichiometrically identified chromium carbides using chromium metal powder and a methane-hydrogen mixture as metal precursor and reactive gases for the carburization reactions. The effects of experimental parameters such as temperature, flow rate of the reactive gas and the methane/hydrogen ratio are investigated and discussed.

Two analysis techniques are used to characterize the products obtained: X-ray diffraction provides structural analysis and Auger electron spectroscopy determines the surface composition.

Depending on the temperature, which is an important parameter in the process of carburization, X-ray diffraction analysis shows the presence of several carbides phases. The sequence of appearance of carbides phases when the temperature increases suggests that the carburization of chromium is progressive. After the reduction of the native chromium oxide layer, chromium is carburized first to the Cr₂₃C₆ phase, then to the Cr₇C₃ phase and finally to the Cr₃C₂ phase.

The use of a reactive gas mixture of 10% methane in hydrogen shows that, for the same reaction time, the formation of chromium carbides starts at lower temperatures than when a reactive gas mixture of 1% methane in hydrogen is used.

An increase of the reactive gas flow rate results in a decrease of the temperature of appearance of each carbide phase regardless the composition of the reactive gas.

Recently, great attention has been devolved to the development of new strategies for the stabilization of metal nanoparticles (MNPs). The chemical stabilization of MNPs by capping metallic clusters with organic ligands has several advantages such as low preparation costs and better NPs size, monodispersity and shape control. The ligands play a double role: they stabilize the MNPs, and, when opportunely selected, they can make the resulting hybrid system better suited for different applications. One of the most interesting properties of MNPs is their Localized Surface Plasmon Resonance (LSPR)[1]. The interaction between MNPs and electromagnetic radiation is constituted by localized surface plasmons, which are coherent oscillations of the metal electrons in resonance with light of a certain frequency (ν). The plasmonic properties are strongly dependent on MNPs interactions, since the near-field on one particle interacts with the one on an adjacent particle, coupling together the plasmon oscillations. This interparticle plasmon coupling is responsible for the intense enhancement of spectroscopic signals from molecules adsorbed on MNPs layers,

providing the capability for single-molecule sensing and detection, as in SERS. The coupled-particle LSPR occurs at a ν shifted from the single particle one, and the magnitude of the plasmon shift depends on the strength of the interparticle coupling that, in turn, depends on the distance between adjacent MNPs[2]. Since the plasmonic field coupling decays exponentially with inter-particle distance, it is of primary importance, for technological applications, to ensure that the MNPs deposited on an opportune surface are regularly arranged and conveniently spaced. Recently, the ability of angular dependent Near Edge X-ray Absorption Spectroscopy (AD-NEXAFS) to probe that appropriate ligands induce an ordered arrangement of MNPs was assessed[4].

Here we present the AD-NEXAFS investigation carried out on small gold nanoparticles (2-4 nm diameter) capped with trimethylsilyl benzene-thiol (SEB). The hybrid systems molecular structure and organization on a TiO_2 surface was investigated by AD-NEXAFS at C K-edge. To obtain a better insight into the organization of small NPs on the substrate, AD-NEXAFS measurements and calculations were also carried out on a free molecule as well as with a molecule anchored to Au cluster representing the self assembling monolayer. The NPs mean size was tuned by varying the Au/thiol stoichiometry in the synthesis procedure, obtaining samples of different mean diameter, with the aim to find a correlation between nanoparticles sizes and degree of order in their arrangement. It was observed that the smallest NPs are more likely induced to self assemble by the intermolecular interactions arising between the thiols aromatic rings.

TaNx films were used as buffer layers for the study of the growth of Carbon Nanotubes CNT, by chemical vapor deposition CVD at 850°C, at room pressure, using ferrocene as catalyst source [1,2]. TaNx films 60nm thick, were deposited on Si substrates using High Power Impulse Magnetron Sputtering HIPIMS in reactive gas conditions [3]. TaNx film properties were analyzed for various discharge conditions, using Ar/N₂ reactive plasmas for Ta target materials. The emission line of metal ionized species Ta⁺ sputtered from the cathode were detected in HIPIMS discharge, as well as the atomic nitrogen lines [4]. The reactivity of the films was checked in the CVD furnace, used for CNT growth, at 850°C under argon flux in ambient atmosphere [2]. The pristine films, the annealed films and the interface formed by the CNT bottom and the TaNx buffer has been studied, coupling the nuclear analysis for elementary composition NRA, RBS, grazing incidence X-Ray diffraction DRX, X-ray photoelectron spectroscopy XPS, and high resolved Scanning Electron Microscopy SEM-Feg. The morphology and characteristic of the CNT are presented in relation first with the properties of the pristine TaNx films and their evolution under heat treatment, secondly with the structure of the interface between the CNT and buffer films.

Destructive versus non destructive methods for compositional depth profiles

T01 Applied Surface Science

#ASS-1-Or-2

N. Benito¹, **R. Escobar Galindo**², **J. Rubio Zuazo**³, **G.R. Castro**³, **C. Palacio**¹.

¹Universidad Autónoma de Madrid - Madrid (Spain), ²ICMM - Madrid (Spain), ³ESRF - Grenoble (France).

The analysis of the near-surface region of solids can be carried out using either non-destructive or destructive methods depending on the thicknesses to be analyzed. For thin films above 10 nm the method most frequently applied to obtain the concentration depth profiles (CDP), that is, the thin film composition with depth, is ion sputtering in combination with AES, XPS or SIMS [1]. The choice of a specific technique depends on the concrete analytical problem to be solved and the general trend is the simultaneous use of several techniques due to the complementary information provided [1]. The main drawback of this approach is related to the surface modifications produced during ion bombardment since the sputtering process can alter the surface composition, the surface chemistry and morphology [1], etc. Rutherford backscattering spectrometry (RBS) has been also used as a non-destructive method to obtain CDP. However, RBS do not provide chemical information and the depth resolution obtained is rather poor.

Other non-destructive methods to obtain CDP are based on the use of XPS in conjunction with the variation of the information depth. The information depth depends on the kinetic energy of the emitted photoelectrons and on its take off angle [2,3]. Conventional XPS laboratory equipments ordinarily use Mg or Al K α (1253.6 or 1486.6 eV, respectively for the photon energy) and experimental setup allowing take off angle modifications from 0-70° which limits the information depth to around 10 nm. The variation of take off angle is named Angle-Resolved XPS (ARXPS) and it is useful for analyzing in a non-destructive sense the very near surface of solids and very thin films [3]. The integral equation relating measured intensities as a function of the take off angle and the concentration depth profiles is a prototype of ill-posed problems and different approaches have been proposed to obtain the CDP from

experimental measurements [3,4].

The kinetic energy of emitted photoelectrons and, as a consequence, the information depth can be increased using synchrotron radiation sources. The technique is named Hard X-ray photoelectron Spectroscopy (HAXPES), it is also a non-destructive one and presents some limitations imposed by the high electron energies to be analyzed. Within this work we aim to explore the capabilities of HAXPES to obtain the CDP either of buried interfaces or of thin films that are of interest for optical applications [5], through a comparative study using ARXPS, XPS and simultaneous sputtering, and HAXPES.

Since wettability is a surface characteristic defined by the hydrophilic or hydrophobic behavior of the material, it is determinant for the interaction of biomaterials with biomolecules or for cells adhesion. The present work determinates the wettability of three different liquids that are involved in biological issues that were tested on pills of hydroxyapatite synthesized by chemical precipitation. This determination was made by the measurement of the contact angle, which gave us the corresponding angles to each solution and pressure of pills. It was concluded that exist a direct relation between the pressures at which the pills were fabricated and the contact angle. Also it was noted that the characteristics of the solutions influence in the calcium phosphates wettability. In the three cases as the pressure increases the contact angles do it to. This behavior due the pressure decreases the space between the calcium phosphates particles. The three liquids tested have the hydrophilic behavior that is desirable for a biomaterial because it is less than 65°. For further uses is better to used pills of hydroxyapatite made at 1 Ton due have them a more hydrophilic behavior.

(Denmark).

The electronic and optical properties of Indium zinc tin oxide (IZTO) films were investigated by X-ray photoelectron spectroscopy (XPS), reflection electron energy loss spectroscopy (REELS), and UV-spectrometer. The EXAFS experiments were carried out to examine the relationship between the local structure and the electrical properties for IZTO thin films, which has not been previously reported. IZTO thin films were grown on glass substrate by RF magnetron sputtering method. The XPS spectra show that all IZTO thin films have mixed metal and oxide phases. REELS spectra revealed that the band gap was increased for IZTO thin films annealed at 350 °C in air due to Burstein Moss Effect, but decreased with increasing Zn/Sn ratios. The values of the band gaps are consistent with the optical band gaps estimated by UV-spectrometer. The optical parameters were determined from the interference fringes of the transmission spectra for the wavelength ranging from 300 to 3000 nm. Quantitative analysis of the experimental cross sections of REEL spectra was performed using the QUEELS- $\epsilon(k,\omega)$ -REELS to determine the dielectric function, refractive index, and transmission of IZTO thin films. The refractive index obtained from the calculated UV-spectrometer is similar to that of the calculated REELS results. Amorphous IZTO films prepared with the zinc content of 48% exhibited high mobility of $30.60 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$, large on-off current ratio of 10^9 , and high transmittance of 85%. The EXAFS and the electrical characteristics indicate that the creation of local conduction paths can result from the nearest neighbors of 4s orbitals of Zn^{2+} ions in

IZTO thin films. Our results can be a guide for device applications for thin-film transistors with high field-effect mobility and good transparency.

ASS-6-Or-5

Corrosion under argon irradiation of titanium and zirconium studied by AFM and Spectroscopic Ellipsometry

T01 Applied Surface Science

#ASS-6-Or-5

D. Gorse-Pomonti ¹, E. Garcia-Caurel ², Y. Serruys ³, N. Béererd ⁴, N. Moncoffre ⁴.

¹CNRS - Palaiseau (France), ²Ecole Polytechnique - Palaiseau (France), ³CEA-DEN - Gif-Sur-Yvette (France), ⁴Institut de Physique Nucléaire - Villeurbanne (France).

Until recently the possible existence of damages caused by ion irradiation to metal surfaces in the low MeV range (1 – 10 MeV) was just ignored. This state of the art could be justified by the fact that a simple plot of both nuclear (S_n) and electronic (S_e) energy losses as a function of the projectile energy does not reveal any “accident” which would have justified special attention in this energy range, whatever the target material considered. On the other hand, one should not forget that both S_n and S_e contribute in principle to the overall slowing down process of the projectile in this energy range, complicating the data analysis.

In this paper, we show that, unexpectedly, argon ion irradiation between 1 and 15 MeV produces damages on both titanium and zirconium surfaces, taking the form of accelerated oxidation and/or craterization effects, varying as a function of the projectile energy and the annealing atmosphere (temperature and pressure) [1].

The mirror-polished titanium and zirconium samples are irradiated using the irradiation cell adapted to the extracted beam line of the 4 MV Van de Graaff accelerator of the Nuclear Physics Institute of Lyon. The irradiation conditions are: 1 to 9 MeV Ar^{n+} ($n = 1, 3$), 3×10^{10} ions $cm^{-2} s^{-1}$ up to 5×10^{14} ions cm^{-2} .

Using AFM, we show that the titanium and zirconium surfaces are attacked under argon ion bombardment at high temperature (up to 500°C) in weakly oxidizing medium (under rarefied dry air pressure ranging from $5,7 \cdot 10^{-5}$ Pa to $5 \cdot 10^{-3}$ Pa) for a fixed dose of about $5 \cdot 10^{14}$ ions/cm². We observe the formation of nanometric craters over the whole titanium surface irradiated between 2 and 9 MeV and the whole zirconium surface irradiated at 4 MeV, the characteristics of which vary depending on the temperature and air pressure. In the case of the Ar/Ti couple, the superficial damage efficiency increases when the projectile energy decreases from 9 to 2 MeV [2]. Moreover, whereas the titanium surface seems to be transparent under the 15 MeV ion beam, the zirconium surface exhibits numerous micrometric craters surrounded by a wide halo.

The crater characteristics (size and superficial density) differ significantly from that observed both in the low energy range (keV) where the energy losses are controlled by ballistic collisions (S_n) and in the high energy range (MeV - GeV) where the energy losses are controlled by electronic excitations (S_e), which was not completely unexpected in this intermediate energy range for which combined $S_n - S_e$ stopping power effects are possibly foreseen.

Using Spectroscopic Ellipsometry, we show that there is an irradiation effect on the thermal oxidation of titanium, enhanced under the argon ion beam, and that there is also an energy effect on the oxide thickness and stoichiometry. More precisely, as seen in Figure 1, we show that there is an oxidation peak as function of the argon ion energy, found maximum at 3 MeV under present experimental conditions [3]. The today available results obtained with zirconium oxidized under irradiation under same conditions strongly suggest the existence of an oxidation peak as function of the argon ion energy, for zirconium as for titanium, in the same projectile energy range.

G. Jakša ¹, J. Kovač ¹, B. Štefane ².

¹Jožef Stefan Institute, Jamova 39 - Ljubljana (Slovenia), ²Faculty of Chemistry and Chemical Technology, Aškerčeva 5 - Ljubljana (Slovenia).

The aim of this work was the preparation and characterization of modified silicon surface, with a purpose for using them in sensor's applications (detection of explosives like TNT, DNT, RDX,...). Single crystal silicon wafers (111) were modified with (3-aminopropyl)-trimethoxysilane (APTMS) and p-aminophenyltrimethoxysilane (APhS). Before the modifications a native oxide layer from the silicon was reduced with HF and then oxidized in a controlled manner by using an oxygen plasma. We deposited the self-assembled layers from a solution of aminosilanes in different solvents under various reaction conditions. The surfaces were characterized using X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM) and Time-of-Flight secondary ion mass spectrometry (TOF-SIMS). The surface composition and the chemical bonding were determined by XPS, the surface morphology and roughness by using AFM and the chemical structure with TOF-SIMS. Our results show that increased mobility of molecules at higher temperatures of reaction mixture leads to greater surface coverage and at the same time the formation of thinner layer. At longer deposition times and at higher concentrations of aminosilanes in solvent, polymerization of molecules occurs and the formation of thick layer is observed. Comparison between aliphatic and aromatic aminosilanes will be given.

InGaAs semiconductor is an important material due to its high electron mobility of 13000 cm²V⁻¹S⁻¹ and small energy band gap of 0.76 eV at 300K [1]. It is widely used for light emission in the range of 1.3–1.5 μm [2] as diode emitter laser radiation and also as detector. Actually it is a very promising material in solar cell fields due to its irradiation resistance [3,4] and the improving overall efficiency of multi-junction based on InGaAs. Its yield can reach 41.3% [5] or 42.3% under a concentration of 500 Suns [6]. In this work we presents results of AFM characterization of the InGaAs/GaAs system, we also study the effect of electron beam irradiation under UHV conditions on InGaAs/GaAs systems using Auger electron spectroscopy (AES) and the electron energy loss spectroscopy (EELS) .

Direct observation of layer-by-layer removal from Si(100) in hydrogen ambient by in situ spectroscopy

T01 Applied Surface Science

#ASS-3-Or-3

P. Kleinschmidt ¹, S. Brückner ¹, O. Supplie ², H. Döscher ¹, T. Hannappel ¹.

¹TU Ilmenau - Ilmenau (Germany), ²Helmholtz-Zentrum Berlin - Berlin (Germany).

Good availability, low cost and mature technology has made silicon the material of choice for many semiconductor applications. Most investigations of relevant step structures on Si(100) thus far have been carried out in ultrahigh vacuum (UHV) where standard surface science techniques can be applied. Experimental and theoretical investigations have shown that of the two possible types of single-domain (and hence double-layer stepped) surfaces, the one with surface dimers of the reconstructed surface parallel to the step edges (denoted as D_B) is energetically favorable, while the one with dimers perpendicular to the step edges (D_A) is unfavorable.

Due to adjustable, superior electronic properties of III-V semiconductors, there is a high incentive to combine these advantages with those of silicon using III-V-on-Si heteroepitaxy. Here, the most applicable preparation methods are molecular beam epitaxy (MBE) and metalorganic vapor phase epitaxy (MOVPE), where the latter provides key advantages relating to cost and scalability.

We have studied the surface structure of Si(100) in the H_2 -based MOVPE environment using reflection anisotropy spectroscopy (RAS), which measures the normalized difference of the reflected signal in two orthogonal directions of linearly polarized light under normal incidence. In the case of the Si(100) surface, the magnitude and sign of the resulting signal reflects the abundance of the two possible dimer orientations at the surface. We have benchmarked the RAS signals of the surface to scanning tunneling microscopy (STM), low-energy electron diffraction, X-ray photoelectron spectroscopy and Fourier-transform infrared spectroscopy, available via a dedicated MOVPE-to-UHV transfer system showing that our surfaces are H-terminated and contamination-free.

We obtained the energetically unfavorable surface with D_A double-layer steps on the Si(100) surface with 2° misorientation in [011] depending on the sequence of hydrogen pressures and temperatures during the process. We attributed the unfavorable step structure to the interplay of surface vacancy generation, diffusion and annihilation at step edges in a certain temperature range. Here we subject the Si(100) surface with 0.1° misorientation to the same processing conditions. We observed elongated vacancy islands on the terraces by STM, and by recording RAS transients during annealing in the crucial temperature range, we directly observed an oscillatory behavior of the major dimer orientation at the surface. Hence, under these process conditions, surface atoms are removed in a layer-by-layer fashion, resulting in a surface structure which alternates between predominantly A-type and predominantly B-type. While similar to reflection high energy electron diffraction (RHEED) oscillations, the RAS oscillations do not reflect oscillating surface roughness but the oscillating majority domain, and the technique is applicable under MOVPE conditions where RHEED is not available. Our results provide direct access to the surface layer removal process and enable quantification of the associated removal rate in dependence on process conditions. The surface layer removal process implies the generation of vacancy islands and corroborates our model for D_A step structure generation on 2° Si(100).

Metallic nanoparticles supported on ceria (CeO₂) subjected to H₂ reduction

T01 Applied Surface Science

#ASS-P1-01

F. Bernardi ¹, A.S. Kilian ¹, L. Luza ², M.C.M. Alves ², J. Morais ¹, J. Dupont ².

¹Instituto de Física, UFRGS - Porto Alegre (Brazil), ²Instituto de Química, UFRGS - Porto Alegre (Brazil).

Ceria (CeO₂) is an advanced material used for catalytic applications that has received much attention in the last past years [1]. The main reason is that oxygen vacancies at the surface can be rapidly formed and eliminated which gives to ceria the property of high capacity for oxygen storage. Due to this property, modern catalysts containing ceria are much more effective, for example, in the automotive exhaust than the previous ones without ceria. Compared to different supports of metallic nanoparticles, ceria also enhances the performance of catalysts constituted of metallic nanoparticles in a variety of reactions such as the water gas-shift and the preferential oxidation of CO [1]. In special, mono and bimetallic Ni and Cu nanoparticles supported on CeO₂ are used in reactions of NO reduction and CO hydrogenation [2-3].

The reduction reaction is a key process employed in catalytic applications. It is very important to understand this process in order to project the final desired properties of the catalysts. For example, when using a reducible support (like ceria) the reduction process can affect the catalytic properties by means of the SMSI effect (geometrical or electronic factor) [4]. The geometrical factor of the SMSI effect can create new catalytic active sites or to block some existing ones, depending on the case studied. In this work it was studied the electronic and structural properties of systems consisting of Ni/CeO₂, Cu/CeO₂ and Cu_{0.5}Ni_{0.5}/CeO₂ nanoparticles subjected to H₂ reduction in situ and ex situ. The metallic nanoparticles were synthesized by using the ionic liquid BMIBF₄ in a procedure described previously [5]. Thereafter, the nanoparticles were supported on CeO₂ and heated up to 500 °C in a H₂ atmosphere. The samples were investigated by means of XPS (X-Ray Photoelectron Spectroscopy), TEM (Transmission Electron Microscopy) and in situ XAS (X-Ray Absorption Spectroscopy) before and after the reduction reaction. In order to obtain kinetic information, in situ DXAS (Dispersive XAS) measurements were employed. All

XAS measurements were performed in the transmission mode at the Ce L_{III} edge, Ni K edge and Cu K edge.

The results show the existence of nanoparticles with ~5 nm diameter. XPS measurements with variable photon incident energy gave us electronic information of the surface of the nanoparticles where Cu and Ni atoms were initially oxidized. The atomic arrangement at the surface of the nanoparticles is discussed based on the XPS results. Structural information was obtained by XAS and DXAS measurements reveal details of the kinetic of H₂ reduction as a function of the reduction temperature and time. The reaction starts at ~285 °C for Cu/CeO₂, ~160 °C for Ni/CeO₂, ~190 °C (Cu) and ~435 °C (Ni) for Cu_{0.5}Ni_{0.5}/CeO₂ nanoparticles. After the beginning of the reduction it takes ~10 min for Cu/CeO₂, ~14 min for Ni/CeO₂, ~12 min (Cu) and ~14 min (Ni) for Cu_{0.5}Ni_{0.5}/CeO₂ to reduce completely the nanoparticles supported.

Polymer foils and paper based substrates for packaging applications are often subject of different surface treatments. Advanced analytical techniques are required to understand and control the basic processes during surfaces treatment. In this work we present X-ray photoelectron spectroscopy – XPS, secondary ion mass spectroscopy – SIMS and atomic force microscopy - AFM for characterization of paper and polymer materials modified by air plasma. The combined use of these techniques is demonstrated in the application examples in which a thin air-plasma deposited sol-gel based layer of triethoxysilane was deposited and characterized. The XPS and SIMS techniques were used to follow the surface composition, chemical bonds of surface atoms, molecular structures and spatial distribution of coated material whereas the AFM technique provided the information about the surface morphology. In this presentation the role of surface characterisation will be presented in the frame of the European project PlasmaNice: Atmospheric plasmas for nanoscale industrial surface processing, funded under the FP7 programme (1). The main objective of PlasmaNice was to develop equipment and process for industrial in-line atmospheric plasma deposition of functional nanocoatings on various fibre- and polymer-based substrates. The project aimed at the improvement of recyclability of conventional fossil fuel based plastics and the replacement by renewable bio-based and biodegradable materials for packaging.

A first-principles view of the Cabrera-Mott Model of Metal Oxidation

T01 Applied Surface Science

#ASS-6-Or-1

A. Hellman, J. Baran, H. Grönbeck.

Competence Centre for Catalysis and Department of Applied Physics,
Chalmers University of Technology - Göteborg (Sweden).

Oxidation of metals is an every-day phenomenon, which can be an unwanted process, e.g., automotive corrosion. However, under controlled conditions oxidation is of enormous practical importance, both in industry and science. For instance, thin oxides are widely used as catalysts, sensors, dielectrics, and corrosion inhibitors. The work of Cabrera and Mott (CM) in the mid-twenty century still remains the main theoretical model for growth of thin oxides on metals [1]. According to CM, electrons from the Fermi level of the metal substrate traverse the developing oxide film by either tunneling or thermionic emission to acceptor levels of oxygen molecules, thereby forming different anions (O^{2-} , O_2^- , O^-) on the oxide surface depending on the outcome of the charge transfer. The negative anions and their positive counterpart at the metal-oxide interface generate an electric potential, called the Mott potential, which effectively lowers the energy barriers for migration of ions through the oxide. As the oxide thickness increase the additional effect of the Mott potentials to the oxidation rate diminishes and the oxidation process effectively stops at some limiting thickness.

Recently, Zhou et al. [2] have experimentally shown that the limiting thickness of the aluminum oxide on Al(111) can be tuned by the oxygen pressure. They observe that the thickness of the alumina film increases with increasing oxygen pressure up to 1 Torr, beyond which it remains constant at thickness of 12.4 Å.

By means of first-principles we have investigated the thickness of the protective oxide layer on aluminum. Our first-principles calculations [3] support many of the key assumptions of the CM model. For instance, based on our results we estimated the limiting thickness of Al_2O_3 on Al(111) to around 16 Å, which agrees well with the experimental data. Furthermore, the charge transfer to adsorbed oxygen molecules generates a Mott potential which value also agrees well with experimental estimates. However, the underlying reason for observing a limiting thickness of the protective oxide is not the diminishing effect of the Mott potential. Instead we will provide

another underlying reason for the limiting thickness based on our first-principles calculations.

The interaction of metals with polymeric and functionalized surfaces and interfaces is of utmost importance for tailoring polymer metal nanocomposite materials and devices [1]: This interaction between the metals and the surface/interface [2,3,4] strongly determines the metal layer morphology. The morphology finally governs the layer's physical properties, which are tuned to the desired application in optical technology, sensors, or photovoltaic devices. Sputter deposition on the other hand is one method of choice and widely used in industry to install tailored metal films on surface or in the near surface region. Therefore, it is mandatory to investigate metal layer growth under real processing conditions in-situ and in real-time when tuning the metal-surface interaction.

As is well known, thiol-based surfaces show a strong interaction with gold. In this study we therefore used as a model system gold and the functionalization via different silanization of silicon wafers, allowing for chemi- or physisorption of the deposited gold atoms. The differently functionalized surfaces were investigated prior to and after gold sputter deposition using optical atomic force microscopy, imaging ellipsometry and contact angle measurements. To observe the difference in growth kinetics in-situ, we combined sputter deposition and microbeam grazing incidence small-angle x-ray scattering (μ GISAXS) at the synchrotron beamline MiNaXS/P03 of DESY, Hamburg, Germany [5]. The analysis of the gold sputter deposition shows clear changes in cluster growth depending on the differently functionalized surfaces. Depending on predominant chemisorption or physisorption, the gold atoms arrange to well defined clusters or more homogenous layers. As an example, fig. 1 shows the

growth of gold layers on a thiol-based functionalized silicon wafer. The clearly visible maxima indicate cluster growth as a function of deposited gold layer thickness.

In situ X-ray photoelectron spectroscopy study of adsorption of (3-aminopropyl) triethoxysilane on rutile TiO₂(110)

T01 Applied Surface Science

#ASS-9-Or-3

S. Chaudhary ¹, N. Johansson ², L. Montelius ³, L. Ye ⁴, J. Schnadt ⁵.

¹Division of Synchrotron Radiation Research, Division of Pure & Applied Biochemistry, Lund University, ENI AB, Malmö, - Lund (Sweden), ²Division of Synchrotron Radiation Research, Lund University - Lund (Sweden), ³Division of Solid State Physics, Lund University, ENI AB, Malmö, - Lund (Sweden), ⁴Division of Pure & Applied Biochemistry, Lund University - Lund (Sweden), ⁵Division of Synchrotron Radiation Research, Lund University - Lund (Sweden).

Covalent immobilization and deliberate orientation of molecular sensing materials at surfaces represents an important route towards achieving a more specific response and reducing unspecific binding towards target materials in biosensors. Commonly used for immobilization of biomolecules such as proteins, enzymes, antibodies, and DNA in biomedical sensing applications are self-assembled silane monolayers. Among the potentially useful surfaces is rutile titanium dioxide. Here we have investigated the modification of a TiO₂(110) surface with (3-aminopropyl) triethoxysilane (APTES), which is expected to be a useful coupling layer towards sensing materials.

Our aim is an atomic-scale characterization of the structure and properties of the APTES binding layer, and therefore we have studied the interaction of APTES with a rutile TiO₂(110) surface using synchrotron radiation based x-ray photoelectron spectroscopy. The studies have been performed both in ultrahigh vacuum (UHV) and ambient pressure mode. Prior to the adsorption of APTES, hydroxyl groups (OH) were created on the TiO₂ surface by adsorption of water at room temperature. The x-ray photoelectron spectra confirm the attachment of APTES on TiO₂. The measurements shows that in ultrahigh vacuum APTES reacts with OH groups through its silicon end to form a silanized surface. After the saturation of APTES on TiO₂ in UHV, the deposition of APTES was continued at ambient pressures up to approximately 0.2 mbar. ^[1] At these pressures we find indications for a reversed

attachment of APTES, i.e. APTES reacts with the surface through the amine group (Fig. 1).^[2] This pressure dependence of the adsorption shows that ultrahigh vacuum studies of silanes not always can be extrapolated to the real system, but that investigations at ambient pressure are necessary for the elucidation of silane surface structures. We need to study the system in more detail by variation of deposition parameters such as silane concentration, reaction temperature, and annealing. For the near future we also plan near -edge X-ray absorption fine structure spectroscopy experiments to obtain more information about the APTES adsorption geometry.

UV Photoelectron Spectroscopy at Near Ambient Pressure in APPES

T01 Applied Surface Science

#ASS-3-Or-2

C. Gopinath, K. Roy.

National Chemical Laboratory - Pune (India).

Ambient pressure photoelectron spectroscopy (APPES) is becoming increasingly popular to explore the catalysis aspects at near ambient pressure (around 1 mbar) and high temperature conditions. It works fine with x-ray photons, or rather high kinetic energy (KE) electrons, mainly due to relatively lower inelastic scattering and hence good S/N is maintained. However, when the KE of photoelectrons are <100 eV, there are problems in observing decent S/N ratio under near ambient pressure. In the recently installed laboratory APPES system at NCL, Pune, we are able to observe the UVPES with He-II excitation source under near ambient conditions. Figure 1 shows the UVPES spectrum obtained on Ag-surfaces at room temperature and different partial pressure of N₂. Indeed well-defined electronic state of molecular N₂ was also observed between 11 and 15 eV. As a test case we explored the oxidation of polycrystalline copper surfaces under molecular O₂ at different partial pressures and temperatures. Changes observed in the valence band spectra were recorded with AlK α and shown in Figure 2 for systematic changes in copper oxidation state. UVPES spectra were also recorded in the above conditions as that of Fig. 2 at near ambient pressure. Indeed both the data are complementary, since the photoionization cross section of Cu 3d and O 2p are high with x-ray and UV photons, respectively. The most important point is the observation of UVPES under high pressure conditions, which demonstrate the possibility of exploring low KE electrons under near ambient conditions. Reasons for the observation of UVPES at near ambient conditions will be presented in detail.

Figure 1: Valence band spectra recorded on Ag foil with He II source at different partial pressure of N₂.

Figure 2: Valence band spectra recorded on Cu foil with monochromatized Al K α x-

ray source at 1 mbar O₂ pressure. Systematic changes in oxidation of copper is observed.

This work aims to synthesize hybrid materials by functionalizing nanostructured tin dioxide (SnO₂) thin films obtained by metal organic chemical vapor deposition technique (MOCVD) [1]. The functionalization of the surface is carried out by electrochemical grafting from the reduction of a diazonium salt [2-3]. This grafted surface is a promising sensor to detect and quantify metallic ions in water samples. The obtained hybrid material (Fig.1) is characterized by several techniques: field emission gun-scanning electron microscopy (FEG-SEM) associated to energy dispersive X-ray spectroscopy (EDS), grazing incidence X-ray diffraction (GIXRD), Fourier transformed infrared spectroscopy (FT-IR) and X-ray photoelectron spectroscopy (XPS).

These characterizations show that MOCVD technique is able to provide a control over the structural properties of the SnO₂ thin film as a function of the experimental parameters used. For example, tetragonal and orthorhombic SnO₂ structures with various nanocrystalline morphologies are obtained in various proportions as a function of the substrate temperature and the deposition frequency used during the process. The modification of the structural properties of the coating is linked to variations of the electrochemical behavior of the surface, which implies various grafting results.

Finally, the sensor properties of the synthesized materials are assessed by electrochemical analytical techniques as cyclic voltammetry (Fig. 2) and reveal that the obtained hybrid material is able to detect, for example, copper ions in water at concentrations lower than 10⁻⁷ mol.L⁻¹.

Oxide dispersion strengthened steels (ODS) are used in many areas such as aeronautics and nuclear industry, especially the future fusion nuclear power plant and the fourth generation of fission plants. In fuel cladding of fission reactors, the ODS will be held at temperatures in the range of 350-600°C for many months. In ODS steel based alloys, the aging is accompanied by an embrittlement called 475°C embrittlement. Spinodal decomposition is often cited as the cause of this phenomenon, thus it is important to study spinodal decomposition kinetics in these materials.

In this study, spinodal decomposition has been studied for application as well as from a fundamental point of view, since the Fe-Cr-O system has similarities with complex ODS materials. However the alloy addition elements can modify the decomposition kinetics. We studied spinodal decomposition in thin films and bulk samples. Thin films have been prepared in two ways: (i) homogeneous composition with an average composition in the spinodal domain (Fe50Cr for example) and (ii) a modulated composition in one direction (fig1 and fig2) in order to observe an increase of the modulation amplitude due to spinodal decomposition. This study was based on atom probe tomography which is an ideal technique for spinodal decomposition studies. Several other characterization techniques (XRD, DSC, sheet resistance) were also used. Finally, our results on thin films were compared with experiments on bulk alloys and Kinetic Monte Carlo simulations.

We observed an unexpected damping of the Fe-Cr oscillations even if the average composition is in spinodal domain. This phenomenon may be due to the presence of oxygen in the Fe-Cr thin films, of grain boundaries or to the unsuited amplitude and wavelength of the modulation. From the damping kinetics, we have extracted an activation energy for the Fe-Cr interdiffusion. An oxide precipitation has also been observed during aging.

Alloy 690 is a high-chromium nickel alloy widely used in nuclear plants, for steam generator (SG) tubes in Pressurized Water Reactors (PWR). During processing, oxides scales develop on SG tubes: it is composed of a Cr-rich inner layer and a Ni-rich external layer. The release of Ni in primary water leads to the increase of the activity. It is known that the Cr-rich layer, acts as diffusion barrier and limits the nickel release.

This work explores the original use of Time of Flight Secondary Ion Mass Spectrometry (ToF-SIMS), in addition to X-ray Photoemission Spectroscopy (XPS) and m-Raman Spectroscopy to characterize thin oxide films formed on Ni-30Cr, a model of Alloy 690, which has been subjected to different oxidizing conditions: thermal oxidation at 900°C in air for 4 hours or exposed to primary water (liquid water at 325°C) during 4 and 31 days.

According to the published data [1-2], the oxide film formed on Ni-Cr (with a Cr content > 20%) should present a triplex structure: 1) outer nickel oxide layer, 2) intermediate nickel chromite layer, and 3) inner chromium oxide layer.

If XPS does not allow an easy distinction of Cr³⁺ in the intermediate or in the inner layers, ToF-SIMS gives a more molecular determination of the spinel and pure oxide compounds [3]. Using ions markers of mixed or pure compounds, the ToF-SIMS depth profiles confirmed the triplex oxide structure of thermally treated Ni-30Cr.

As regards the oxides formed in primary water: the thickness and composition are different. This approach was also applied to Alloy 690.

The changes in composition, as deduced from the molecular study of the oxide film, are discussed in terms of passivation mechanisms.

ASS-P3-12

A combined in situ study of chlorine adsorption on Cu(110) surface by means of EC-STM, RAS, CV and XPS

T01 Applied Surface Science

#ASS-P3-12

B. Bonanni¹, G. Bussetti¹, M. Di Giovannantonio¹, G. Serrano¹, A. Violante¹, C. Goletti¹, S. Breuer², K. Gentz², K. Wandelt².

¹Department of Physics, University of Tor Vergata, Via Ricerca Scientifica 1, 00133 - Rome (Italy), ²Institute for Physical and Theoretical Chemistry, University of Bonn, Wegeler Strasse 12, 53115 - Bonn (Germany).

We have investigated the adsorption of chlorine on the Cu(110) surface in electrochemical (EC) cell by using different techniques, in order to get deeper insight on halide adsorption on this crystal surface. Indeed, the adsorption of chlorine on Cu(100) and Cu(111) from solution is well studied and understood, whereas the situation on Cu(110) is more unclear and different structures have been published for the chlorine layer [1–2].

Our study has been performed by means of in situ electrochemical scanning tunnelling microscopy (EC-STM), in situ reflectance anisotropy spectroscopy (RAS, an optical technique with an enhanced sensitivity for surface optical properties [3]), and cyclic voltammetry (CV) and has been completed by XPS measurements.

The process of chlorine adsorption on a Cu(110) surface has been studied in a EC potential range from hydrogen evolution regime to copper dissolution. The real space structure has been investigated by EC-STM, revealing a strong potential-depending evolution of the surface layer morphology between the bare copper surface and the chlorine covered surface. EC-STM images clearly show the formation of stripes along the [001] direction, as reported in literature, very likely due to Cl⁻ adsorption.

The morphological changes detected at the nanometer scale by EC-STM have been related to the optical properties of the same Cl⁻ covered surface as measured by RAS: the optical anisotropy spectrum has been measured in the range 275-800 nm and exhibits a maximum of intensity when the polarized light is aligned along the

[001] direction. The RAS signal has been monitored also at fixed wavelength of 500 nm, corresponding to RAS maximum, while varying the EC potential in the range of values probed in EC-STM: we have recorded a RAS cycle that we have compared with the CV cycle measured on the same system, obtaining a better comprehension of the effects at the liquid/metal interface during application of varying EC potential.

The in situ studies have been complemented by XPS experiments on a Cu(110) surface prepared in an EC cell with the same procedure followed in EC-STM and RAS experiments. The EC cell was directly connected to the UHV chamber equipped with the XPS facility, so that, after the EC preparation, the Cu(110) has been transferred in the XPS system for chemical analysis. The XPS measurements have confirmed the adsorption and desorption of chlorine ions upon variation of the EC potential in the range of the EC-STM and RAS experiments.

In conclusion, thanks to the employ of different in situ techniques we are able to follow and explain the chlorine adsorption and desorption processes on Cu(110) on the timescale of the potential change.

Mortars were elaborated using a matrix of compositions for two different types of refined sand, and substituting the water of mixed by a dilution of a pyrrolic analogous of melanin (QK) to the 0.4% in water, varying from 0,4 to 1,0 the Water/QK rate. Analysis of surface by Scanning Electron Microscopy reveals a significant diminishing of the porosity as a function of the content of QK, while the diffraction patterns of samples aging the same time, they shows variations in the development of phases, attributed to the presence of the bio-polymer. Likewise, the analysis of the electric measurements on the surface for constant proportions of water or QK show that the pyrrolic analogous induces variations in the relation I-V in all the proportions of liquids tested. The same phenomena were observed into mortars prepared with red or white sand, and they are explained as a capacity of the pyrrolic analogous to produce chelate compounds and to exchange weakly bound water with the cement; regulating so much the formation of hydration products as the particle size [1-4]. All the tests shown correspond to mortars with aging of 180 days.

Effect of the surface of calcium fluoride particles on the non-isothermal crystallization behavior of poly(ethylene terephthalate)

T01 Applied Surface Science

#ASS-P1-02

M. Sánchez Loredo ¹, R.J. Sánchez Leija ¹, O. Domínguez Espinós ¹, D. Cayuela Marín ².

¹UASLP - San Luis Potosí (Mexico), ²UPC - Terrassa (Spain).

The incorporation of inorganic materials in polymer matrices has been an attractive path for improving mechanical, thermal, tribological, electrical, optical, fire resistance, UV resistance and permeability properties. In this work, calcium fluoride particles of different sizes, some of them surface-modified with the organic reagents triethanolamine (TEA) and Cyanex® 921 (tri-n-octylphosphine oxide, TOPO), were incorporated into poly(ethylene terephthalate) (PET) matrices. As far we know, only very few investigations report the addition of inorganic fluorides into polymers [1]. The CaF₂ particles were synthesized by chemical precipitation where the particle size was controlled by addition of different amounts of triethanolamine to the precursors solutions. To modify some of the particles, a heat-treatment with tri-n-octylphosphine oxide in isopropanol, was carried out. The composite materials were prepared by melt-blending PET and particles at different filler loadings.

The influence of the particles surface modification on the non-isothermal crystallization behavior of PET was investigated by using differential scanning calorimetry and field emission scanning electron microscopy. The Jeziorny-modified Avrami equation was applied in order to study the crystallization kinetics and several parameters were calculated (half-crystallization time, Avrami exponent and rate constant). According to the results, the calcium fluoride particles act in general as nucleating agents, accelerating the PET crystallization rate. However, the effect on the polymer crystallization rate was more important with the addition of the non-modified particles, where the surface could play an important role for epitaxial crystallization. Halide crystals were already found to influence the mode of crystallization of various polymers. Their surfaces have the capability to specifically

orient numerous inorganic and organic compounds. Some authors have proposed that epitaxial crystallization between nucleating surfaces and polymer crystals controls nucleation, where the polymer chains align themselves parallel to the substrate [2].

On the contrary, the addition of the particles with an organic coating layer on the surface resulted in a crystallization behavior more similar to the observed for PET. The presence at the surface of adsorbed TOPO, a highly lipophilic long-chain organophosphorous compound, or adsorbed TEA, an organic compound that is both a tertiary amine and a triol, probably alters the chemical nature of the particles; reducing its nucleation ability and perturbing the crystallization temperatures as experimentally detected. Tentatively, the organic coating on the surface of the CaF₂ particles may prevent epitaxial crystallization, giving a hint of the role the surface nature of inorganic fillers play on the epitaxial nucleation of polymers.

(Mexico), ³UNIDAD DE BIOQUIMICA E INMUNOLOGIA, INSTITUTO TECNOLÓGICO DE OAXACA - Oaxaca, Oax. (Mexico).

The saccharide biomolecules attached to proteins and lipids, or present on cell surfaces, participate actively in numerous physiological and pathological processes. The structural flexibility of these molecules allows them to function as unique sequences of identity, such as DNA or proteins. Lectins can recognize differences in glycan composition even in its conjugated state, so they are very useful tools in deciphering the "glycocode" associated with a particular physiological or pathological process¹. These properties are used for analysing lymphoproliferative and cytotoxic functions in mononuclear cells, caused by certain drugs, also for detecting chromosomal abnormalities, for studying the structural changes in glycoconjugates present on cell surfaces, and for detecting malignant cellular transformations². Lectins that join with blood type specificity GalNAc are the most diverse since its taxonomic classification. *Phaseolus lunatus* var. Silvester lectin has a MW of 120 kDa, a content of 4.5% carbohydrate, with higher mannose content, GluNAc, fucose, traces of arabinose and xylose. They are mitogenic for human peripheral T lymphocytes, but no for B lymphocytes. The CNTs are cylinders constructed from a hexagonal array of sp²-hybridized carbon atoms, they are relatively flexible, interact with cell membranes and penetrate several biological surfaces. The objective of CNT functionalization is to increase the tubes affinity and to improve its chemical reactivity with other molecules, as well as to create new structures with improved capabilities

for translocation across cell membranes, and to increased solubilization, stability and bioavailability of the biomolecules. Therefore, the aim of this project was to functionalize multi-walled CNT with *Phaseolus lunatus* lectin var. silvester for biomedical application.

For CNTs preparation and functionalization, they were treated with a mixture of H₂SO₄ and HNO₃, and were subjected to ultrasound for 3 h. The CNTs carboxylated were dispersed in a 1-pirenbutanoico acid solution and were incubated for 1 h under constant stirring. The 1-pirenbutanoico acid residual polymer was removed by centrifugation at 7500 rpm/5 min and the complex formed was washed with pure methanol for obtaining CNT functionalized. A volume of 50 µl of FITC-lectin (20 µg/ml) was added into the CNTs functionalized. It was incubated for 18 h and was washed by centrifugation at 7500 rpm/7 min to remove unbound material. The efficiency of conjugation was visualized with FITC, which had been conjugated lectin previously. The CNT-lectin adhesion was confirmed by agglutination tests, inhibition with specific sugar, by fluorescence microscopy and scanning electron microscopy. The electron microscopy analyses (SEM), fourier transform infrared spectroscopy (FTIR) and Raman showed peaks corresponding to the amino and carboxyl groups, indicating that the CNT-lectin conjugation was performed. The efficiency shown by this type of interaction is high, because once the carbon nanotubes are dispersed by sonication, they can be diluted in a considerable volume.

ASS-P1-19

Characterization of localized electric fields in InAs/GaAs quantum dots interface by photoreflectance spectroscopy

T01 Applied Surface Science

#ASS-P1-19

J. Kim ¹, I.S. Han ¹, S.J. Lee ¹, S.K. Noh ².

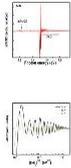

¹Department of Physics, Yeungnam University - Gyeongsan (Korea, republic of), ²Korea Research Institute of Standards and Science - Daejeon (Korea, republic of).

In this work, we have investigated the optical properties of InAs/GaAs quantum dots (QD) by photoreflectance spectroscopy (PR). To investigate the localized electric fields in InAs/GaAs QD interface, we fabricated InAs/GaAs QD by using molecular beam epitaxy. The InAs/GaAs QD samples were grown on GaAs(100) surface. A 500 nm thick GaAs buffer layer was grown on undoped -GaAs substrate at the substrate temperature (T_s) of 580 °C. To form the InAs QD by Stranski-Krastanow mode on GaAs surface, the T_s was decreased 400 °C. Finally, a GaAs capping layer with a thickness of 10 nm was grown at T_s of 400 °C.

For the investigation interface electric fields induced by strain between InAs QD and GaAs interface, PR measurements were carried out at various temperatures (14~300 K). Figure 1 shows (a) the PR spectrum for the InAs/GaAs QD and (b) the selected Franz-Keldysh oscillation (FKO) at different PR measurement temperatures (14, 50, and 77 K). In PR spectra of InAs/GaAs QD, we have observed FKO. In general, at a given localized electric field in GaAs, we expect two components of FKO period in PR spectra due to the heavy-hole (hh) and light-hole (lh) transitions. The localized electric field distributions of InAs/GaAs QDs have been determined from the period of FKO using fast Fourier transform (FFT) method. We also suggested that the localized electric fields are strongly correlated to QDs strain field distribution on GaAs interface.

Cold rolled carbon steel (1018) is a commonly used structural material in various applications, including the construction of fuel storage tanks for naval ships. *Desulfoglaeba alkanexedens* (strain ALDCT) is a known fuel-degrading, anaerobic, sulfate-reducing bacterium (SRB) [1, 2] that thrives at fuel-water interfaces in marine environments and can influence the pitting corrosion of carbon steel. It has long been postulated that MnS inclusions in carbon steel can act as sites of pitting initiation [3]. The propagation of pitting corrosion is relatively well understood; however, the initiation of pits is still a subject of controversy [4, 5]. A careful study of pit initiation and propagation associated with sulfide inclusions, particularly as they relate to microbial influenced corrosion (MIC) under anaerobic conditions, has been lacking, partly because these inclusions are mostly submicron-sized and the evolution of their corrosion is difficult to monitor. The use of nanoprobes instead of microprobes is required to determine the elemental and chemical composition and to map out the elemental distributions at the submicron scale. Quantitative surface sensitive techniques such as Auger electron spectroscopy [4, 5] are essential for monitoring the nanoscale changes associated with surface-related phenomena, including MIC. This presentation will review the results of comprehensive and systematic studies of nano-inclusions on carbon steel surfaces prior to and following exposure of the steel to a solution of a mature ALDCT culture and to abiotic sulfide as a control. The nano-inclusions were carefully characterized using a field emission Auger nanoprobe with a spatial resolution of approximately 10 nm for imaging and spectroscopy and compared with results obtained using X-ray microprobes, which typically have a

spatial resolution of around 1000 nm for spectroscopy and 10 nm for imaging. The study elucidates biologically driven corrosion reactions taking place in and around nano-inclusions. The impact of this fundamental analysis on the understanding of MIC phenomenon will be discussed.

Development of Ion Mapping for SIMS with an EEM

T01 Applied Surface Science

#ASS-5-Or-5

M. Eller ¹, S.V. Verkhoturov ², S. Della-Negra ¹, E.A. Schweikert ².

¹Institut de Physique Nucléaire d'Orsay, Université Paris-Sud 11 UMR 8608, CNRS/IN2P3, F-91406 - Orsay (France), ²Department of Chemistry, Texas A&M University - College Station (United states).

Secondary Ion Mass Spectrometry, SIMS, is a surface analytical technique capable of analyzing myriad of samples including metals, polymers, organic, biological samples, and nano-objects. The surface sensitivity (top 5-10nm) coupled to mass spectrometry makes SIMS a versatile surface analysis tool. The use of SIMS in the event-by-event bombardment detection mode offers several key advantages: investigation of co-localization of molecules within a 100nm² area, quantification of surface coverage of molecules and analysis of individual nano-objects.^[1,2] However, generating maps or images of the surface with the event by event mode is challenging, as the traditional method of scanning a focused ion beam is time consuming due to low beam fluence. An alternative approach is to localize each projectile impact via the emitted electrons with an electron emission microscope, EEM. In this novel approach, the secondary ions are collected and analyzed with a time of flight mass spectrometer, and the electrons are imaged with an EEM. The result is a mass spectrum with a corresponding impact coordinates. In practice a series of impacts are collected, $\sim 10^5$ - 10^6 individual impacts, and summed to generate a chemical map of the surface ($\sim 50 \times 50 \mu\text{m}$). The instrumentation to couple an EEM to a C₆₀ cluster-SIMS instrument is presented (15-75keV total impact energy). The results from a cholesterol pattern are presented to demonstrate molecular ion mapping with $\sim 1 \mu\text{m}$ spatial resolution.

Further improvements using event-by-event mapping are possible by increasing the secondary ion yield. Using 100qkeV Au₄₀₀⁺⁴ as a projectile has been shown to increase the yield of molecular ions by $\sim 10\times$.^[3] If the molecular ion yields are increased each pixel will contain more information resulting in more informative maps. Additionally, the success rate for determining the impact coordinates may be improved via enhanced electron emission from a MeV nano-particle projectile. A new

instrument designed to achieve this enhanced secondary ion yield and increased electron emission is under construction at IPN-Orsay, Andromede Project (program for future investment EQUIPEX, ANR-10-EQPX-23). Preliminary results from the new nano-particle ion source are presented: secondary ion yields from lipopolysaccharide samples (analyzed with Au⁴⁰⁰⁺ at 1qMeV) and correlation calculations which demonstrates the power of performing nano-scale mass spectrometry in the event-by-event mode.

¹Université Libre de Bruxelles, Bd de triomphe 2 - Brussels (Belgium), ²PMR, Université of Namur, Rue de Bruxelles 2 - Namur (Belgium).

Polymeric surfaces may be modified by plasma treatment to optimize the adhesion needed for the deposition of subsequent layers with good barrier properties suitable for food packaging. The surface modification of low density polyethylene (LDPE) overcomes several disadvantages such as low surface energy, low roughness, and high chemical inertness. Two RF atmospheric plasma torches (Ar/O₂ and He/O₂) are mounted onto a robotic arm which can move in 3D, thus allowing the treatment of large area samples. The surface chemical and physical modifications of LDPE films induced by radiofrequency plasma treatments were correlated with the characteristics of the discharge parameters and the chemical composition of the plasma itself. Water contact angle measurements have been performed, as well as AFM and XPS analyzes, to determine the wettability, the morphology and the chemical composition of the films surfaces respectively. A comparison was established between both plasma treatments at different source-substrate distances. Figure 1 shows the decreasing roughness and the decreasing weight loss as the surface polymer is away from the plasma source. More material removal is observed in the case of Ar treatment. Optical emission spectroscopy of the gas phase was performed to determine the role of the plasma species on the surface modifications observed. Although this has still to be confirmed by other data, it is suggested that etching could be provoked partly by some noble gas excited or metastable species and/or the ions bombardment, while surface chemical modifications could be due to the action of neutral species on the

plasma-activated polymer surface. A correlation between the etching rate of the ejected material and the abundance of plasma species was established.

Figure 1. Root mean squared (Rrms) roughness values and weight loss observed on the surface of LDPE films treated in Ar or He plasma during 30 s with 60W of power at different source-to-substrate distances (gaps)

Determination of film uniformity and mechanical strength are important factors in engineering porous low-k materials in the field of interconnection technology. Such layers, especially in porous form, challenge to be optimized both for low density and mechanically strong structure. Integration in the device preparation process requires the layer to be stable as a function of temperature, i.e., no thickness or composition change is allowed during high temperature process steps. Such important factor is the uniaxial CTE (Coefficient of Thermal Expansion) which measures the layer thickness change with temperature. In case of an interconnect multilayer structure, each composing material should be compatible in terms of thermal expansion in order to avoid any mechanical interferences, eg., cracks or delamination. CTE of low-k materials is reported to be significantly higher than that of other materials in the same structure which leads to mechanism for stress formation in the structure. Thus, lowering of thick porous low-k CTE is essential to reach closer value to that of Cu (50-60 vs. 17 ppm/°C) for high-temperature process.

A unique vacuum chamber tool (PS-2000H) was developed at Semilab Co. Ltd., which enables features of:

- vacuum levels <1 mTorr;
- heating up the 200 or 300 mm wafers up to 350 °C with temperature stability <0.1 °C;
- in-situ spectroscopic ellipsometry measurement for *layer thickness* and *refractive index*;
- measurement of the *uniaxial CTE* by determining the layer thickness – temperature dependence (see Fig. 1);

- mapping measurement of the wafers with the „Rho-Theta” stage;
- access to conventional organic vapor ellipsometric porosimetry functions (*film porosity, pore size distributions, Young’s modulus*) by integrating the solvent capability;
- measurement of the *above quantities* at the same probing area of $< 1\text{mm}^2$

Fig. 1. Typical measurement result of CTE for a thick low-k layer on 300 mm wafer as obtained with Semilab’s PS-2000H tool

ASS-6-In-1 ENVIRONMENTAL INTERACTIONS WITH METAL SURFACES : ANALYTICAL APPROACH, MECHANISMS, AND MODELLING

T01 Applied Surface Science

#ASS-6-In-1

P. Marcus.

Laboratory of Physical Chemistry of Surfaces CNRS – Chimie ParisTech (UMR 7045) - Paris (France).

Metal and alloy surfaces interact with their environment (gas or liquid). The understanding and control of the surface interactions is a key factor for the development of metallic materials with extended and predictable life time. Chemical interactions at metal and alloy surfaces (adsorption, oxidation, corrosion) can be studied using advanced surface characterization techniques (surface spectroscopies and microscopies) and modelling and simulation methods. The aim of this lecture is to review recent results obtained by combining Time-of-Flight Secondary Ions Mass Spectrometry (ToF-SIMS), X-ray Photoelectron Spectroscopy (XPS), Scanning Tunneling Microscopy (STM), Scanning Tunneling Spectroscopy (STS), and Density Functional Theory (DFT). The reviewed data provide a better understanding of metal surfaces, metal-oxide interfaces, and oxide films properties, including corrosion and corrosion resistance mechanisms.

The following issues will be addressed :

- Corrosion at the nanoscale using STM and STS : nanostructure of passive oxide films, local electronic properties
- Formation of vacancies at metal-oxide interfaces
- Early oxidation stages studied by advanced surface analytical techniques (XPS, ToF-SIMS) with applications in the aeronautic and nuclear industries
- DFT modelling of the reactivity of oxide films with corrosive species (Cl⁻)

The selected examples will cover various metals and alloys (nickel and nickel-base alloys, stainless steels, titanium aluminides).

ASS-4-In-1 COMBINED SURFACE AND REACTOR STUDIES OF INTERMETALLIC COMPOUNDS LEAD TO INNOVATIVE CATALYSTS

T01 Applied Surface Science

#ASS-4-In-1

M. Armbrüster.

Max-Planck-Institut für Chemische Physik fester Stoffe - Dresden (Germany).

Heterogeneous catalysis on intermetallic compounds is an interesting interdisciplinary and fast growing field. Intermetallic compounds combine unique electronic properties and well-ordered crystal structures. Often covalent bonding prevails, resulting in high stability of the intermetallic compounds under catalytic reaction conditions. This enables to pre-select compounds with appropriate electronic and structural properties in order to obtain high catalytic activity and especially selectivity. The approach is applied to develop highly innovative catalysts for the selective hydrogenation of acetylene and the steam reforming of methanol. In this contribution I focus on the benefit of combining in situ surface and reactor studies in the quest of innovative catalytic materials.

Micro-alloying of high strength steels with small amounts of elements with very high affinity to carbon and nitrogen, such as Nb, Ti and V contribute to a significant improvement of its mechanical properties. Steel micro-alloying using these elements allows obtaining a mechanical strength and good toughness at low cost as compared with conventional alloy steels.

If the metallurgical processes for obtaining (steelmaking and refining) and thermo-mechanical processing (rolling, forging etc.) are appropriate, precipitates may act within the material by blocking the movement of grain boundaries, which allows the increasing of toughness and thermal stability characteristics at high temperatures. To study the effects of thermal regime on the microstructure and microhardness of steels micro-alloyed with niobium and vanadium were made several charges, with different chemical composition, using two types of metallurgical units: a Balzers type vacuum induction furnace – VIM and a vacuum arc remelting equipment – VAR. In order to estimate the effect that the applied thermal regime have on the steel microstructure and hardness characteristics, samples of steel micro-alloyed with Nb and V were normalized at 950 – 970 oC for 20 minutes, after which they were cooled in air. Microstructure analysis by optical and electron microscopy and microhardness measurements were performed. It was found that after applying the normalization treatment, for most analyzed steel samples, the microhardness has decreased with different values, depending on the chemical composition.

DENSITY FUNCTIONAL THEORY CALCULATIONS AS A TOOL FOR UNDERSTANDING/PREDICTING ADSORPTION AND CHEMICAL REACTIONS ON BIMETALLIC AND INTERMETALLIC CATALYSTS

T01 Applied Surface Science

#ASS-2-In-1

A. Juan.

Departamento de Física e IFISUR (UNS-CONICET) - Bahia Blanca (Argentina).

Catalysts are complicated materials and there are an enormous number of interesting catalytic processes. About 20% of manufacturing in the industrialized world is dependent on catalysis. Most catalysts used in industry are solids, and the catalysis takes place on the surface of nanoparticles of the active material or in the particle/support interface. Density functional theory (DFT) calculations can provide insight into the atomic-scale reaction mechanisms helping to interpret a large amount of experimental data collected during decades. This presentation shows how DFT and bonding analysis can be used to describe the state of the surface during chemical reactions and the geometrical and electronic changes in both the surface and the adsorbed species. Our research has recently focused on the adsorption of hydrogen, carbon, benzene and CO on bimetallic (FePd, FeNi and PtCo) and intermetallic compounds (PdGa). In our approach the models are build from experimental information. The geometry and surface chemical bonding is described using quantum chemical calculations.

ASS-3-In-1 NEW PEEM (DISPLAY-TYPE ELLIPSOIDAL MESH ANALYZER: DELMA) FOR PHOTOELECTRON HOLOGRAPHY AND STEREO- PHOTOGRAPH

Usual PEEM cannot measure angular distribution of photoelectrons at above several hundred eV, therefore cannot measure photoelectron holography or stereophotograph [1] of atomic arrangement. We have developed a new PEEM (called DELMA: Display-type Ellipsoidal Mesh Analyzer [2]) using a wide acceptance angle electrostatic lens (WAAEL) [3]. DELMA can display the angular distribution of photoelectrons from the selected small area up to $\pm 60^\circ$ even at high kinetic energies as well as the magnified image of the sample. DELMA has been successfully installed at BL07LSU in Spring-8, where strong variable-polarization soft x-ray can be used. DELMA is being used to measure (1) photoelectron diffraction from small area such as graphene, (2) band-mapping for several Brillouin zones, and (3) photoelectron holography or stereophotograph of atomic arrangement.

LOOKING BENEATH THE SURFACE AT BURIED LAYERS AND INTERFACES WITH STANDING-WAVE AND HARD X-RAY PHOTOEMISSION

T01 Applied Surface Science

#ASS-1-Kn-1

C. Fadley.

Department of Physics, University of California Davis, Materials Sciences Division, Lawrence Berkeley National Laboratory - Davis (United states).

Quantitatively characterizing buried layers and the interfaces between them is one of the great challenges of surface and materials science. I will discuss two recent developments in photoemission (photoelectron spectroscopy) that have proven capable of providing unique types of information on depth profiles of composition, chemical state, and magnetic order in multilayer nanostructures, including interface-specific properties. In standing-wave excited photoemission, Bragg reflection of x-rays from a multilayer mirror (either as the sample or on which the sample is grown) creates a strong reflected wave, which by interference with the incident wave in turn generates a strong sinusoidal standing-wave electric-field profile. This profile can be scanned vertically through the sample in several ways so as to focus on different depths in the sample and thus much enhance the depth resolution in photoemission. X-ray energies in both the soft ($0.5 < h\nu < 2$ keV) and hard ($2 < h\nu < 6$ keV) regimes have been used for such studies. In hard x-ray photoemission, the energies of excitation are increased to as high as 10 keV, with the resulting greater inelastic mean free paths of the photoelectrons leading to a measurement that is capable of looking at buried layers and interfaces as deep as 30 nm. After introducing the basic principles of these methods, I will illustrate these new capabilities with several example applications to systems of interest in

spintronics, complex
oxide heterostructures, and semiconductor technology.

LEAD (II) EXTRACTION BY POLYMER INCLUSION MEMBRANE USING ALIQUAT 336 AS MOBILE CARRIER

T01 Applied Surface Science

#ASS-P1-12

N. Sabba ¹, O. Arous ¹, O. Arous ², D.E. Akretche ¹.

¹Laboratoire d'Hydrométallurgie et de Chimie Inorganique Moléculaire, U.S.T.H.B, Faculté de Chimie - Alger (Algeria), ²Centre de Recherche en Analyses Physico-chimiques CRAPC - Alger (Algeria).

The polymeric membranes used for the selective transport and separation of metal species have emerged in recent years. In this work, the extraction and transport of Pb(II) in polymeric membranes (PM) using tricapryl chloride ammonium (Aliquat 336) as mobile carrier has been investigated. The optimum conditions of liquid – liquid extraction were determined. The liquid - liquid extraction tests showed a maximum extraction when the agitation time was greater than eight minutes. A good elimination of lead (extraction efficiency 80% to 94%) was observed. The membrane is made up of cellulose triacetate (CTA) modified by Aliquat 336 incorporated into the polymer as carrier and tris- ethyl - hexyl - phosphate (TEHP) as a hydrophobic plasticizer. The membrane polymer + plasticizer + carrier was characterised using chemical techniques as well as Fourier Transform Infra – Red spectroscopy (FTIR). The metal concentrations were determined by sampling at different time intervals aliquots from both the feed and strip solutions analyzed with an atomic absorption spectrophotometer. Thickness (10 to 20 μm) and water content values showed that carrier inclusion in CTA membrane resulted in a homogeneous and hydrophobic polymer inclusion membranes. The CTA polymerization process in presence of carrier and plasticizer should cause changes in intermolecular interaction of CTA chains. However, any sign for new chemical bonds between CTA, Aliquat 336 and TEHP using FTIR spectroscopy were observed. In transport experiments, the trans-membrane flux increased with increasing carrier concentration reaching a limiting value at greater than 10^{-3} M concentration. The optimum of other fundamental parameters (metal concentration and pH) was determined. $1 \leq \text{pH} \leq 2$ have been shown to be the best conditions for maximum efficiency of the studied systems. Our results indicate that facilitated transport through plasticized membranes is an

attractive and effective way to solve the enduring problem of membrane stability whilst improving the permeability to metal ions.

Synthesis of a biradical ligand by reactivity of diphenylthiocarbazone with Mo(V)

T01 Applied Surface Science

#ASS-P1-13

Z. Izrig, S. Boutamine, H. Slaouti.

Université des Sciences et de la Technologie Houari Boumediène, Laboratoire d'Electrochimie-Corrosion, Métallurgie et Chimie Minérale, Faculté de Chimie - Alger (Algeria).

In this work, we have presented various aspects of the reactivity of diphenylthiocarbazone $C_{13}H_{12}N_4S$ (HL) with molybdenum(V) based on the pH of the aqueous metal solution and the ligand metal ratio. The reaction of an ethanolic solution of diphenylthiocarbazone with an aqueous solution of $MoCl_5$ was investigated at two pH values (2 and 9) for a ligand metal ratio equalling 1. At pH 5.2, purple dimeric complex $Mo_2O_3(HL)_2Cl_2 \cdot 1/2H_2O$ was synthesized, whereby HL was the deprotonated species of diphenylthiocarbazone (Complex C1).

A similar reaction was conducted at pH 9, leading to the formation of a biradicalar organic compound, $C_{13}H_{10}N_4S$. The two compounds were characterized by elemental analyses and spectral (IR, UV-Visible, ESR, 1H NMR and ^{95}Mo NMR) data. The biradicalar ligand was also crystallographically characterized and identified by DRX. This technique reveals no existence of molybdenum and the disappearance of the initially-existing N-H groups in free diphenylthiocarbazone. The biradical crystallizes in the monolinic space group C_2/C .

Stainless steel is commonly used material for industrial, chemical, medical and food processing applications. The adhesion of bacteria to stainless steel enhances corrosion of material, decreases the performance of processing equipment and presents chronic source of microbial contamination in food and medical industries [1, 2]. The adhesion process is governed by many factors, including environment, bacterial properties and material surface properties, such as surface roughness, topography and chemical composition [1, 3].

Adhesion behaviour of bacteria *Escherichia coli* DH5 alpha on austenitic stainless steel (AISI 316 L) with different surface roughness and topography was studied, focusing on the number and distribution of adhered cells. Material surface characterization was made by atomic force microscopy (AFM), Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS) and contact angle goniometer. Samples with various surface roughness (Ra values ranging from 0.002 – 0.4 µm) and topography were exposed to bacterial suspension. The non-adhering bacteria were removed by rinsing the substrate with sterile phosphate buffered saline (PBS). The number and distribution of adhered cells was observed using field emission scanning electron microscopy (FE-SEM).

Escherichia coli was found to adhere to all stainless steel samples, however the number and distribution of the attached bacteria varied. Adhesion level was found to depend on the substrate roughness with minimum at Ra = 0.08 µm. Attachment to both smoother and rougher surfaces was higher. The surface topography influence bacterial adhesion particularly when the surface irregularities (pits, crevices and grooves) are comparable to the size of the bacteria and can provide shelter from

unfavourable environmental factors. The pattern of bacterial adhesion follows these surface irregularities (Figure 1).

ASS-P1-08

A study of the properties of the AES inherited noise

T01 Applied Surface Science

#ASS-P1-08

B. Poniku, I. Belic, M. Jenko.

Institute of Metals and Technology - Ljubljana (Slovenia).

Our research work is aiming to fully automate the AES (Auger Electron Spectroscopy) spectral analysis. The task has not been accomplished yet since the AES produces a very complex signal consisting of at least three elements, the characteristic peaks, the spectral background, and the noise. In order to be able to perform the automated analysis, the spectral signal should be as free as possible of the background as well as the noise component. We are not studying the phenomena or physical processes that actually result in producing the noise, our focus is to analyse the already existing noise which gets recorded with the spectra and find the ways to suppress it without the significant distortion of the spectra. This should be done in the processing stage of the spectra, after the measurement has been completed and the data have been gathered. The paper reports on the work done to extract the important properties of the AES inherited noise such as the noise distribution, and the noise amplitude envelope function as the function of the electron energy. Knowing the statistical properties of the noise which is to some extent unique for the used AES equipment enables us to use the statistical methods to suppress the noise to the acceptable level thus improving the signal/noise ratio. On the other hand the gained knowledge enables us to improve the already operational AES simulator which was developed in our laboratory and is in use as the test platform for the different spectra analysis algorithms.

By putting in use the AES simulator just mentioned above we wanted to also reflect upon a common practice in Surface Analysis laboratories. In routine analysis it is common practice to average the spectra for the purpose of increasing the signal to noise ratio by most often averaging three measured Auger spectra in order to obtain spectra with fairly good signal to noise ratio while not spending exceedingly long times for performing one measurement. Even though this practice improves the signal to noise ratio slightly and enables in most cases the identification of the characteristic peaks without too many problems, we wanted to do a quantitative evaluation of the effectivity of this practice by generating simulated spectra with randomly generated noise of a certain profile similar to that which is found in

measured Auger spectra, and then averaging a number of trials. Our findings in this regard will also be reported.

Keywords: Auger Electron Spectroscopy, noise, white noise, spectral distribution, amplitude distribution, amplitude envelope function

Laser Surface Structuring for Anti-biofouling Surfaces

T01 Applied Surface Science

#BI/ASS/NST-P1-14

T. Kokalj ¹, D. Kovacic ², M. Jenko ¹.

¹IMT-Institute of Metals and Technology - Ljubljana (Slovenia), ²LPKF - Naklo (Slovenia).

The studied biological anti-biofouling surfaces typically consist of hierarchical structure where nanostructure is superimposed on the micro structured pattern. With microstructure the surface gain the resistivity to larger fouling organisms, while the nanostructure combined with the proper surface energy prevents biofouling of smallest microorganisms.

Recently IMT is developing some bio-mimetic micro-/nano- patterns using laser structuring. For the large surfaces we use laser structuring directly on the various metal surfaces. The laser beam in this case has sufficient power to change the metal surface morphology directly. The laser beam diameter is around 15 μm , however the molten metal splashing which is inherent to this kind of laser fabrication creates droplets of sub-micrometer dimensions. This creates a hierarchical micro-/nano-structure as can be seen in Fig. 1a. This surfaces exhibit a huge change in contact angle with water, compared with non-treated surface (Fig. 1b).

The properties of the substrate material and the laser machining parameters define the change of wettability of the surface. However, the further chemical modification of the surface can additionally change the surface energy and change the contact angle as well as make the surface more resistant to biofouling.

The change of surface properties depending on surface structuring strategies and selection of substrate material will be presented.

Figure 1: Hierarchical micro-/nano-structure on the laser treated copper surface (1a) and high water contact angle on this surface (1b).

TAILORING THE BIOELECTRONIC INTERFACE

T01 Applied Surface Science

#ASS-8-In-1

J. Vörös.

Laboratory of Biosensors and Bioelectronics, Institute for Biomedical Engineering, ETH - Zurich (Switzerland).

Surface science has achieved a very high level control over the physical and chemical properties of particles and interfaces. A recent trend and some applications desire not only spatial but also temporal control over such properties. Electrodes and electrochemistry provide a convenient mean to switch surface properties on command. Several examples for such concepts will be presented in this talk: Polyelectrolytes can be removed on command at electrodes using the locally induced pH changes during electrolysis. This effect then can also be used to control the adhesion, growth and migration of cells. [1]

Nanotechnology also provides the possibility to interface cells in their natural environment at the nanometer scale. The FluidFM is a nanosyringe that can be used to inject, patch, or manipulate single cells without compromising their integrity. In addition, biomolecules or nanoobjects can be picked and placed with nanometer precision in liquid environment. [2-5]

Finally, stretchable and biocompatible microelectrode arrays can be used to stimulate intact spinal cord circuits below an injury to control the movement of the limbs aiding rehabilitation and increasing recovery of spinal-cord injured patients.

ASS-5-In-1

Measuring molecular attachment to nanoparticles

T01 Applied Surface Science

#ASS-5-In-1

A. Shard.

NATIONAL PHYSICAL LABORATORY - Teddington (United kingdom).

Surfaces exposed to a biological environment will, almost invariably, acquire an adsorbed layer of proteins. For nanoparticles, this process is important both for the designed attachment of proteins for diagnostic and therapeutic applications and for understanding how nanoparticles interact with living systems. Using model systems of poly(ethylene glycol) thiol and immunoglobulin on gold nanoparticles, we compare different techniques which could be used to measure molecular attachment including light scattering, sedimentation, particle tracking and local plasmon resonance. These techniques provide rather different answers unless the data is interpreted correctly, but through a combination of methods it is possible to estimate the average number of molecules attached to each particle and achieve reasonable agreement between the techniques. More information may be obtained by vacuum-based, spectroscopic methods, such as XPS, but in this case, sample preparation and data interpretation are specialised skills. In this talk, accurate and straightforward methods for XPS data interpretation are described and some approaches to sample preparation outlined.

ASS-10-In-1

Scanning Photoemission Microscopy

Applications In Surface Chemistry

T01 Applied Surface Science

#ASS-10-In-1

L. Gregoratti.

Elettra Sincrotrone Trieste - Trieste (Italy).

The Scanning Photoemission Microscopes (SPEM) operating at synchrotron radiation sources use the power of the surface sensitive photoelectron spectroscopy to obtain chemical characterization of materials with spatial resolution down to 50 nm and probing depth up to a few tens Å. In the last years this microscopy has been widely used for understanding the most relevant processes and degradation phenomena which characterize the new technologies for the production of energies such as fuel cells. However the application of this technique to the investigation of real devices is strictly linked to its capability to overcome the limits imposed by the so called “pressure gap” which imposes a high vacuum sample environment. In this respect the SPEM at Elettra offers new and challenging tools for the photoemission spectromicroscopy of the future

ATS-3-Or-6

Spectroscopic Studies of Interstellar Precursor Molecules

T02 Astronomical Frontiers for Surface Science

#ATS-3-Or-6

M. Whelan, N. Panjwani, W. Brown.

UCL - London (United kingdom).

(Abstract for ASTROSURF meeting)

Interstellar dust grains, once thought to be merely an annoyance to astronomers, have been shown to have an active role in the formation of many chemical species observed in the interstellar medium (ISM). Whilst many observed species are produced efficiently in the gas phase, many are also destroyed or consumed upon formation. It was this realisation that prompted scientists to appreciate the importance of dust grain surface reactions. Dust grains provide heterogeneous catalytic sites, which facilitate formation of molecules and ices, and a medium in which the energy released in bond formation can be dissipated.

Formic acid, despite being detected in both the solid and gas phase in a number of different environments, has received relatively little attention from the astrochemistry community. Understanding the formation of formic acid, which is proposed to occur in the gas phase and on the grain surface, is of significant importance for explaining the chemical composition of the ISM. Formic acid is relatively reactive and partakes in the formation of other, larger, organic species. Examples of some of these are the isomers methyl formate, ethanoic acid and glycolaldehyde (GA). Of particular interest is GA, since it has been proposed to have an important role in the formation of amino acids in space and hence may be related to the origins of life.

In addition to its reactive pathways, formic acid is also of interest due to its ability to

hydrogen bond. This is important in the ISM since the most dominant molecule observed in the solid phase is water, which shows a strong propensity for hydrogen bonding.

In light of the importance of formic acid in the ISM, the work presented here focuses on surface science studies of the behaviour of pure formic acid and formic acid in astronomically relevant ices. The studies were conducted using temperature programmed desorption (TPD) and reflection absorption infrared spectroscopy (RAIRS). Investigations of pure formic acid on graphite, an interstellar dust grain analogue, showed a clear phase change of the formic acid and subsequently, a change in its desorption temperature. Studies of coadsorbed layers and mixtures of formic acid and water showed that the two molecules are inextricably linked when both are in a single ice. The significance of these observations with respect to real interstellar ices will be discussed.

Accretion Disk Origin of Earth's Water

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-7

M. Rocca ¹, L. Vattuone ¹, L. Savio ¹, M. Smerieri ¹, A. Asaduzzaman ², K. Muralidharan ², M.J. Drake ³.

¹Dept of Physics University of Genoa - Genoa (Italy), ²Department of Materials Sciences and Engineering, University of Arizona - Tucson (United states), ³Lunar and Planetary Laboratory, University of Arizona - Tucson (United states).

The presence of water on the Earth is an enigma. It is generally agreed that it was too hot at 1 Astronomical unit (AU) for hydrous minerals to be stable in the accretion disk. Thus, Earth's water is conventionally believed to have been delivered by comets or wet asteroids after Earth formed. However, wet asteroids and comets have elemental and isotopic properties that are inconsistent with those of Earth, limiting the amount of water derived from such objects.

It was thus proposed that water was introduced during planet growth in the accretion disk in a form stable under high temperature conditions. This hypothesis is supported by the presence of water in the disks around young stars and by numerical simulations of water adsorption on silicate grains under conditions corresponding to those in the accretion disk. Such studies, yet to be confirmed experimentally, showed that molecular chemisorption of water on forsterite (Mg-rich end member of olivine, one of the main constituent of the dust grains) might occur and account for the formation of several Earth oceans but neglected water dissociation [1].

Here we apply surface science methods to the study of this astrophysical problem. Water adsorption experiments were performed under ultra high vacuum conditions using a supersonic molecular beam of water and the retarded reflector method to measure the sticking probability. Ab initio, numerical simulations were performed, too, including now also the possibility of dissociation. We find indeed that water adsorbs dissociatively on the olivine {100} surface, implying that this happens also at the temperature (500-1500 K) and water pressure (10^{-8} bar) expected for the accretion disk. Water leaves an OH adlayer that is stable at least up to 900 K. This mechanism may result in the formation of many Earth oceans, provided that a viable mechanism to produce water from hydroxyl exists [2].

This adsorption process must occur in all disk environments around young stars. The inevitable conclusion is that water should be prevalent on terrestrial planets in the habitable zone around other stars.

For a better understanding of the formation of interstellar molecules a D₂O ice covered highly-oriented pyrolytic graphite (HOPG) surface is investigated. This analog of interstellar ice covered dust grains, is irradiated with XUV radiation ($h\nu = 38$ eV), provided by the free electron laser at Hamburg (FLASH). In a so far unknown reaction cascade O₂⁺ ions are formed and emitted with a highly nonlinear dependence on the FLASH intensity proportional to I^3 [1]. To investigate the formation process of the desorbing molecular oxygen ions a non-linear XUV pump - XUV probe measurement with a beamsplitter and delay-line device for the energy range of 24 – 200 eV is used. A two-pulse autocorrelation curve of desorbing O₂⁺ ions is measured. The time constants for the fitted asymmetric Gaussian points to an electronic process initiating the reaction and long decay time of the O₂⁺-signal suggests a motion of molecular constituents during the reaction.

Adsorption-induced nuclear-spin conversion of hydrogen on surfaces

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-9

K. Fukutani ¹, K. Niki ², T. Okano ¹.

¹University of Tokyo - Tokyo (Japan), ²Chiba University - Chiba (Japan).

Molecular hydrogen consisting of two identical nuclei exists in nuclear-spin modifications of ortho and para species according to the total nuclear spin (I). Due to the symmetry of the total wave function with respect to the permutation of the two nuclei, ortho-H₂ of $I=1$ is in the rotational state with odd rotational quantum numbers (J), while para-H₂ of $I=0$ has even J . Although the transition between the ortho and para states is slow in gas phase, the conversion is promoted by the interaction with solid surfaces. We have studied H₂ ortho-para conversion and D₂ para-ortho conversion in physisorption states on Ag [1,2] and ice surfaces [3]. In these studies, we have noticed that the ortho/para ratio right after adsorption on surfaces deviates from the nuclear-spin degeneracy, which suggests ortho-para conversion takes place during the adsorption on surfaces. In the present paper, we have studied possible ortho-para conversion during the adsorption process of H₂ on Ag with a use of a pure ortho-H₂ source.

The experiments were performed in a UHV chamber. Pure ortho-H₂ was prepared by the adsorption separation method on the basis of the difference for the desorption energy between ortho and para H₂. The ortho-H₂ was admitted to the surface with a pulse valve, and subsequently the surface coverages of ortho and para H₂ were monitored by the REMPI technique combined with photostimulated desorption [1]. After the Ag surface was exposed to the pure ortho-H₂ at 7 K, the para H₂ was found to be on the surface with an intensity of about 20 % of the ortho H₂. Since almost no para-H₂ was present in the ortho-H₂ source, the para-H₂ observed on the surface originates from ortho-H₂ incident to the surface. It is noted that the time evolution of the ortho-H₂ coverage after the adsorption reveals an exponential decay with a time constant of about 600 s [1,2]. When H₂ is in the adsorption well, ortho-para conversion proceeds with a conversion time of about 600 s. On the other hand, adsorption of H₂ is regarded as vibrational relaxation in the adsorption well. We therefore argue that ortho-para conversion is induced during the vibrational relaxation in the potential well.

Refractive indices of organic thin films simulating Titan aerosols

T02 Astronomical Frontiers for Surface Science

#ATS-P1-02

G. Cernogora, A. Mahjoub, P.R. Dahoo, N. Carrasco, T. Gautier.

UVSQ-LATMOS - Guyancourt (France).

Titan, the biggest Saturn satellite has a dense atmosphere composed of N₂ and CH₄. In this atmosphere, solid organic aerosols are produced by photochemistry induced by solar photons and by ionic chemistry induced by energetic particles from Saturn's magnetosphere.

In order to simulate in laboratory the formation of these organic aerosols, a low pressure Radio Frequency Capacitively Coupled Plasma discharge is used. The experimental device is described in details in [1]. This discharge can run in N₂ CH₄ gas mixtures with 1% to 10% of CH₄ in order to simulate Titan's conditions. Gas mixture is introduced continuously. Silicon substrates are placed on the grounded electrode. Films of organic material are then produced during 2 or 3 hours in order to obtain film with thickness lower than 1 μm. The substrates are at room temperature or can be cooled down to 105 K by a liquid nitrogen flow through the polarised electrode.

Films are observed ex-situ by Spectroscopic Ellipsometry (SE) from 340 to 1000 nm. SE is an optical technique based on the measurement of the change in polarized light upon light reflection on a sample. Two parameters are measured: $\tan(\Psi)$, the ratio of the amplitudes and Δ the relative difference in phase for the p- and s-polarized reflected light the film surface. The real and imaginary refractive index (n and k) are deduced from the fit of the ellipsometric parameters Δ and ψ using a physical description, based on a Tauc Lorentz model for the film dielectric constant (correlated with the optical indices). The films thickness and roughness are also deduced from the fit [2].

For films produced at room temperature or at 105 K the imaginary refractive index k decreases when the CH₄ amount increases. Then the films are less absorbent for higher CH₄ concentrations. From elemental analysis [3] it is shown that this effect is due to a decay of nitrogen incorporation in the films. Moreover, IR absorption measurements [4] confirm the increase of the amine functions with lower amounts of CH₄.

It is shown that for the same gas mixture and deposition duration, the thickness of

the films produced at 105 K is smaller than for those produced at room temperature. When the substrate is cooled down to 105 K, for the same gas mixture conditions, the films are less absorbent than films produced at room temperature. The changes in k values at low temperature are attributed to a change in the chemical composition of the gas mixture when the plasma is on, measured in situ by mass spectrometry. Nitrides are condensed on the reactor wall at low temperature. This reduction of nitrogen containing compounds in the gas phase leads to a decay of nitrogen in the films and a decrease of absorption.

These results are compared with the optical properties' of Titan's aerosols deduced from the Cassini Huygens probe measurements.

The interaction between atomic hydrogen and PAHs: Implications for molecular hydrogen formation

T02 Astronomical Frontiers for Surface Science

#ATS-1-Or-2

J. Thrower, B. Jørgensen, E. Friis, A. Skov, H. Lemaître, A. Cassidy, R. Balog, M. Andersen, B. Hammer, L. Hornekær.

Department of Physics and Astronomy, Aarhus University - Aarhus (Denmark).

Polycyclic aromatic hydrocarbons (PAHs) account for a significant fraction of the cosmic carbon budget, being observed in a wide range of astrophysical environments. and are thought to play an important part in interstellar chemistry. We have considered the interaction between this important class of interstellar molecule and atomic hydrogen. In addition to forming superhydrogenated PAH species (HPAH) our measurements reveal a previously unexplored route to molecular hydrogen (H_2) formation (See **Fig. 1**). The formation of H_2 is inefficient in the gas phase and requires surface chemistry to be invoked to explain the observed abundance. Numerous investigations have revealed the efficiency of the surface recombination of physisorbed H atoms at the low temperatures found in molecular clouds. At higher temperatures, for example in photodissociation regions (PDRs), reduced residence times mean that alternative mechanisms are required in order to explain the observed H_2 formation rate. The observed correlation between H_2 formation rate and PAH emission in PDRs suggests that PAHs may play a role in H_2 formation in such environments [1]. Density functional theory (DFT) calculations [2] have shown that H-atom addition to PAH molecules can lead to the formation of HPAH species through the addition of H atoms to both the edge and center sites of PAH molecules. They also revealed the presence of energetically favourable abstraction pathways leading to the formation of H_2 molecules. The formation of such HPAH species with additional H atoms is consistent with the observed $3.4 \mu m$ band previously attributed to PAH species with additional peripheral H atoms [3,4]. We have confirmed the results of these calculations experimentally using a combination of thermal desorption and scanning tunneling microscopy (STM) measurements. Exposure of a monolayer of coronene ($C_{24}H_{12}$) adsorbed on a graphite substrate to a beam of atomic hydrogen results in the formation of superhydrogenated coronene

molecules [5]. The observed product mass distribution indicates that addition to edge and center sites occurs, along abstraction reactions leading to H₂. The STM measurements provide a direct observation of the adsorbed HPAH species following exposure to the H beam.

It has recently been discovered at the ASTRID laboratory at Aarhus University that solid cryofilms of simple species such as nitrous oxide (N₂O), propane or toluene spontaneously polarise and give rise to significant surface potentials of typically several volts, corresponding to electric fields in excess of 10⁸ V.m⁻¹. It has been suggested that the spontelectric fields form due to the alignment of the permanent dipoles of the molecules in the films.¹⁻³

Although the spontelectric effect cannot be directly observed with infrared spectroscopy, this tool can provide information on the degree of dipole alignment in the film.⁴ To this aim, we performed reflection-absorption infrared spectroscopy (RAIRS) experiments on pure N₂O films and on dilute N₂O:Xe mixtures, where the spontelectric effect is retained. The influence of deposition temperature on the structure of solid N₂O is discussed in terms of dipole alignment in the film. Segregation of N₂O does not occur in Xe, suggesting that the dipole alignment believed to give rise to the observed spontelectric field is due to an extended network of dipole-dipole interactions within the film.

The spontelectric effect may have important astrophysical implications: in the dense regions of the molecular clouds, dust grains are coated with tens of monolayers of carbon monoxide (CO). CO molecules have a permanent dipole moment; therefore

CO films may exhibit a spontelectric character. This would have consequences for the chemistry of the interstellar medium, which will be discussed in this presentation.

Astrophysical studies of comets and forming planetary systems have gathered spectroscopic evidence for abnormally low ratios of ortho-H₂O / para-H₂O, reflecting a surprisingly low spin temperature of the gas phase water molecules (e.g. [1]). Suggestions have been made that such low spin temperatures can be related back to the formation conditions of stellar systems due to the extremely slow rate of nuclear spin conversion. While this ability to look into the past is particularly valuable, a fundamental requirement for reliably interpreting these results is a good understanding of nuclear spin conversion mechanisms, both in the gas phase and when interacting with cold solid surfaces. Unfortunately, the current understanding of these conversion mechanisms is rather limited, mostly due to the lack of experimental methods which can separate spin isomers of astrophysically relevant molecules in general and the two spin isomers of H₂O in particular.

A potential breakthrough was reported a decade ago, where selective physical adsorption seemed to enable separation of the H₂O water isomers [2], however, several subsequent attempts to reproduce these results have not been successful. In a recent set of experiments, we have successfully formed a molecular beam of ortho-H₂O by magnetically focusing a slow molecular beam [3]. This unique molecular beam source opens up the possibility of performing highly controlled laboratory studies of nuclear spin conversion of water molecules and other astrophysically relevant molecules. We will present recent infra red spectroscopy measurements

which demonstrate the high H₂O spin isomer purity produced by our molecular beam source and also examine the ability to store the ortho molecules for prolonged times within isolated rare-gas matrices[4].

Synthesis of Cosmic Dust Analogues

T02 Astronomical Frontiers for Surface Science

#ATS-1-Or-3

V. Frankland, A. James, J. Plane.

University of Leeds - Leeds (United kingdom).

The harsh conditions of the interstellar medium (ISM) prevent gas-phase chemistry alone from being sufficient to explain the observation of over 150 different molecules [1]. Instead, the dust grains can provide a surface on which the formation of key species, including H₂, can occur.

Sol-gel and microfluidic techniques have been used to synthesize cosmic dust analogues. Particle analysis has revealed that these nanoparticles are highly microporous and provide a suitable surface for ice formation to occur on. Surface chemistry performed in a Knudsen Cell has been used to explore the heterogeneous reactions and adsorption kinetics of a range of gases on the cosmic dust particles mimicking the gas-dust chemistry in the atmospheres of planets and moons and in the ISM.

Desorption of O₂, CO and N₂ from astronomically relevant surfaces

T02 Astronomical Frontiers for Surface Science

#ATS-3-Or-3

A. Rosu-Finsen¹, V. Frankland², J. Lasne¹, M. Collings¹, M. Mccoustra¹.

¹Heriot-Watt University - Edinburgh (United kingdom), ²Leeds University - Leeds (United kingdom).

In the interstellar medium (ISM), a range of molecules have been observed in the gas phase or condensed onto icy surfaces of dust grains. Oxygen (O₂), carbon monoxide (CO) and nitrogen (N₂) are predicted to be among the most abundant small molecules in dense cores.^{1,2,3} Although the concentrations of most species, such as CO, agree well with the observed molecular abundance using gas-phase chemistry, the models are unable to explain the formation and abundance of several molecules, including O₂ and N₂.^{1,4} Then, the models need to include the adsorption and desorption processes of these species from the icy grains to match the observed abundances. To this aim, we performed Temperature-Programmed Desorption (TPD) experiments coupled with kinetic modelling to study the desorption kinetics of O₂, CO and N₂ sub-monolayers and multilayers from amorphous silica. Desorption of O₂ from compact and porous amorphous solid water-covered silica is also reported. Our results show that the morphology of the underlying silica surface affects the desorption kinetics of O₂, CO and N₂ and give insights into the understanding of the processes taking place in the ISM.

Chemical surface reactions on dust grains are a possible way of molecule formation in the Interstellar Medium (ISM) [1]. These grains typically consist of graphitic and silicate particles embedded in icy mantels which are formed by molecules like CO, CO₂, H₂O or CH₄. In recent times more than 140 different gases have been reported in the dense regions of interstellar space [2]. Temperature programmed desorption (TPD) is used to investigate the binding energy and reaction order of several interstellar relevant molecules like CO, CO₂, CH₄ and D₂O on different interstellar silicate analogues like Forsterite (Mg₂SiO₄) and Olivine [(Mg,Fe)₂SiO₄] shown in the figures below. The experimental set-up consists of a quadruple mass spectrometer, a dosing chamber and a liquid helium cooled sample holder. Due to this set-up it is possible to investigate the behaviour of these molecules at very low temperatures (~ 5 K) comparable to the ISM. Further due to the dosing chamber it is possible to prepare a sample with a precise mixture of different kind of gases and a low coverage. We present desorption spectra, binding energies and their coverage dependence on both Olivine and single crystal Forsterite.

Abstract for ASTROSURF meeting

There is currently great interest among astronomers in the inventory of organic molecules in space. The role surface science plays in astrophysical processes is considerable, ranging from the birth and formation of stars and planets and extending to the origins of life. The importance of surface processes within interstellar ices comes from the observation that the abundance of many molecules detected within interstellar clouds cannot be explained by astrophysical models using only gas-phase processes. These models become more accurate when reactions on the surfaces of dust grains are incorporated, since grains open up reaction pathways to adsorbed atoms/molecules that are not available in the gas-phase. Amongst the most important organic species detected in space is glycolaldehyde (CH_2OHCHO), an isomer of methyl formate (HCOOCH_3) and acetic acid (CH_3COOH). It is postulated that glycolaldehyde may have a role in the origins of life in our universe.

We present a detailed investigation of the adsorption and desorption of glycolaldehyde, methyl formate and acetic acid from a model interstellar dust grain using temperature programmed desorption (TPD) and reflection absorption infrared spectroscopy (RAIRS). Primarily we will study the stability of glycolaldehyde/water containing ices to electron/UV irradiation. Electron irradiation (simulating the effect of cosmic ray ionisation) and UV irradiation (over a range of wavelengths) is used to examine competing routes for non-thermal desorption, decomposition and formation. RAIRS and TPD will be used to identify any reaction products and to monitor the desorption/decomposition of glycolaldehyde as a function of irradiation time.

This work forms part of a larger project, incorporating experiment, theory and astrochemical modelling, investigating the formation of glycolaldehyde in space.

The presence of CH₃CN in the interstellar medium (ISM) is of significance due to its potential as a reactant in the formation of amino acids in astrophysical environments [1]. It has been detected in comets [2], the atmosphere of Titan [3], and as a gas phase molecule in the ISM [4]. CH₃CN is likely to be formed on icy grains from reactions involving CH₃ and CN radicals and injected into the gas phase as the icy grain mantles desorb at temperatures above 90 K [5]. In this study we report on collaborative investigations made as part of the activities of the European network LASSIE, particularly with the Osservatorio Astrofisico di Catania [6] focussing on the investigation of energetic processing of icy mantles where a competition exists between chemical processes and physical processes. To this end the structure and bonding of solid acetonitrile (CH₃CN) films on amorphous silica are studied and chemical and physical processes under irradiation with 200 keV protons and 250 - 400 eV electrons are quantified using transmission infrared spectroscopy (TIRS), reflection absorption infrared spectroscopy (RAIRS), and temperature programmed desorption (TPD), with the assistance of basic computational chemistry and nuclear materials calculations. Astrophysical implications are eventually discussed.

Interaction of Benzene with Molecular Solids - The Importance of Hydrogen Bonding

T02 Astronomical Frontiers for Surface Science

#ATS-1-Or-1

M. Mccoustra, D. Marchione, A. Abdulgalil, M. Collings.

Heriot-Watt University - Edinburgh (United kingdom).

Polycyclic aromatic hydrocarbons (PAHs) are large and stable molecules containing about 10-20% of the total available cosmic carbon. While in diffuse cloud environments they are thought to exist in gas phase, in dense clouds IR absorption features attributable to PAHs hints to their presence both in gas and condensed phase. As previous work [1,2] by this group, benzene was conveniently chosen as a prototypical PAH, representing the main building block, but as also because it has been detected around the protoplanetary nebula CRL 618 [3]. Therefore there is potential for benzene to be adsorbed on ices of different chemical nature in conditions close to those in the interstellar medium. Reflection-absorption infrared spectroscopy (RAIRS) and a quadrupole mass spectrometry (QMS) have been used to characterise dynamical processes of astrophysical relevance and investigate the role of intramolecular interactions both at the interface and in the bulk ice. Astrophysical implications of our observations will be discussed.

Modelling Non-Thermal Desorption in Interstellar Environments

T02 Astronomical Frontiers for Surface Science

#ATS-3-Or-2

M. Collings, A. Abdulgalil, M. Mccoustra.

Institute of Chemical Sciences, Heriot-Watt University - Edinburgh (United Kingdom).

In the coldest, densest regions of molecular clouds, the time-scale for adsorption of molecular species onto dust grains is much shorter than the typical lifetime of such objects [1], therefore, complete freeze-out of molecular species might be expected. However, observations demonstrate that a significant gas-phase population of molecular species is maintained [2]. Therefore, non-thermal desorption mechanisms that enable return of mantle species to the gas phase are required to balance the freeze-out process. Such non-thermal desorption mechanisms remain poorly understood for interstellar ices [3], and are poorly characterised by experimental data.

Here, we present models of desorption in a range of astrophysical environments, in the absence of gas phase chemistry. These models include thermal desorption and various mechanisms of non-thermal desorption, based on recent laboratory results. The relative importance of different desorption mechanisms can thus be tested against the astrophysical conditions.

In the interstellar medium (ISM), dust grains play a key role in mediating the formation of molecular species. In order to understand and quantitatively describe the related reactive processes, it is of a strong interest to study the interactions (and reactions) of H, C, O atoms present in the interstellar clouds with (and at) grain surfaces.

Many studies have been devoted to the adsorption of hydrogen atoms, the most abundant atomic species in interstellar clouds, and to the formation of H₂ by H recombination/abstraction processes onto the surface of carbonaceous dust grains. We have shown that the atomic adsorption characteristics (physisorption/chemisorption wells, adsorption barrier, defects) play a major role in the molecular formation [1], [2].

In the ISM, the oxygen is the third abundant element after H and He. The atomic oxygen is implied in the formation of heavier molecules such as OH [3], H₂O. In this context, we have studied the adsorption of the atomic oxygen in the fundamental state ³P on a carbonaceous grain. Indeed previous works have been mainly devoted to the singlet state and only a few to the triplet state [4] [5].

Our theoretical studies have been performed by means of spin polarized DFT/GGA calculations. The grain surface is modeled either as a graphene sheet or as PAH molecules (C₂₄H₁₂, C₅₄H₁₈). We have considered several adsorption sites: on top of a C atom of the surface, bridged between 2 adjacent C atoms of the surface.

We have obtained adsorption energies and geometries in agreement with previous works [4] [5]. Our main result is the barrierless chemisorption of the atomic oxygen in the ³P state onto graphenic surfaces. The chemisorption characteristics are site dependent. Regardless of the surface considered, the more stable chemisorption site is the top site.

At larger surface-oxygen distances, the physisorption of the atomic oxygen in the 3P state onto graphenic surfaces is also obtained. Depending on the surface, the physisorption characteristics are weakly site dependent.

All these electronic/structural studies, including relaxation of surrounding carbon atoms, are the first step needed for the study of the OH/H₂O formation dynamics in order to obtain reaction probabilities, energy sharing between the nascent molecules and the surface.

Tracking the thermal desorption of thin water ice films by optical reflection measurements

T02 Astronomical Frontiers for Surface Science

#ATS-1-Or-6

A. Clemens, L. Hellberg, D. Chakarov.

Chalmers University of Technology - Gothenburg (Sweden).

Experimental desorption studies of water ice from surfaces are of high importance to improve astrochemical modeling. Thermal desorption in particular is relevant for modeling of hot core regions where it represents the predominant desorption process of water ice adsorbed on interstellar grains.

In addition to the commonly used methods of temperature programmed desorption (TPD) with mass spectrometry and vibrational spectroscopy methods [1] we present a method of tracking desorption of water ice optically.

Here we address two specific issues of relevance: (i) the role of nanostructured carbon surfaces in the desorption process and (ii) interpretation of the spectral dependence of the reflected light.

The model substrate for water ice desorption consists of truncated cone structures of highly oriented pyrolytic graphite (HOPG), with an upper diameter of 190 nm and a height of 100 nm that cover approximately 30% of the sample surface. The structures are prepared by colloidal lithography and oxygen plasma etching.

Desorption of water ice can be followed by recording the intensity of diffusely reflected light from the surface during a thermal desorption experiment.

The enhanced (resonant) optical absorption in the nanostructured samples (described before by us in [2]) results in a minimum in optical reflection at visible wavelengths. Due to that water ice desorption of initial water coverages as low as two monolayers could be tracked optically with high sensitivity at UV wavelengths.

H₂ formation and interaction on interstellar silicate analogs via REMPI(2+1) spectroscopy

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-3

L. Gavilan, J.L. Lemaire, G. Vidali.

Paris Observatory/Univ. Cergy-Pontoise - Paris (France).

Silicate dust surfaces catalyze the formation of molecular hydrogen, the most abundant molecule in the universe. The formation and sticking of this molecule on dust drives the chemical complexity of the ISM. Silicate dust properties depend on their location and lifetime in the ISM, where they can be irradiated by energetic photons and ions. We present this project in collaboration with the Laboratory Astrophysics Group in Jena (Germany), where we produced nanometer sized silicate samples via laser ablation. These are used as surface catalysts in molecular formation experiments within the FORMOLISM setup located in Cergy-Pontoise (France). Silicate samples are prepared according to extreme ISM parameters: structural (fully crystalline or amorphous), and chemical (the forsterite and fayalite endmembers of the olivine family). We present preliminary results on H₂ formation on such silicates and the dependance on temperature, possible nuclear spin conversion effects, and rotationally "hot H₂".

Interstellar water formation has been intensively investigated in the past decade. Many studies from different groups have shown an efficient formation through the hydrogenation/deuteration of O, O₂ and O₃ ices [1-4] mostly in the multilayer regime [1,2]. The formation of the first water molecules on bare dust grains (silicates and/or carbonaceous materials) is of primary importance to understand the growth of the icy mantle in dense and cold molecular clouds where the temperature is as low as 10 K. We present the first experimental results of D₂O and D₂O₂ formation through O₂ +D pathway in the sub-and monolayer regimes on bare amorphous silicate grain analogs. For comparison, we also studied the formation of water molecules on porous and non-porous amorphous water ices surfaces held at 10K [5].

The experiments were performed with the FORMOLISM setup located at the university of Cergy Pontoise using atomic deuterium and molecular oxygen triply differential pumping beam lines. The gas surface reactions are analyzed with

Reflection Absorption Infra-Red Spectroscopy (RAIRS) and with Temperature-Programmed Desorption (TPD) techniques.

Results showed that the formation of D₂O water molecules through O₂+D pathway is very efficient (80-90%), but one fraction of the newly formed water stays on the dust grains at 10K, and the other fraction is released into the gas phase. The fraction of water molecules desorbing into the gas phase upon formation depends strongly on the substrate (silicate or water ice). In the case of the silicate substrate, more than 85 % of D₂O water molecules desorb into the gas phase upon formation on the cold surface through the barrierless OD+D->D₂O reaction. The non-thermal desorption, also called the chemical desorption of the newly formed water molecules is induced by the heat released from the exothermic surface reaction between the radicals OD and D atoms [6]. These results are supported by a simple kinetic model taking into account the high desorption rate of water products.

ATS-2-Or-6

NH₂OH formation via barrierless hydrogenation reactions of NO under dark interstellar cloud conditions

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-6

E. Congiu.

LERMA Univ. Cergy-Pontoise - Obs. de Paris (France).

In surface reactions and solid state chemistry nitric oxide, NO, is thought to be the main precursor species of the NO bonded molecules [1, 2] and one of the precursor molecules of nitrogen-containing organics [3, 4]. Interstellar nitrogen chemistry, however, is rather poorly understood as well as the mechanisms leading to the inclusion of nitrogen into (still) unknown reservoirs of interstellar nitrogen. Charnley et al. [2] proposed that accreted NO might be converted to HNO and hydroxylamine - NH₂OH- via hydrogenation surface reactions in quiescent dense clouds. In the present laboratory study, temperature-programmed desorption (TPD) and reflection-absorption infrared spectroscopy (RAIRS) techniques are used to investigate hydrogenation reactions of NO molecules under interstellar dark cloud conditions. In this talk, I will focus on the reactivity of NO and H (D-)atoms and present a study of hydroxylamine formation on crystalline H₂O and amorphous silicate – two very realistic analogs of grain surface materials in the interstellar medium – at low temperature (10 K) and in a low-coverage regime (~ 1 monolayer) [5 - 7]. We show that at very low temperatures NH₂OH can be formed efficiently in a series of subsequent H-atom addition reactions of solid NO. The novelty of this reaction scheme is that the whole reaction takes place without adding energy. This adds a new perspective to the way molecules of biological importance may form in space. The model predictions show that hydroxylamine is to be abundant in the solid phase well before a protostar evolves to become a star and should be detectable with ALMA, the new astronomical flagship facility starting up in Chile. The present results add to the discussion whether the seeds of life are disseminated all over the Universe and may have been delivered to planets through impacting celestial bodies [4, 8].

ATS-2-Or-2

Quantum Diffusion and reactivity of Oxygen atoms

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-2

M. Minissale.

Observatoire de Paris and Université de Cergy Pontoise - Paris (France).

The solid state astrochemistry at low temperature is governed by the possibility of reactants to meet each others. Hydrogenation of numerous species such as H, CO, NO, O₂, O ... as been the subject of recent intense experimental investigations. We propose now to focus for the first time on oxidation.

The experiments presented have been performed with the FORMOLISM device, set in Université de Cergy Pontoise, Observatoire de Paris. Via a triply differentially pumped beam, O atoms (and O₂ molecules) are aimed at a cold (6-25K) sample held in UHV chamber. The products are probed using Thermally Programmed Desorption or Reflexion Absorption Infrared Spectroscopy.

We have varied the following parameters:

- 1) Substrate morphology (Amorphous water ice, porous and compact, crystalline ice, amorphous silicates, graphite)
- 2) Coverage, from 0.1 to 1 ML
- 3) Substrate temperature, from 6.3 to 25 K
- 4) Dissociation rate (from 35% to 80 %)

From all this set of experimental parameters, we have found that the O+O reaction and the O+O₂ reaction are limited by diffusion of O atoms on the substrate. We derive the diffusion temperature law and observe, like in quantum physics handbooks, the dramatic transition from quantum to classical diffusion. Despite of the high mass of O, quantum tunneling is efficient even at 6K. As a consequence, the solid-state astrochemistry of cold regions should be reconsidered and should include larger organic molecules than previously expected.

The role of the substrate in composition (water ice, silicate or graphite) and morphology (crystalline or amorphous) also reveals some unexpected results.

Competing Mechanisms of Catalytic H₂ Formation and Dissociation on an Ultrasmall Silicate Nanocluster Dust Precursor

T02 Astronomical Frontiers for Surface Science

#ATS-1-Or-5

B. Kerkeni ¹, S. Bromley ².

¹Laboratoire Physique de la Matière Condensée (LPMC), Faculté des Sciences de Tunis, Campus Universitaire - Tunis (Tunisia), ²Departament de Química Física i Institut de Química Teòrica i Computacional (IQTCUB) Universitat de Barcelona - Barcelona (Spain).

Silicate dust grains adsorb hydrogen atoms and are thought to be essential in catalysing the formation of H₂ (Gould & Salpeter 1963; Kemper et al. 2004; Molster & Kemper 2005); the most abundant molecule in the interstellar medium (ISM). It has been estimated that up to 10 per cent of the mass of interstellar silicates may be in < 1.5 nm sized particles (Draine & Li 2001), these are fundamental intermediates in the formation of silicate dust grains in stellar outflows, and are likely to be ubiquitous in the ISM. In order to investigate the possibility of H₂ catalytic formation and dissociation on such nanosilicates we have conducted *ab initio* quantum chemical calculations to study hydrogen interactions with a stable nanosized silicate dust precursor (see Fig. 1). Specifically, we consider a 1.2 nm diameter nanosilicate composed of 21 atoms having the stoichiometry of forsterite, (MgO)₆(SiO₂)₃.

Due to its small size and high percentage of surface atoms our ultrasmall particle inherently does not possess the bulk crystalline structure and offers a number of hydrogen chemisorption and physisorption sites, presumably similar to those that larger amorphous silicates would offer. The best fit by (Katz et al. 1999) to experimental temperature programmed desorption curves for H₂ formation on polycrystalline olivine involved three parameters resulting from solving the rate equations: the barrier for atomic desorption (E_1) is approximately half of our smallest value ($E_1=724$ K), which corresponds to a H atom physisorbed over the centre of a

(MgOSiOMgO) ring. The experimental value is also a third of that reported on a crystalline forsterite surface (010) (Goumans et al. 2009).

We find a variety of reaction paths for the catalysis of H₂ formation all starting from mechanisms involving a double chemisorption of gas phase H atoms. One striking finding is a H₂ formation route with a barrier of 1515 K and an exothermicity of -7102 K which is energetically more favourable than that predicted previously on a bulk forsterite (010) surface (Goumans et al. 2009). We also find that our nanoparticle allows for many other exothermic H₂ formation routes and also a number of pathways for H₂ catalytic dissociation.

Hydrogen atom diffusion on amorphous solid water

T02 Astronomical Frontiers for Surface Science

#ATS-2-Or-1

G. Nyman, B. Senevirathne, S. Andersson.

University of Gothenburg - Gothenburg (Sweden).

H₂ is the most abundant molecule in interstellar space. Its formation in gas phase is too slow to explain its abundance. It is believed that formation on grain surfaces is the dominant route. Such surfaces are often covered with a mantle of water ice. If hydrogen atom diffusion is fast on such surfaces this could lead to adsorbed hydrogen atoms moving around to find each other to form hydrogen molecules, which may then desorb from the surface. Experiments have been carried out to investigate how fast hydrogen atom diffusion is on amorphous solid water with apparently conflicting results [1-4]. A recent experiment by N. Watanabe and coworkers [5] sheds light on this and provides an explanation that hinges on the binding energies of the adsorption sites. Here we investigate theoretically the hydrogen atoms diffusion. We are able to verify the interpretation of Watanabe. We calculate barrier heights, see Fig. 1., and rate constants, using harmonic quantum transition state theory to treat tunneling, see Fig. 2, for hopping between local minima on the surface of both crystalline and amorphous ice. We also calculate the diffusion rate constants for hydrogen atom motion on the surfaces, which will be discussed.

“Paris” meteorite is a fragment from a primitive planetesimal, asteroid or comet. A piece of this meteorite is provided by the Museum National d'Histoire Naturelle in Paris and classified as a carbonaceous chondrite CM type belonging to the undifferentiated family ^[1, 2]. This kind of meteorites keeps the memory of their primary history and contains carbonaceous matter which permits to understand the prebiotic chemistry.

In this paper we present a new analysis approach combining multi complementary techniques elemental and structural ones. This study is performed on a 500*500 μm^2 of the Paris meteorite using mass spectrometry ToF-SIMS coupled to imaging, micro Infra Red, micro Raman and Ion Beam Analysis (Particle Induced X-ray Emission “PIXE”, micro PIXE, Rutherford Backscattering “RBS”). The ToF-SIMS analyzes are performed using bismuth (Bi^+ , Bi_3^+ at 25 keV, 1.3 pA) and argon Ar_{1000} (10keV) beams delivered by an ION-TOFV of the Lebanese Atomic Energy Commission (CNRSL-LAEC). PIXE and RBS are performed using a 3 MeV proton beam delivered by a 1.7 MV tandem accelerator of LAEC while the μ -PIXE (3MeV proton) experiments are performed at the AGLAE (Accélérateur Grand Louvre d'Analyse Elementaire). The micro IR Spectra (1.5-15 μm) are registered at the Soleil SMIS (Spectroscopy and Microscopy in the Infrared using Synchrotron) beam line using a NicPlan microscope, coupled to a FTIR spectrometer operating in confocal reflection. Raman micro-spectroscopy uses a DXR Raman spectrometer from Thermo Fisher with a 532 nm exciting laser radiation.

In this paper, we shall discuss the results of the “Paris” fragment analysis obtained by the different complementary techniques. ToF-SIMS permits to identify and localize different elements, minerals and different types of organic compounds (CN-CNO and CxHy). An additional analysis in depth using the argon cluster is done in order to localize, in depth, the different components and especially the organic ones. While micro-IR and micro Raman permit the identification of different mineral compounds (Forsterite, enstatite, calcium sulfate and carbonate) and aromatic carbon ones. Additionally, we used the Ion Beam Analysis (PIXE and RBS) to determine the elemental composition and μ -PIXE to determine the local composition of different minerals like olivine and pyroxene crystal families.

In this presentation, we shall discuss the “Paris” meteorite results obtained with traditional astrophysical methods (μ -IR, μ -Raman) with an emphasis on the ToF-SIMS measurements completed by the IBA results. We conclude the presentation by the advantages and the limitations of these methods.

Vacuum UV photodesorption of molecular ices is believed to be a major non-thermal process that can explain the presence of gas in various cold interstellar environments (edge of molecular clouds, dense clouds, star-forming regions, protoplanetary disks etc..). Quantitative first estimates of these photodesorption yields for some major interstellar components could be derived in recent years using broadband lamps, but the underlying mechanisms responsible for the photodesorption couldn't be constrained. Using the monochromatized vacuum UV output of synchrotron radiation (SOLEIL) we show how, for the first time, energy-resolved desorption spectra has revealed indirect surface mechanism, triggered by the electronic excitation of subsurface molecules, and strongly influenced by the intermolecular interactions in the ice. Typical examples will be presented considering pure and mixed ices samples. Desorption induced after photodissociation and open remaining questions will be also discussed.

TRANSFORMING CARBON ONIONS INTO NANODIAMOND: A NEW PATHWAY WITH ASTROPHYSICAL IMPLICATIONS

T02 Astronomical Frontiers for Surface Science

#ATS-2-Kn-1

N. Marks ¹, M. Lattemann ¹, D.R. McKenzie ².

¹Physics & Astronomy, Curtin University - Perth (Australia), ²School of Physics, The University of Sydney - Sydney (Australia).

Nanometre-sized diamond grains are commonly found in primitive chondritic meteorites, but their origin is puzzling [1]. Using evidence from atomistic simulation we establish a mechanism by which nanodiamonds form abundantly in space in a two-stage process involving condensation of vapour to form carbon onions followed by transformation to nanodiamond in an energetic impact [2]. This non-equilibrium process is consistent with common environments in space and invokes the fewest assumptions of any proposed model. Accordingly, the model can explain nanodiamond formation in both presolar and solar environments.

The simulations employ the Environment Dependent Interaction Potential (EDIP) [3] which provides an accurate description of bond formation processes. They reveal that within an optimal energy window of around 1-2 eV/atom carbon onions are efficiently transformed into nanodiamond on the timescale of a picosecond. The process differs substantially from conventional mechanisms for accessing the diamond phase which require high temperature and/or high pressure.

Non-label Imaging of Essential Ions in Physiological and Pathological Angiogenesis in the Retina using TOF-SIMS

T03 BioInterphases

#BI/ASS/NST-P1-03

J. Kim ¹, T.G. Lee ², K.W. Kim ³, J.H. Kim ⁴.

¹Seoul National Univerisity Hospital - Seoul (Korea, republic of), ²KRISS - Daejeon (Korea, republic of), ³Seoul National University - Seoul (Korea, republic of), ⁴Seoul National University Hospital - Seoul (Korea, republic of).

Purpose: The pathological angiogenesis in the retina is the major cause of vision loss at all ages. This study was to investigate non-label essential ions imaging in the retinal tissue which would confirm the critical role of ion distribution in physiological and pathological angiogenesis in the retina

Methods: Time-of-flight secondary ion mass spectrometry (TOF-SIMS) was used to obtain non-labeled high-resolution analytic images of ion distribution in the retinas of developing mice and oxygen-induced retinopathy (OIR) mice. To determine the relation of ion distribution with retinal angiogenesis, expression of transient receptor potential (TRP) channels was evaluated by RT-PCR and Western blot analysis in retina and retinal endothelial cells. In addition the role of calcium in retinal angiogenesis was confirmed by anti-angiogenic activity of calcium chelator and calcium channel inhibitor to in vitro angiogenesis assays (migration and tube formation) and retinal neovascularization of oxygen-induced retinopathy.

Results: Marked changes in Ca²⁺ distribution, compared with other fundamental ions, such as Na⁺, K⁺, and Mg²⁺, were detected during physiological and pathological angiogenesis in the retina. Most of all, ion mapping of zinc was

successfully obtained, whose distribution was however not significantly changed in retinal angiogenesis. Interestingly, TRP channel 1, 4 and 6 are prominently expressed in the retinal endothelial cell and retina. Blockade of TRP channels in the retina by SKF 96365 and 2-APB significantly inhibited in vitro angiogenesis of migration and tube formation under sub-lethal concentration. Moreover, TRP channels inhibitors effectively suppressed retinal neovascularization in a mouse model of retinopathy of prematurity, and showed no retinal toxicity.

Conclusions: The distribution of essential ions during physiological and pathological angiogenesis in the retina could be simultaneously evaluated without labeling. Interestingly calcium but not zinc would play a critical role in retinal angiogenesis.

Bionanoparticles based chemical sensor
Man Wu and Zhongwei Niu

National Engineering Research Center of Engineering Plastics, Technical Institute of Physics and Chemistry, CAS, Beijing 100190, China Man.wu@mail.ipc.ac.cn

The classical fluorescent chemical sensor has poor water solubility and probably cytotoxic. This could limit its applications in the analysis of biological environment. To overcome this problem, bionanoparticle, especially tobacco mosaic virus (TMV), was used as carrier to prepare a well-structured and size-controlled fluorescent chemical sensor. Tobacco mosaic virus (TMV) is considered biocompatible, biodegradable, non-infectious and non-hazardous in human and mammalian. It has a hollow cylinder structure with a protein coat constructed from 2130 identical protein subunits arranged helically around a single stranded RNA. After removing the genome, TMV coat protein (CP) is capable to self-reassemble in hollow rod-like particle with desired length. Moreover, this rod-like particle has a particular structure of two open-ends. Chemical modifications can be easily realized on either the exterior or interior surface of TMV CP assembly by bioconjugation protocols. This endows assembly with the multifunctional properties by covalent attachment of functional molecule, such as sensor molecules. In other hand, pre-modified and raw CPs could also reassemble into well-structured rod-like structure with defined numbers of sensor molecules grafted either on the outer surface or inside the inner cavity. The influence of the position and ratio of grafted sensor molecule on the protein coat surface and the size of TMV CP-sensor system were systematically studied.

Figure: Schema representation of preparation of TMV CP-sensor system. A). TMV CP; B). well-structured and size-controlled assembly of TMV CP; C). sensor molecules grafted onto surface of TMV CP assembly.

Nitinol, a group of nearly equiatomic Ni-Ti alloys, have unique mechanical properties, shape memory effect, superelasticity, and its biocompatibility. A number of useful items have already been produced, such as orthodontic implants, stents orthopaedic staples and even occluding structures to heal congenital heart defects [1,2]. Medical applications are still hindered by the concern for the release of Ni into surrounding tissues. Concerns have been raised about the composition of Nitinol, specifically with the presence of nickel, a known allergenic carcinogen that exhibits one of the highest sensitivities in metallic allergen tests [3]. The patterns of Ni release from Nitinol modify depending on the type of material; NiTi alloys with low or no processing versus commercial sheets[4]. A thick TiO₂ layer is often considered as a reliable barrier against Ni release, but it was shown that Nitinol with the thickest oxide TiO₂ showed the highest Ni release [4,5].

Results of our previous research [6,7] showed that the surface of a melt spun NiTi shape memory alloy was covered with a thin oxide film. The thickness of the native oxide film was about 10 nm. After experiments on biocompatibility the oxide film thickness increased to about 20 nm. The oxide film before and after the biocompatibility tests consisted of titanium oxide and near the surface inhomogeneously distributed metallic Ni nano grains.

In order to improve the biocompatibility and to prevent Ni release, the material has been cleaned by hydrogen plasma and exposed to fully dissociated oxygen plasma. The oxides were characterized by field emission Auger electron spectroscopy (AES) depth profiling and X-ray photoelectron spectroscopy depth profiling (XPS). The AES depth profiling showed that the oxide thickness increased with increasing oxygen plasma treatment time. After treatment from 6 s, to 10 s, the oxide film was estimated from 30 nm to 500 nm. In all cases the oxide film contained TiO₂ and TiO_x, near the surface and no Ni. We have also studied the mechanical properties of oxides.

In situ X-ray fluorescence analysis of barnacle larvae and juvenile barnacles

T03 BioInterphases

#BI-2-Or-1

T. Senkbeil ¹, T. Mohamed ¹, M. Grunze ¹, A. Rosenhahn ².

¹IFG - Karlsruhe Institute of Technology - Eggenstein-Leopoldshafen (Germany), ²Analytical Chemistry - Biointerfaces, Ruhr-University Bochum - Bochum (Germany).

Biofouling is the unwanted growth of marine organisms on man-made surfaces with a high ecological and economic impact. Barnacles – as a major macro fouler – contribute substantially to this phenomenon. In order to develop anti-fouling coatings avoiding their settlement on submerged surfaces, it is important to characterize their under-water cement and the mechanism of initial attachment of the motile barnacle larvae. Besides understanding the chemistry side, it is of pivotal importance to decipher the mechanism how the adhesive is able to cure and to adhere to the surface [1]. Here, we are especially interested in the metal distribution in adhesives used by barnacles. In general, studies on underwater cement are hampered by such obstacles as insoluble and/or sticky nature of the sample and poor development of micro-analytical methods for identifying the functions of underwater attachment. While the organic components, namely proteins and polysaccharides are intensively studied [2], inorganic components are barely addressed. Minerals used for calcification are rather obvious (e.g. Ca) and analysis on further metal ions is usually focused on those present in relatively high concentrations (Zn, P) and the accumulation of toxic components in barnacles (Cu, Pb, Cd) [3,4]. While in the adhesive of mussels or algae, iron and vanadium, respectively, play important roles, the function of trace elements in the adhesive of barnacles is not yet clear. Few reports indicate that trace elements, such as iron are present in barnacles [5]. We used X-ray fluorescence at the dedicated X-ray fluorescence end-station FLUO of the synchrotron storage ring ANKA (Karlsruhe Institute of Technology, Germany) to investigate the elemental composition of marine adhesives present in barnacles. The young invertebrates, provided by our biological collaborators (Prof. Clare, Newcastle University) had been settled on an 8 µm Kapton film sealing a small plastic cup filled with artificial seawater to provide a suitable environment for the living marine organisms. Using a focused 17 keV photon beam we were able to obtain elemental distribution maps of the organisms at a spatial resolution of

approximately 15 μm . As the X-ray photons are able to penetrate the whole organism, the images correspond rather to a 2D projection of the elemental distribution, with the depth-visibility of every element depending on the corresponding X-ray fluorescence photon energy. In order to distinguish signals originating from the contact area from those coming from the organism behind, we additionally used a confocal measurement setup providing a depth resolution below 20 μm allowing us to focus on the substances in direct contact with the Kapton substrate.

Nanoparticle click functionalization by photochemical thiol-yne reaction, towards double chemoselective functionalization.

T03 BioInterphases

#BI-1-Or-1

E. Guénin ¹, E. Nehlig ¹, P. Demay-Drouard ¹, J. Hardouin ², L. Motte ².

¹Université Paris 13 - Bobigny (France), ²Université Rouen - Rouen (France).

In a decade click chemistry has emerged as the method of choice for the coupling of a large panel of molecules (fluorophores, polymers, biomolecules, ...) onto various surfaces (SAM, nanoparticles, MOF, ...). This chemical development collides with another growing field: the engineering of nanoparticle's surface functionalization¹ for the design of new system at the nanometric level. In the domain of nanobiomedicine the use of click chemistry becomes predominant among the plethora of existing functionalization methodologies due to its versatility, easiness, selectivity and of course biocompatibility. These assets represent some of the criteria proposed by Sharpless and collaborators for a reaction to be designated as "click chemistry". Among all the reactions suitable to be named as click reactions, the Huisgen 1,3 cycloaddition between an azide and an alkyne (Cu-catalysed azide-alkyne cycloaddition: CuAAC) is from far the most popular one. It has been extensively used in nanoscience and was recently thoroughly reviewed.² But a variety of other click reactions could and have been used to graft molecules onto nanoparticles: other cycloadditions, thiol-ene reaction, Michael additions, Here we want to report the use of a long known reaction recently rediscovered (essentially by polymer scientists) for the functionalization of nanoparticles. Thiol-yne reaction is a water compatible radical reaction that can be done photothermally.³ Under UV, in presence of a radical initiator two thiol functions are added successively onto an alkyne function. It doesn't require any metal catalysis and while it is described as a little bit slower than thiol-ene it remains fairly quick and more importantly completely irreversible at the difference of thiol-ene. Moreover thiol-yne reaction presents another advantage that makes it really suitable for surface chemistry: since the reaction allows two consecutive additions of thiols onto the alkyne, high surface density of the grafting could be reached quite easily.

So ongoing with our research on the development of multimodal nanoplateform with aim in biomedical and catalysis applications,⁴⁻⁵ we decided to study the use of thiol-yne reaction for the functionalization of iron oxide superparamagnetic nanoparticles. We used a nanoplateform consisting of γ -Fe₂O₃ nanoparticles coated by a bifunctional molecule from bisphosphonic acid family: (1-hydroxy-1-phosphonohept-6-ynyl)phosphonic Acid (BPheptyne). This nanoplateform so present alkyne functions on its surface on which we evaluated the photochemical coupling of various thiol molecules. We also investigated multiple click chemistry coupling onto this nanoplateform. To our knowledge this work represents the first functionalization of nanoparticles by thiol-yne reaction and the first double click process on the same nanoparticle surface.

BI/ASS/NST-P1-02

The effect of hyaluronic acid on the formation of calcium phosphate on CoCrMo alloy

T03 BioInterphases

#BI/ASS/NST-P1-02

I. Milosev ¹, J. Hmeljak ², A. Coer ².

¹Jozef Stefan Institute - Ljubljana (Slovenia), ²University of Primorska - Izola (Slovenia).

Hyaluronic acid is a component of synovial joint fluid, so the behaviour of orthopaedic alloys in its presence needs to be assessed. HA regulates many important physiological and pathophysiological reactions. It is a glycosaminoglycan (GAG) or mucopolysaccharide, a long, unbranched polysaccharide composed of repeating units of disaccharide N-acetyl-D-glucosamine and D-glucuronic acid (1) – the only non-sulfated GAG and a high molecular mass polymer in excess of 106 Da. It affects cell proliferation and migration and is responsible for the viscosity and resistance to compressive stress of synovial fluid. Electrochemical methods, X-ray photoelectron spectroscopy and scanning electron microscopy have been used to analyse the composition, thickness and morphology of any layers formed on the CoCrMo alloy. The behaviour of CoCrMo alloy has been studied in two simulated physiological solutions – NaCl and Hanks' solutions – each containing the sodium salt of hyaluronic acid. The addition of hyaluronic acid affects the electrochemical parameters of the CoCrMo alloy (2). Further, the presence of hyaluronic acid in simulated Hanks' physiological solution stimulates the formation of a calcium phosphate layer that is homogeneous even at a nano-sized level (Figure). The viability of human osteoblast-like was determined using the Alamar Blue Assay, while the osteogenic activity was evaluated by alkaline phosphatase activity. The presence of hyaluronic acid affects the alkaline phosphatase activity. The obtained results open up the possibility for tailoring the surface properties of CoCrMo alloy.

Chemical and electrical function of diamond in biointerfaces

T03 BioInterphases

#BI/ASS-1-Or-2

B. Rezek.

Institute of Physics ASCR - Prague (Czech republic).

Understanding the interaction between the biological environment (tissues, cells, proteins, electrolytes, etc.) and a solid surface is crucial for biomedical applications such as bio-sensors, bio-electronics, tissue engineering and the optimization of implant materials. Cell adhesion, proliferations, and differentiation are complex processes which strongly depend on the cell cultivation conditions including the type of substrate. Materials which are commonly employed as substrates for in vitro testing are polystyrene and glass. In this context, diamond as a technological material can provide a relatively unique combination of excellent semiconducting, mechanical, chemical as well as biological properties [1].

Here we will present the influence of micro-structuring morphology and atomic termination of diamond thin film surfaces on cell growth and assembly [2-4]. We will investigate the influence of key parameters such as the seeding concentration of cells, the type of the applied cells, the duration of cultivation, the concentration of fetal bovine serum (FBS) in the cultivation medium, the dimensions and shape of microstructures, and surface roughness. We will show that the adsorption of proteins from the FBS serum is the key factor. Atomic force microscopy (AFM) both in solution and in air is applied in order to characterize the morphology of the FBS layers adsorbed on differently terminated diamond substrates. The conformation of proteins and hereby also adhesion and growth of the cells is controlled by the diamond surface atoms, independent of substrate doping. The influence of proteins and cells on the electronic properties of diamond will be demonstrated by employing a field-effect transistor based on nanocrystalline hydrogen-terminated diamond, whose gate is exposed to a solution (SG-FET) [5-6]. These results are discussed from the point of view of fundamental physics and biology as well as the prospects in medicine.

This research was financially supported by the projects P108/12/0996 (GACR), P108/12/G108 (GACR), doctoral project 202/09/H041, and by the Fellowship J.E. Purkyne. This work occurred in frame of the LNSM infrastructure.

Comparison of thiol/NHS ester bifunctional SAMs on gold formed from symmetric and asymmetric disulfide linkers

T03 BioInterphases

#BI-1-Or-2

C. Ng ¹, B. Espiña ¹, E. Fernandes ², V. Martins ¹, D. Petrovykh ¹.

¹International Iberian Nanotechnology Laboratory - Braga (Portugal), ²IBB-Institute for Biotechnology and Bioengineering, Centre of Biological Engineering, University of Minho Campus de Gualtar - Braga (Portugal).

The aim of this work is to analyze the monolayers formed by two different common commercial thiol/NHS ester bifunctional linkers, sulfosuccinimidyl 6-(3'-[2-pyridyldithio]-propionamido)hexanoate (sulfo-LC-SPDP) and 3,3'-dithiobis(sulfosuccinimidylpropionate) (DTSSP), using X-ray photoelectron spectroscopy (XPS). We chose to compare these two molecules, because both are commonly used to link biomolecules to gold, but DTSSP is a symmetric disulfide, while sulfo-LC-SPDP is an asymmetric disulfide, so they may form bifunctional monolayers of different structures. We compared their performance in terms of the attachment chemistry on gold surfaces and the ability to present the reactive NHS ester group post attachment. We find that in most cases, sulfo-LC-SPDP forms a more uniform monolayer than does DTSSP, presumably because the short chain fragment acts as a diluent and reduces steric constraints in the growing monolayer. We observe that sulfo-LC-SPDP produces a monolayer with single-component thiol-gold attachment chemistry, while multiple thiol-gold chemistries are typically present in DTSSP monolayers.

Unexpectedly, in contrast to the common wisdom that NHS esters are easily degraded by reaction with water,[1] we find that during deposition from aqueous solutions, the immobilization time has little effect on the integrity of NHS ester group on the resulting surfaces. However, the NHS ester groups do degrade significantly when exposed to the atmosphere, suggesting that a different degradation mechanism may operate in air and in solution. We quantified the amount of NHS

ester groups available for amine coupling by using a fluorine-labeled amine as a model molecule that produces a distinct XPS signal. Using this method, we compared the efficiency of amine coupling to DTSSP and sulfo-LC-SPDP bifunctional SAMs under different conditions. Without exposure to air, we find that between 50% and 100% of the linkers retain the NHS ester functional group that is available for coupling.

While many different protocols are used for surface attachment of DTSSP and SPDP, there is no previous systematic investigation of how different factors (such as pH, choice of buffer, ionic strength, and reaction time) in the attachment procedure affect the quality of the monolayer. Despite the presence of the charged sulfonate group in both DTSSP and SPDP linkers, we found that in the range of pH 5.7-8.0, the choice of buffer and ionic strength did not have a significant effect on the properties of the bifunctional monolayer.

Microplasma processes carried out in homogeneous alkaline electrolytes allow synthesizing bioactive coatings with high Ca/P ratio and satisfactory adhesion on the surface of implants made of valve metals [1]. The paper discusses the effects of the two main factors (electrical mode and electrolyte composition) on synthesis of bioactive calcium phosphate (Ca–P) coatings on nano-structured titanium.

Firstly, the variation of the electrical mode parameters results in a change of the temperature conditions of coating synthesis, which in turn might cause the variability of both coating composition and morphology. It was shown that optimal biocompatible coatings (with thickness 40–45 μm and roughness 4–5 μm) with satisfactory adhesion can be synthesized via successive implementation of the anodic pulse mode with a no-current pause followed by the alternative current mode with a no-current pause.

Secondly, the increase of component concentrations of an electrolyte leads to the formation of more uniform coatings. Additionally, a specific technique allowing to

synthesize calcium phosphate coatings containing prescribed quantity of magnesium was developed.

Furthermore, with the aim of increase of hydroxyapatite content, the possibilities of additional chemical treatment with buffer solutions of calcium phosphate (Ca–P) containing coatings were studied

TOF-SIMS Evaluation of Silica/ γ -PGA Hybrids for Bone Regeneration

T03 BioInterphases

#BI/NST-1-Or-1

D. Wang¹, J. Nakamura², G. Poologasundarampillai¹, E.M. Valliant¹, J.R. Jones¹, D.S. Mcphail¹.

¹Imperial College London - London (United kingdom), ²Nagoya Institute of Technology - Nagoya (Japan).

Hybrids have the potential to have tailored mechanical properties and degradation rates when they are used as scaffolds for tissue engineering. The aim was to apply ToF-SIMS to determine the distribution of critical elements (e.g. silicon and calcium) in sol-gel silica/poly- γ -glutamic acid (γ -PGA) hybrids. Two hybrid systems were studied: i) silica/ γ -PGA where the silica precursor was TEOS with GPTMS employed as a coupling agent; ii) silica/ γ -PGA where the silica source was GPTMS. In i) the use of the free acid form of γ -PGA with CaCl_2 as the calcium source was compared to use of the calcium salt form of γ -PGA. In ii) dimethyl carbonate (DMC) was used to improve the covalent coupling between GPTMS and γ -PGA and its role in the process was examined here.

The data showed that silicon, the network former of the inorganic component in the hybrids, and calcium were unevenly distributed in the silica/ γ -PGA (free acid form) hybrids with CaCl_2 as the calcium source (Fig. 1a and 2a). A homogenous distribution was obtained when the calcium salt form of the γ -PGA was used (Fig. 1b and 2b). When DMC was added after the formation of the sol, high concentration Si regions were observed while there was no calcium signal in the same areas (Fig. 1c and 2c), implying that silicon-rich particles formed. In contrast, when DMC was added at the start of the sol-gel process, both silicon and calcium were distributed evenly (Fig. 1d and 2d).

The results revealed that the calcium salt form of γ -PGA was promising for calcium incorporation. If DMC is used in hybrid synthesis it should be added at the start of the process to maintain homogeneity. ToF-SIMS can compare inorganic/organic hybrids and can obtain the information throughout the material.

Fig. 1 (left) and 2 (right). Distribution of silicon (Fig. 1) and calcium (Fig. 2) in (a) the free acid form of γ -PGA and CaCl_2 as the calcium source; (b-d) the calcium salt form of γ -PGA (b) without DMC, (c) with the addition of DMC after the sol was produced and (d) with the addition of DMC at the start of the sol-gel process.

BI/ASS/NST-P1-04

Characterization of interfaces between polypeptide and DNA layers using X-ray photoelectron spectroscopy

T03 BioInterphases

#BI/ASS/NST-P1-04

S. Reiff, S. Ptasinska.

University of Notre Dame - Notre Dame (United states).

The interaction between proteins and DNA is critical for cells, with DNA binding proteins fulfilling a number of functions including packing DNA into the chromatin structure, assisting with transcription, and the cleaving of DNA molecules. Understanding the interfaces between DNA and protein molecules is of utmost importance for elucidating how these biological processes occur. Of special interest is the role of water in facilitating the interfacial bonding between the two molecules [1,2]. In this study the interface between layers of polypeptides, short chains of amino acids linked by peptide bonds, and DNA were examined using X-ray photoelectron spectroscopy (XPS).

XPS is a powerful surface science technique which can be used to qualitatively and quantitatively characterize the composition of a surface. High resolution spectra of electron core-levels can be obtained to assess chemical bonds present within a sample.

Here, we build upon our previous research of examining a poly-peptide, poly-L-arginine, by constructing bilayer samples of polypeptides and DNA. The bilayer samples were deposited using a layer by layer (LBL) technique, which uses the electrostatic attraction between the positively charged polypeptide and the negatively charged DNA molecule to create layers. We present a study of a number of different peptide-DNA bilayer films (1, 2, 3, 5, and 10 layers) fabricated using either poly-L-arginine or poly-L-lysine and DNA. In addition, single layers of just poly-peptides were measured to examine the interface between the poly-peptide and the silicon substrate.

BI-2-Or-2

Synchrotron radiation as a probe for structural, elemental and chemical properties of melanosomes

T03 BioInterphases

#BI-2-Or-2

T. Gorniak ¹, T. Haraszti ², M. Anderson ³, M. Grunze ², A. Rosenhahn ¹.

¹KIT, Institute for Functional Interfaces - Eggenstein-Leopoldshafen (Germany), ²Applied Physical Chemistry, Ruprecht-Karls-University Heidelberg - Heidelberg (Germany), ³Department of Molecular Physiology and Biophysics, The University of Iowa - Iowa City (United states).

It is of tremendous scientific interest whether the ultrastructure of melanosomes [1], organelles found in the iris cells, is connected with the development of glaucoma, a disease in which the optic nerve suffers damage. The name of these intracellular, membrane bound organelles is derived from the chemical substance they produce and store: melanin [2]. On the one hand, melanosomes are beneficial as they provide photoprotection to the human body and are responsible for the colour of hair, skin and iris. On the other hand a disorder of their functionality is potentially harmful, resulting in an elevated (10 – 50 fold) risk of skin cancer or, in the eye, in the development of glaucoma. The detailed processes and mechanisms of failure are still unknown. However, it is believed that toxic chemical components and proteins, which are part of the organelle's synthesis of melanin [3,4] leach into the surrounding tissue and cause damage to vital cells, when the function of metabolization or containment of the cytotoxic substances is disturbed. We aim to determine if the granularity of the melanosome's internal ultrastructure develops differently for healthy mice and those with a genetic disposition to develop glaucoma. A structural change of the organelles could point towards a disturbed encapsulation of cytotoxic substances and thus play a key role in the development of diseases of pigmented tissue. Since melanin is an exceptionally dense material – making it challenging to probe the melanosomes' ultrastructure with methods like transmission electron microscopy (TEM) – the unperturbed morphology of these organelles is still unknown. In our approach, which relies on hard X-rays with a high penetration depth, melanosomes are characterized by small-angle X-ray scattering (SAXS) and these diffraction fingerprints are correlated with the genetic background to identify possible differences. We supplement the results from these experiments with data from complementary

techniques – namely soft X-ray tomography and NEXAFS spectroscopy [5] – in order to obtain a broader picture allowing for conclusions relevant for an improved treatment of glaucoma

Functionalized organic monolayers covalently anchored to the silicon surface are promising systems for the development of biosensors and microarrays. They can be modified in a controllable way for covalently attaching molecular probes at the surfaces, allowing for specific interactions with biological targets. Among the various strategies for biofunctionalization, the copper-catalyzed azide-alkyne cycloaddition reaction, namely “click” reaction, is widely used due to its specificity and versatility.¹

We have developed a new carbohydrate sensor based on silicon using “click chemistry” for the study of glycans/glycan binding proteins such as lectins.² In this talk, we will present the multi-step modification of crystalline silicon surfaces by azido moieties containing polyoxoethylene groups aimed at avoiding the nonspecific adsorption of proteins. The click reaction was done with a propargyl-terminated mannose or lactose. Each step was carefully analyzed by AFM imaging, XPS and quantitative IR-ATR, allowing us to determine the surface concentration of the immobilized molecules. The specificity of glycans/lectins recognition was demonstrated. The affinity constant for mannose-lectin from lens interaction has been measured, suggesting a multivalency of the binding. The influence of the density of grafted mannoses on the efficiency of the binding will be presented.

Optical resonators are emerging in the field of biosensors as one of the sensitive technology that does not require amplification or labeling of the analyte [1]. In particular whispering gallery mode (WGM) resonators are receiving a growing interest as optical structures suitable for the realization of miniaturized sensors with high sensitivity [2]. When properly excited, WGM microresonators are able to strongly confine light, through a total internal reflection, along the equatorial plane of the microresonator. The corresponding supported resonances show low losses and a quality factor Q that depends both from the geometrical shape of resonators and from the materials involved. In this work we present two different microresonators: a spherical microcavity with a Q factor value of 10^7 , and a planar wedge microdisk [3] with a Q factor value of 10^4 . Any minimum change in the surface of the microresonator or in the physical and optical properties of the surrounding environment reduces the Q factor value and modifies the spectral position of the resonances. From a direct measurement of this resonance shift, one can infer the amount of analyte that produces this variation. A crucial step for producing reliable biosensors is their surface functionalization, preserving the starting Q factor values of the resonators. In this work we report a functionalization process based on the use of DNA aptamers, short oligonucleotide sequences that bind to non-nucleic acid targets with high affinity and specificity. Different thrombin and vascular endothelial growth factor (VEGF) specific aptamers are utilized: thrombin belongs to the coagulation cascade and it is involved in many pathological diseases, like atherosclerosis and thromboembolic diseases. VEGF is an important regulator of angiogenesis and it promotes the migration and proliferation of endothelial cells and the formation of new

blood vessels from pre-existing capillaries. The functionalization procedure adopted, preserved the quality factors of both utilized microresonators allowing the target protein recognition in the nM range. Moreover, when using the spherical microcavity, the protein detection is successfully performed in 10% diluted non-filtered human serum sample [4]. In addition, both aptasensors were chemically regenerated by NaOH treatment and then used again. All the regenerated spherical sensors maintained more than 95% of the WGM shift. We have demonstrated that WGM techniques feature low cost, simple detection procedure, rapid response time and high specificity in complex samples.

Biofilms are assemblages of bacteria attached to a surface and enclosed in an adhesive matrix of extracellular polymeric substances (EPS) [1]. Biofilms form on most surfaces, e.g., medical devices such as catheters and implants, but also in industrial environments such as food processing plants or in cooling systems. Thus, they are of major concern in medicine and in many commercial enterprises. Biofilm formation results from a sequence of events: first microbial adherence, then microcolony formation and proliferation, and finally matrix production and biofilm maturation [2]. However the nature of this serial transition is not fully understood. As the morphology and elemental composition of bacterial aggregates on interfaces is of great interest in this topic, synchrotron radiation-based hard X-ray microscopy techniques as a non-destructive approach were applied for investigating biofilms. Microtomography experiments with minimum sample preparation using full-field transmission X-ray microscopy (TXM) [3] with Zernike phase contrast were performed on different biofilm-habitat interfaces. The microbial morphology and distribution can be visualized in three dimensions with tens of nanometers resolution (compare figure 1). Furthermore, we demonstrate the possibility to quantitatively study the elemental content of individual bacteria with sub-cellular spatial resolution by X-ray fluorescence analysis [4]. By correlative measurements at different stages of the biofilm formation on diverse

surfaces, we aim to gain a deeper understanding of the mechanisms involved in this process.

The understanding of protein adsorption mechanisms on surfaces is of major interest in both fundamental research and applications such as implants, biosensors and dialysis membranes. Among the applications, development of nanomaterials has created a novel biointerphase with its own specificities, together with enlarged possibilities for experimental studies. To study protein interactions with a mineral surface, we chose silica NP and a model well-known blood protein, pig hemoglobin (Hb). Protein adsorption has been characterized in connection with protein structure and function changes. Indeed protein activity is sensitive to adsorption on mineral surfaces (1) and changes observed on NP can be related both to a surface effect, which is similar to what is observed on plane surfaces, and to a curvature or geometry effect that is specific to NP.

Adsorption of Hb on silica NP has been investigated at the chemical, structural and functional levels by UV-visible spectroscopy, circular dichroism and oxygen binding measurements. Hb adsorption is pH dependent and shifts from total adsorption at pH 6 to no adsorption at pH 9. Circular dichroism spectra of adsorbed Hb reveal a partial loss of helix secondary structure. Oxygen affinity of adsorbed Hb increases from 17.1 mmHg to 8.7 mmHg at pH 6 whereas oxygen binding cooperativity decreases from 2.8 to 1.6 (Fig 1A). Binding of inositol hexaphosphate effector (IHP) decreases the oxygen affinity of both free and adsorbed Hb, which suggests that Hb keeps its tetrameric form upon adsorption (Fig 1B). Moreover Hb desorption is achieved in soft

conditions at pH 9 and both Hb structure and activity are recovered after desorption. Thus adsorption of hemoglobin on silica NP represents a new approach to increase the oxygen affinity of the protein in a reversible manner.

One key point for applications in the fields of biosensor and biomaterial researches is the preservation or not of the bioactivity of proteins once immobilised on a surface. Using time-of-flight secondary ion mass spectrometry (ToF-SIMS) and principal component analysis (PCA), in combination with a series of complementary techniques (PM-IRRAS, QCM-D and XPS), a methodology was established to explore protein adsorption and orientation on surfaces. Our first results demonstrated the effect of the surface chemistry on the adsorption of β -Lactoglobulin. A model of the protein orientation on gold substrates modified by self-assembled monolayers (SAMs) with different endgroups (-CH₃ and -NH₂) was proposed [1]. In the present study, a similar procedure is used to investigate a more realistic case involving an antibody / antigen couple used in medical tests. For this purpose, Anti-GDH antibodies were adsorbed on bare gold, on -CH₃ and on -COOH terminated SAMs and, finally, they were grafted to the -COOH terminated SAMs activated by NHS-EDC. ToF-SIMS measurements were carried out and PCA performed on the protein peaks of all the samples. PCA couldn't separate samples adsorbed on the bare gold or the -CH₃ terminated SAMs, in contrast, it showed a clear separation between the mass spectra of the Anti-GDH either adsorbed or grafted on -COOH terminated SAMs and also a separation of those from the two first test surfaces. This could indicate that two different preferential orientations are obtained for the -COOH terminated SAMs and a preferential orientation or a random adsorption for bare gold or the -CH₃ terminated SAMs. In addition, the PCA results provide detailed information on the amino-acids that are preferentially displayed at the extreme surface of the samples. Further experiments were carried out to test the biorecognition of the corresponding antigen by the antibodies on the different surfaces. No clear recognition was detected for antibodies adsorbed on bare gold or -CH₃ SAMs when PM-IRRAS and QCM-D data indicate that more antigens are

recognized in the case of the adsorbed antibody than the grafted one on -COOH SAMs. These results suggest that the antibody is in a more favourable orientation for bio-recognition for Anti-GDH simply adsorbed on -COOH terminated surfaces.

The control of biomolecules adsorption (such as proteins) and other microorganisms is of high interest for various fields of biotechnology, such as bioanalytics, cell biology, tissue engineering and biomaterials. An efficient method to control adsorption includes the use of well-defined oligo(ethylene glycol)-terminated self-assembled monolayer (SAM). However, multiple processing steps are often required to prepare SAM onto substrate.

Based on the thiolene reaction process, we developed a two-step method to prepare self-assembled monolayer [1]. This surface modification can either be performed on glass, metal oxides or alloys to control bioadhesion on surfaces starting from commercially available building blocks. By taking advantage of the photoinitiation step, adhesive and anti-adhesive-patterned systems are easily designed.

Such well-controlled grafting strategy has been applied to different metal oxides: from silicon substrates for the methodology set-up to model metal oxides formed on biocompatible metals and alloys. The obtained films are robust; the process is low-cost, simple, and efficient.

Surface characterization as X-ray Photoelectron Spectroscopy (XPS), Time of Flight Secondary Ion Mass Spectrometry (ToF-SIMS) and Infra-Red Surface Spectroscopy

(ATR-IRFT) were used to check the surface composition at different steps of the reactions: the thiolene reaction, the PEG grafting, as well as after interaction with protein solutions: albumin for preliminary tests, and fibronectin, an adhesive protein present in the extra-cellular matrix.

In addition to quantitative information, obtained by XPS, about the oxide composition and thickness at the different steps, and qualitative information, obtained by XPS and ToF-SIMS, surface patterning could be emphasized with ToF-SIMS chemical surface imaging.

The as-proposed grafting method conditions (e.g. poly(ethylene glycol)chain length, chain end functionality, exposure time, or reactive dilution) had been implemented to bind other biomolecules on these chemically patterned surfaces. In that way, peptide sequence or species cell lines were also used to exhibit the site-specific located reaction.

Nanotechnology has opened attractive broad application opportunities in various industrial fields from electronics to medical devices. In particular, several nano-sized tools are already employed for diagnostic and therapeutic purpose in medicine (nanomedicine) [1,2,3]. For instance, gold nanoparticles have become popular substrates for a broad range of biomedical applications as well as for chemical, biological and clinical diagnostics [4]. Furthermore magnetic NPs such as ferrites (Fe₃O₄) and cobalt ferrites (CoFe₂O₄), are also used in biomedicine as drug delivery carriers, hyperthermia treatments in cancer therapy and magnetic resonance imaging (MRI) contrast enhancement [5, 6]. However, the increasing use of nanomaterials and in particular nanoparticles in nanomedicine has raised the growing concern about the health hazards related to their possible toxic effects, not only in the human body, but also in the environment. The lacking information about the NPs impact on environment and on human health, as well as data on risk assessment, requires development of a reliable methodology for control and prediction. Among the promising detection methods, synchrotron radiation X-ray Fluorescence (SRXRF) has already demonstrated its potential in bio-medical research for exploring e.g. neurodegenerative disorders [6, 7]. The application of SRXRF with soft X-rays [7] has also provided access to light elements, which are major constituents of the living matter. In this work, we report examples of SRXRF investigations of the distribution and chemistry of nanoparticles NPs in different cell lines. In particular, U87 astrocytoma glioblastoma and Balb 3T3 mouse fibroblast cells have been exposed to metal oxides (ferrites, ZnO, CuO and cobalt ferrites) and SiO₂ NPs at different concentrations for 24h. The SRXRF maps show that NPs are accumulating in the cell cytosol near the perinuclear region. However, in the case of

cobalt ferrites, micro-spot spectra indicate that, for concentrations higher than 500 μM , Co and Fe are present also in the nuclear region of the cell, with sensible accumulation of Co[9]. A co-localization of P, Ca and Fe at high concentration has also been observed indicating intracellular sequestration mechanisms as a response or in an attempt to reduce the nanoparticles toxic effects.

Surface immobilised biomolecules quantification and prevention of non-specific biomolecules binding

T03 BioInterphases

#BI-1-Or-7

S. Ray, A. Bella, F. Green, A. Shard.

National Physical Laboratory - London (United kingdom).

In Bioanalytical devices, it is frequently required to control the specific attachment of target biomolecules or protein and to prevent non-specific protein adsorption on surfaces for bio-sensing and diagnostics. To overcome these major challenges, an efficient method for robust chemical modification was developed to achieve excellent specific bio-recognition and stability in complex bio-media suppressing non-specific biomolecule adsorption.

In this work, both pure and mixed PEG-Thiol monolayer with carboxylic acid (-COOH) and hydroxyl (-OH) terminal groups on gold coated silicon wafers were prepared. Surfaces were characterized by using spectroscopic ellipsometry, atomic force microscopy and x-ray photoelectron spectroscopy. By varying the surface coverage of mixed PEG thiols and activating available -COOH sites for amide bond formation using uronium/aminium (HBTU) coupling, we have successfully controlled the amount of attached synthetic peptides. Fig.1 shows the variation of atomic percentage of nitrogen by varying the surface fraction of PEG end groups, with higher nitrogen representing higher attachment of peptide. Without the amide coupling activation process, non-specific binding of peptides and proteins were prevented. This method for surfaces modification and controlled attachment of surface bound biomolecules could be used in ultrasensitive bio-sensing and diagnostics in the future.

Figure 1. Atomic percentage variation of nitrogen arising from adsorbed synthetic peptides by varying the surface fraction of carboxylic acid terminated PEG-Thiols. The other fraction of the surface is hydroxyl terminated PEG-thiols.

The search for biocompatible materials has become one of the key issues in modern medicine. In addition to biocompatibility aspects, the development of artificial joints requires optimization of lubrication under shear forces and pressure. To copy the principles of lubrication observed in natural joints it is important to understand the underlying mechanisms. In natural joints, the opposing bones are coated by cartilage and separated by the synovial fluid which mainly consists of hyaluronic acid (HA) - a high molecular weight, linear polysaccharide. The cartilage, in turn, is covered with phospholipid layers, and it is claimed that in particular the combination of phospholipids and HA plays an important role in lubrication.

In order to elucidate the underlying mechanisms on a molecular scale, we investigated the impact of HA on the structure and stability of supported phospholipid membranes as a function of temperature, pressure and shear by neutron reflectivity and *in situ* infrared spectroscopy. In contact with pure D₂O and below the main phase transition temperature of the system, T_M, a lamellar spacing of 65 Å is observed for the membranes. When temperature is raised above T_M, all lipid bilayers detach except for the innermost lipid lamella directly adsorbed to the silicon support. In contact with a solution of HA in D₂O the oligolamellar lipid system starts swelling. In addition, it is stabilized so that heating above T_M does not result in detachment of the lipid membranes into the liquid phase. The interfacial lipid coating adopts a swollen new lamellar state with an increase in d-spacing by 380% to 247 Å measured after 43 days of incubation with the model synovial fluid. Neutron reflectivity data point to the formation of an interfacial hydrogel layer from phospholipids and interlinked high molecular weight HA, which might exhibit important joint lubrication and protective wear functionalities. Experiments on the shear stability of phospholipid membranes are ongoing.

Spatially and temporally coordinated processes of cells at molecular to cellular scales

T03 BioInterphases

#BI-1-In-1

J. Spatz.

Max Planck Institut for Intelligent Systems & University of Heidelberg - Stuttgart (Germany).

Our approach to engineer cellular environments is based on self-organizing spatial positioning of single signaling molecules attached to synthetic extracellular matrices, which offers the highest spatial resolution with respect to the position of single signaling molecules. This approach allows tuning tissue with respect to its most relevant properties, i.e., viscoelasticity, peptide composition, nanotopography and spatial nanopatterning of signaling molecule. Such materials are defined as “nano-digital materials” since they enable the counting of individual signaling molecules, separated by a biologically inert background. Within these materials, the regulation of cellular responses is based on a biologically inert background which does not initiate any cell activation, which is then patterned with specific signaling molecules such as peptide ligands in well defined nanoscopic geometries. This approach is very powerful, since it enables the testing of cellular responses to individual, specific signaling molecules and their spatial ordering. Detailed consideration is also given to the fact that protein clusters such as those found at focal adhesion sites represent, to a large extent, hierarchically-organized cooperativity among various proteins. We found that integrin cluster have a functional packing density which is defined by an integrin-integrin spacing of approximately 68 nanometers. Such critical spacing values vary as matter of transmembrane receptor choice of interest. We have also developed methods which allows the light initiated activation of adhesion processes by switching the chemical composition of the extracellular matrix. This enabled us to identify the frequency of leader cell formation in collective cell migration as a matter of initial cell cluster pattern size and geometry. Moreover, “nano-digital supports” such as those described herein are clearly capable of involvement in such dynamic cellular processes as protein ordering at the cell’s periphery which in turn leads to programming cell responses.

Investigating Charge Gradients on Polyelectrolyte brushes

T03 BioInterphases

#BI-2-Or-5

Z. Yenice ¹, R. Köhler ², J. Genzer ³, R. Von Klitzing ¹.

¹Stranski Laboratory, Institute of Chemistry - Berlin (Germany), ²Stranski Laboratory, Institute of Chemistry & Institute Soft Matter and Functional Materials, Helmholtz-Center Berlin for Materials and Energy - Berlin (Germany), ³Department of Chemical & Biomolecular Engineering, NCSU - Raleigh (United states).

The modification of surfaces with thin polymer films like polymer brushes is widely used to tailor surface properties such as wettability, biocompatibility, corrosion resistance and friction. With further modifications, materials that express specific bio-responsive properties, including antibacterial (biocide) properties can be made. Also nanoparticles can be immobilized on these systems. In this study poly(2-(dimethylamino) ethyl methacrylate) (PDMAEMA), which is a weak polyelectrolyte with pH dependent properties is used and charge gradients were made along the surface-grafted brush resulting on a change in the water contact angle degree. These charges also act as biocides. More investigation was done regarding the charge distribution. Neutron reflectivity is used to detect the change of density and thickness after quaternizing the brush gradually and to see the charge distribution along the brush in both lateral and perpendicular directions. A schematic illustration of the quaternization, of surface-grafted polyelectrolyte brushes is shown below in Figure 1.

BI/NST-1-Or-2

Patterned polymer brushes as a matrix for controlled immobilization of gold nanoparticles

T03 BioInterphases

#BI/NST-1-Or-2

S. Christau, R. Von Klitzing.

Stranski-Laboratorium für Physikalische und Theoretische Chemie, Institute for Chemistry, Technical University Berlin - Berlin (Germany).

In the last years, the modification of surfaces by depositing polymer brushes has become of big interest for nano- and biotechnology applications. The possibility of suppressing or controlling protein or cell adhesion makes them an important tool for the use of otherwise incompatible solids in biological applications [1].

Polymer brushes represent a class of coatings where the polymer chains are tethered to the substrate chemically [2]. Brush systems are promising candidates for the ordering of particles due to their response to external stimuli like pH, temperature, ionic strength or solvent [1]. By adsorbing gold nanoparticles within the polymer brushes, interesting optical properties are induced into the brush system which can be useful for sensor applications. By forming patterns of polymer brushes, the brush system can serve as a matrix for the ordering of immobilized AuNPs (*fig. 1*).

Polymer brushes of (N,N-dimethylamino)ethyl methacrylate (DMAEMA) and N-isopropylacrylamide (NIPAM) are grown from a 2-bromo-2-methyl-(3-(triethoxysilyl)propyl)propanamide (BTPAm)-covered silicon surface via surface-initiated atom transfer radical polymerization (SI-ATRP). For the synthesis of both initiator-covered self-assembled monolayer (SAM) and polymer brushes a new type of sealed reactor is used that provides a constant nitrogen flux. The grafted chains are investigated using ellipsometry, atomic force microscopy (AFM), X-ray reflectometry and scanning electron microscopy (SEM).

To study the influence of the polymer's chemical composition and the brush thickness on the particle distribution, patterning of polymer brushes is carried out using UV lithography. Different approaches of patterning are addressed.

Mechanical properties of poly-L-lysine (PLL) / hyaluronic acid (HA) multilayer films measured by AFM nano-indentation

T03 BioInterphases

#BI/NST-1-Or-3

J. Hellwig, C. Üzümler, R. Von Klitzing.

Stranski-Laboratorium, Department of Chemistry, TU Berlin - Berlin (Germany).

In recent years smart biomaterials have become a highly developing field of interest for biomedical applications, e.g. drug delivery(1). The layer-by-layer (LbL) technique (2) gives the opportunity to build up self assembled polyelectrolyte multilayer films (PEM) with defined architecture, physical and chemical properties. PEM made of poly-L-lysine (PLL) and hyaluronic acid (HA) were produced by using the LbL technique. Potential applications of these PEMs require controlling of the adhesion behaviour by tuning their elastic/viscoelastic properties.

In this study mechanical properties of LbL coated poly(L-lysine)/hyaluronan PLL/HA films were studied by scanning- and colloidal-probe atomic force microscopy as a function of indentation velocity, number of polymer deposition steps and temperature. Film growth was investigated by two independent AFM methods: scratch-and-scan and full-indentation(3). Film thickness increases linearly with polymer deposition steps (Image 1). The Young's modulus ranges between 15 and 40 kPa and does not depend on the film thickness (Image 2). Stress relaxation and creep compliance measurements indicate a viscoelastic film behaviour with multiple relaxation mechanisms.

The investigation of biological membrane processes plays an essential role in order to understand cell-cell interaction since cells communicate with their environment via various transport processes through the cell membrane. To mimic these biomembranes, suspended metal membranes with an array of nanoholes, so called nanopores, can be used. These can be optically monitored and by controlling the pore size, single molecules can be flown through the pore in one-by-one manner, and then be captured at the most sensitive position of the sensor where electric field is enhanced [1]. Fabrication of such nanopores are normally expensive and time consuming, as it generally involves the use of focused ion beam (FIB), electron beam (EB), or multiple etching steps. Therefore, we introduce a novel fabrication approach of plasmonic nanopores combining colloidal lithography and a carbon film transfer method for transmission electron microscopy (TEM).

A short-range-ordered nanohole array is fabricated on a solid substrate by colloidal lithography [2]. On top of this colloidal mask a thin film of aluminum (Al), which will serve as sacrificial layer and carbon are deposited. After the mask particles have been removed, the carbon film is separated from the substrate by wet-etching the sacrificial Al layer. The suspended carbon film with the nanopore array can then be re-deposited on a supporting TEM mesh. Through additional sputtering of dielectric materials and gold (Au) layers, the hole size can be further reduced. Finally, the initial carbon film can be removed by plasma or UV ozone etching.

We successfully produced suspended nanopores in carbon films and managed to shrink the initial pore size by additional deposition of aluminum nitride (AlN). In Fig.1 the TEM image of such size reduced nanopores is depicted, where the carbon film was removed by plasma etching. The reduction of the pore size alters the shape of the pore to a funnel (inset SEM image), which is advantageous for molecular filtering or capturing depending on the molecular sizes. Furthermore, we have prepared first AlN/Au nanopores with plasmon resonance and plan to do biosensing experiments by detecting the passing biomolecules optically by plasmon resonance shift and by electrical measurements.

BI/ASS-1-In-1 DNA Diagnostics – Optical or by Electronics?

T03 BioInterphases

#BI/ASS-1-In-1

W. Knoll.

AIT Austrian Institute of Technology - Vienna (Austria).

The race in DNA diagnostics between optical detection principles (fluorescence, surface plasmons) and electrical/electrochemical/electronic concepts is not decided yet. Both scientific communities continue to offer solutions for fast, multiplexed, simple and cheap detection of oligonucleotides, PCR amplicons, genomic DNA (fragments), etc. Most likely, the competition will never see a single winner that meets all needs because the different practical formats and applicational environments, as well as, market requirements may ask for specific and unique solutions that could be better achieved in one case by optics and in another situation by electronics.

Along these lines, we will briefly review the state of the art in both categories of DNA diagnostics and will then present a number of examples of what has been demonstrated for the sensitive detection of DNA in (from) solution by monitoring surface hybridization reactions of target strands binding from the analyte solution to surface-attached capture oligonucleotides. A particular emphasis will be put on the physico-chemical principles of these surface recognition and binding (or dissociation) reactions in order to be able to develop criteria of how to optimize sensitivity, selectivity, e.g., for the detection of single nucleotide polymorphisms (SNPs), etc., in DNA diagnostics.

The examples given include

- SNP detection in singly and doubly mismatched oligonucleotides and amplicons;
- demonstration of the limit of detection in these surface hybridization reactions;
- multiplexed recording of surface hybridization reactions via quantum dot- labelled targets;
- surface polymerase chain reactions;
- the use of uncharged peptide nucleic acids (PNAs) as capture probes instead of the highly charged DNA;

- label-free detection of DNA by electrochemical techniques, and
- organic field-effect transistor- (OFET-) based monitoring of hybridization reactions.

BI-1-In-2

NONLINEAR OPTICAL

SPECTROSCOPY OF INTERFACES

T03 BioInterphases

#BI-1-In-2

H. Arnolds.

UNIVERSITY OF LIVERPOOL - Liverpool (United kingdom).

Vibrational spectroscopy is powerful because intrinsic vibrations of the sample under study provide us with chemical information. Despite the existence of commercial infrared and Raman spectrometers, it is still a challenge to study specifically interfacial molecules, as IR and Raman typically have limited surface sensitivity, and the response of a minor portion of interfacial molecules may be obscured by the bulk response on either side of the interface. The use of even-order nonlinear optical techniques like infrared-visible sum frequency generation, where two incoming photons create a new photon, solves this challenge as their selection rules result in the suppression of the signal from the isotropic bulk, making them inherently sensitive to the region where the bulk structure breaks down, i.e. the interface.

In my talk I will discuss the application of SFG to understand protein adsorption on hydrophobic and hydrophilic self-assembled layers on gold and silicon in comparison to infrared and surface-enhanced Raman spectroscopy, and give a critical overview of the limitations of the technique.

BI/ASS-1-In-2 FABRICATION OF PROTEIN AND SSDNA PATTERNS IN THE PROTEIN- REPELLING MATRIX BY ELECTRON BEAM AND ULTRAVIOLET LITHOGRAPHY

T03 BioInterphases

#BI/ASS-1-In-2

M. Zharnikov.

**Angewandte Physikalische Chemie, Universität Heidelberg - Heidelberg
(Germany).**

Fabrication of well-defined protein patterns on solid substrates is important for cell culture research, proteomics, and biosensors. Frequently, such patterning involves the use of protein-repelling poly(ethylene glycol) (PEG) films or oligo(ethylene glycol) terminated alkanethiolate (OEG-AT) monolayers as a background, which is necessary to prevent the nonspecific adsorption of proteins beyond the preselected areas. Usually, the OEG-AT species are introduced by backfilling process, after patterning protein-binding molecules on the substrate. I present here an alternative, more simple and straightforward approach, viz. the writing of protein-affinity patterns directly in the protein-repelling OEG-AT or PEG matrix by electron beam or ultraviolet lithography (EBL and UVL, respectively). Utilizing the high sensitivity of the OEG and PEG backbones to electrons and UV light, they can be continuously damaged with progressive irradiation, resulting in a gradual and controlled change of the protein-repelling properties. Based on this behaviour, protein affinity patterns can be directly written in a protein-repelling matrix and serve as templates for the subsequent attachment of proteins. Employing this direct writing (DW) approach not only simple “black-white” but also comparably complex “gray-scale” (gradient-like) patterning of proteins was achieved. The only limitation is that the DW procedure relies basically on non-specific adsorption of proteins, which is not always desirable and, in some selected cases, can lead to denaturation of the proteins thereby affecting further their performance and activity. However, a non-specific, OEG-AT based template, generated by EBL or UVL, can be transformed to a specific one by employing irradiation-promoted exchange reaction (IPER). Within this approach, an irradiated

OEG-AT monolayer is subjected to exchange reaction in the course of which the partly damaged OEG-AT moieties in the primary matrix are exchanged for potential molecular substituents bearing a special receptor group for specific binding of the target protein or ssDNA strand. The rate and extent of IPER depend on the density of irradiation-induced defects in the OEG-AT monolayer, which can be precisely controlled by the selection of a suitable dose within a certain dose range. Using the DW and IPER approaches in combination with EBL and UVL, we demonstrated the fabrication of complex non-specific, specific, and multiple protein patterns as well as ssDNA patterns and polymer brushes formed on the ssDNA/OEG-AT templates by surface-initiated enzymatic polymerization.

BI/NST-1-Kn-1 BIOMIMETIC NANOPARTICLE FUNCTIONALIZATION AND SMART MEMBRANE ASSEMBLY OF CORE- SHELL NANOPARTICLES FOR TRIGGERED RELEASE APPLICATION

T03 BioInterphases

#BI/NST-1-Kn-1

M. Textor.

ETH ZURICH - Zurich (Switzerland).

The first part of my talk will cover the stabilization and functionalization of ultrasmall, superparamagnetic iron oxide nanoparticles (SPIONs) by surface self-assembly of linear and dendritic polymers and adhesion chemistry based on substituted catechols. In the second part, I will demonstrate that SPIONs with dedicated, hydrophobic properties can be incorporated into the lipid membrane of liposomes and allow for controlled release triggered by an external (alternating) magnetic field. Potential applications relate to areas such as contrast agents for Magnetic Resonance Imaging (MRI) and triggered/targeted release of nanomedicines, and their combination.

Micro-pattern transfer on metal surface by wet etching

T03 BioInterphases

#BI/ASS/NST-P1-12

K. Zelic, T. Kokalj, M. Jenko.

IMT -Institute of metals and technology - Ljubljana (Slovenia).

Surface structuring is one of the major fields of Micro/Nano-technology in recent years. It has been widely investigated due to numerous possible applications. Among the most investigated applications of surface patterning are self cleaning surfaces and anti biofouling surfaces. Especially later is desired on metal surfaces to prevent the adhesion of bio organisms in medicine and ship industry. Preventing of biofilm formation could significantly reduce maintenance and corrosion expenses. There is a lot of different, mainly lithographic methods to structure the metal surface but rare of them are convenient for a large-scale industrial use..

We are testing two newly designed metal surface patterning methods. Both methods are a combination of imprint and wet etching methods. The idea of both methods is to transfer the pattern fabricated by photolithography on a metal surface. Both methods include the pattern transfer from previously designed elastomer stamp to the metal surface by chemical etching. The stamp was made of PDMS polymer patterned with the laser direct imaging lithographic method, with the sub micron resolution (0.8 μm). However, the tested pattern contained the features of a different sizes (from 3 μm to 80 μm).

The methods were tested on a electropolished(?) copper surface. In the first method the patterned PDMS stamp is covered with etchant and then pressed to the surface. In the regions where stamp features touches the copper surface, the etching does not occur and we obtain direct imprint of a stamp on the surface. The second method includes the use of the ink as a blocker for etchant. The ink is imprinted on the surface by the PDMS stamp. Surface is then exposed to etchant that etch only the regions of surface not covered by ink. Later the ink is removed.

Preliminary experiments show some promising results of micro-pattern transfer from elastomer template to a metallic surface, however further research is needed to optimize the process parameters and improve control over the process.

BI/ASS-1-In-3 SYNTHETIC PEPTIDES FOR ENZYMATIC SENSING

T03 BioInterphases

#BI/ASS-1-In-3

B. Liedberg.

Center for Biomimetic Sensor Science, Nanyang Technological University - Singapore (Singapore).

Synthetic peptides have become an attractive alternative to antibodies for the development of robust binders for biosensing. This contribution describes how synthetic four-helix bundle motifs can be turned into high-affinity binders for detection of range of biomedically relevant targets. The concept is based on site-selective modification of the four-helix bundle motif by small molecule ligands followed adaptive fitting of the construct to the binding interface of the target molecule. The so-prepared binders are integrated with plasmonic nanoparticles for aggregation-based colorimetric detection of human carbonic anhydrase (HCA) and C-reactive protein (CRP). A few other examples are also described where a set of linear and digestible peptides are utilized for naked-eye detection of environmental toxins, including, Botulinum serotype A, one of the most toxic substances known to man.

³Coligro Oy - Helsinki (Finland).

A new treatment method based on total immersion in a fluorosurfactant-containing solution has been developed to hydrophobize marble tiles completely throughout their porous network. The processing parameters like the type of surfactant, concentration, solvent, temperature, and time have been investigated to obtain the optimal hydrophobic treatment. When using the optimized parameters, capillary water absorption measurements (EN 15801) proves that the marble stones are efficiently hydrophobized down to at least 5 mm, which was proven by removing the outer surface through grinding and measuring capillary absorption on the remaining piece. The same treatment method has also been employed to successfully hydrophobize 5x5x5 cm marble cubes and larger marble panels.

Furthermore, a new spectrophotometric assay method is employed to prove that the fluorosurfactant is present in the cores of the marble cubes. The new assay is further used to study the penetration behavior of the fluorosurfactant and the penetration kinetics.

The hydrophobized stones are also subjected to several ageing tests to quantify the stability of the fluorosurfactant as well as the advantages the hydrophobization of the porous network provides. In-house ageing tests include: freeze-thaw cycling, acid rain exposure and UV exposure resistance. The hydrophobization of the porous network within the stone proved to give the stones an extremely good hydrophobic stability, even after the outer surface had dissolved through acid attack.

Even if some of the initial treatment methods gave the stones excellent hydrophobic exterior surfaces (water contact angle $> 120^\circ$), these samples could fail to prevent water uptake even after short ageing times, e.g. 1 week under a strong UV light. However, for the optimized protocol, the marble stones could withstand water uptake after very harsh ageing tests because of the deep hydrophobization effect.

Preparation and characterization of a Keramsit to replace the lightweight concretes in contemporary construction by using different types of organic additions

T04 Cultural Heritage

#CH-P1-01

H. Chemani.

Department of Materials Engineering, Faculty of Engineering Sciences,
University M'Hamed Bougara - Boumerdes (Algeria).

Current climate changes call for vigilance and encourage man to develop materials of construction ecological simple and durable. Texture and constitution must meet certain fundamental criteria. The study is carried on the fabrication and characterization of a lightweight granulate type "keramsit" obtained from expanded clay to replace traditional lightweight concrete. Three types of organic named porosants agents: AX, BY and CZ are used in the mixture mass for achieve the best product expansion clay. Chemical analysis, mineralogical and granulometric is performed on the material base. The instruments used are: the fluorescence spectrometer, diffractometer, the Robinson pipette and "Laser granulometer". The nature of the clay and its capacity to expand is determined from the diagram "Riley». The preparation of samples is carried out on 05 mixtures with proportions of 1 to 3% of additions. Two types of samples were prepared: the form of (aggregates and test pieces). Firing is carried out at the temperatures 1100, 1150, 1200 and 1250°C. The characterization is carried on: the shrinkage, absorption, density, porosity and the mechanical strength. After optimization analysis it was found that (aggregates and test pieces) cooked at 1250°C with 3% of AX give better expansion. Values corresponding bulk densities are respectively: 05,3g/cm³ and 0.54g/cm³. Above the temperature 1150°C the expansion coefficient increases by more than 3 times. The resulting material has properties sufficient to replace the traditional concrete. These products are characterized by good thermal insulation, good resistance to fire, and insensitivity to physical and chemical. They allow advancing towards new horizons of construction as well as in renovation of old buildings, thanks to the great lightness.

Identification of natural organic dyes used in art works by laser desorption mass spectrometry

T04 Cultural Heritage

#CH-1-Or-4

S. Kuckova ¹, M. Styblova ², I. Krizova ¹, R. Hynek ¹, T.M. Grygar ³.

¹Department of Biochemistry and Microbiology, Institute of Chemical Technology - Prague (Czech republic), ²Department of Chemistry and Chemical Education, Charles University - Prague (Czech republic), ³Institute of Inorganic Chemistry, Academy of Sciences of the Czech Republic - Rez (Czech republic).

The reliable identification of natural organic dyes that are used in works of art is essential for restorers, conservators and art historians for selection of proper restoration process, improving our knowledge about the painters and for attribution of the artworks.

Identification of the colouring agents in the paint layers of art works is a complex task due to the simultaneous presence of dyes, pigments, inorganic fillers, polysaccharides, proteins, oils, and resins. Pigment identification in paint layers has been relatively well developed for inorganic substances: in restoration practice it is mainly done by optical microscopy in normal and UV light, and by elemental analysis (scanning electron microscopy (SEM-EDX), X-ray diffraction (XRD) or X-ray fluorescence (XRF)) [1-3].

However, the characterization of majority of natural organic dyes has not been satisfactorily solved till now, mainly because of similarity of their elemental composition (C, H, O) and structure, presence in low concentrations, immobilization by chemisorption on inorganic substrates, and difficulty of extractions from complex matrices of the paint layers of the artworks. All these mentioned complications hinder the use of common analytical methods such as liquid chromatography [4], FTIR and Raman spectroscopy [5].

In this work, we apply laser desorption mass spectrometry on the direct identification of the natural dyes in their pure forms, precipitates on inorganic substrates, their mixtures with organic binders, and in real samples of paint layers and textile fibres. The method enables fast and reliable identification without any chemical and time consuming preliminary treatments. Additionally, the method could be considered as a non-destructive because of analysing extremely small amount of samples that is very important in the preservation of cultural heritage objects.

CH-1-Or-7

Sub micrometer gold leaf for art gilding: how and when was it obtained? A mechanical analysis of gold foil thinning

T04 Cultural Heritage

#CH-1-Or-7

M. Aucouturier ¹, E. Felder ², E. Darque-Ceretti ².

¹Centre de Recherche et de Restauration des Musées de France - Paris (France), ²MINES ParisTech, CEMEF - Sophia-Antipolis (France).

Foil or leaf gilding to decorate artworks or architectural items is used since very ancient antiquity, and still practiced. It has been applied on all kind of supports, wood, Egyptian cartonnage, metal, ceramic, stone, paper.

It is known that gold films used for gilding had very variable thickness [1]. The artisans could use quite thick foils of several micrometers thickness fixed on the artwork by mechanical means or very thin leaves with a thickness down to 0.1 μm (fig. 1). A convention proposed by English speaking scientists [1] is to use the word leaf when the gold foil used for gilding has a thickness so small that it cannot oppose to its own weight, roughly less than 1 or 2 micrometer.

The practice of gold thinning started at a very early period; Egyptian artisans were able to thin gold foils to leaves with a thickness smaller than 1 μm [2]. Pliny the Elder stated that it was possible to reach thinness down to 0.4 micrometer. So the thickness of the gold leaf used for gilding cannot be used as a criterion to propose a dating for objects.

The operation of gold thinning to obtain very thin leaves as observed in modern workshops [3] has been detailed in various encyclopaedias at different periods [4]. Two overall steps are practiced: the first one is a pre-thinning of the gold ingot by hammering (in old times) or rolling (after the invention of the rolling mill). After that, a second series of mechanical operations is performed grouped under the appellation of beating.

The present communication draws a summarised history of gold leaf elaboration and describes a mechanical analysis of the rolling and beating processes. The distribution of deformation and stresses during the steps of rolling and beating is described and quantified to understand the necessity of the beating operation to

obtain sub-micrometer-thick gold leaves. It shows why it is mechanically impossible to reach by simple rolling a thickness smaller than several micrometers. Foil thinning by beating is the result of a biaxial strain effect, due to the elastic deformation of the polymer intermediate and the biaxial stretching of gold.

Presence of nanolayers controlling the corrosion processes on iron based archaeological artefacts, detected by high spatial resolution Raman, TEM, STXM and nanoSIMS analyses.

T04 Cultural Heritage

#CH-1-Or-5

P. Dillmann ¹, J.P. Gallien ², E. Foy ², D. Neff ².

¹CNRS - Gif Sur Yvette (France), ²CEA - Gif Sur Yvette (France).

The corrosion of low alloy steels in anoxic media during several centuries is a crucial issue in several domains. On the one hand, some archaeological sites are submitted to anoxic conditions and the long term mechanisms must be enlighten for in-situ conservation purposes. On the other hand, in France, nuclear wastes will be submitted to deep geological repository and the overcontainer of low alloy steel will be submitted to anoxic corrosion processes during several centuries.

For that reason, numerous studies focus on understanding the mechanisms controlling the corrosion kinetics. In that frame, both laboratory simulation on short term and specific studies made on archaeological analogues seems to indicate that in addition to a layer of several 100 µm made of iron carbonates (siderite, chukanovite), a sub micrometric layer, located at the metal/corrosion products interface could influence the corrosion processes. Nevertheless, no precise characterisation data has been published on this layer and the way it controls the mechanisms is not unravelled up to now.

This study presents the characterisation results obtained on 400 hundred year old archaeological artefacts corroded in anoxic aqueous media, investigated at the metal/corrosion product interface. Transverse sections and thin films made on these transverse sections were investigated by coupling different structural and chemical methods giving information on the phase nature at the sub micrometric scale. Last developments of High Spatial Resolution Raman allow to investigate a sample with a 500 nm resolution. STXM under synchrotron radiation was used to investigate the iron L edge and to map its variation around the interface with a 25 nm resolution. In a complementary way electron diffraction on TEM was used to investigate the same

zone. The coupling of these methods allowed us to clearly evidence a continuous layer made of a mix of FeII and FeIII species (probably a mix of maghemite and magnetite), separating the metallic substrate from the carbonate (siderite and chukanovite), this latter constituting the main part of the layer. The thickness of this intermediate oxide layer varies on the same artefact from several 10 nm to several 100 nm.

In a complementary way, the investigated archaeological artefacts were put in a D2O deaerated solution, representative of the water of the archaeological site, during several months. After this treatment, nanoSIMS observation of ^{16}O distribution and D/H ratios clearly showed that water (D2O in our case) does not reach the metal by penetrating the pores of the corrosion layer but seems to be stopped by the nanometric interfacial oxide layer that is apparently much less porous than the carbonate corrosion products.

These new data will enlighten the corrosion mechanisms and are an important step for further comprehension and modelling of the long term corrosion processes.

Stochastic computer simulation : the prediction of porosity nanostructures into solids surface as a result of ions implantation

T04 Cultural Heritage

#CH-P1-02

G. Zmievskaya, A. Bondareva.

M.V. Keldysh institute of applied mathematics RA - Moscow (Russian federation).

For solution of unstable phase transitions in solid matter problems the numerical method of solving the quasilinear parabolical equations in partial derivatives by replacing them with stochastic analog in form of Ito-Stratonovich differential equations was being developed. The properties of Markovian random processes are used for the creation of the mathematical models of fast-evolving processes of the fluctuative nature in materials under radiation flow treatment. The nucleation of 1st order phase transition (the pore formation in crystal lattice etc.) is investigated on the example of defect formation on the nonlinear stage of phase transition under inert gas flows treatment. The role of fluctuation instability of phase transition in the formation of Si porosity is being investigated (for the the media with a periodical structure of photonic crystals which are usually obtained by crystal etching). The estimate of the momentary elastic deformation of Si crystal lattice with spherical vacancy-gas pore nucleation induced by the pressure contrast on its boundary is conducted with the account for the defect distribution in the sample as the result of Brownian pore movement under the influence of indirect elastic interaction between pores by exciting the acoustic phonons of the lattice and Fridel oscillations of electron density in metal[1]. The method of phase transition nucleation simulation [2] is generalized for the formation of elongated radiation-induced linear defects in the form of vacancy discs, dislocations, planar defects (dislocation loops). Methods of stochastic simulation of nonlinear processes arising with defect movement of dislocation type, such as defect immobilization, multiplying and annihilation of dislocations etc., are modified on the models in which Ito-Stratonovich equations by continuous measure (nucleus clusterization and Brownian movement) are complemented by Ito equations by point measure (for the collision processes

description) and their numerical solution algorithms. The kinetic distribution function of stochastic dynamical variables (size and location of defects) are used for calculation porosity, radiation damage principles, which may be used for nondestructive control of defect formation (in the historical heritage objects) and materials of technical purpose, as well as aid the creation of materials with novel properties (porous silicon). Numerical investigation of elastic plastic deformation mechanism on the initial stage of phase transformations induced by implantation with change and distribution of dislocation densities in materials are examined. Authors are thankful prof. Giuseppe Maino (Italy) for new idea in applications of computer simulation models in problems of preservation of cultural heritage and Donatella Biagi Maino (Italy) (prof. of cultural heritage restoration). Work is partially supported by the RFBR grants 11-01-00282-a, 12-01-00490-a and 12-01-00708-a.

Departamento de História, Avenida de Berna 26-C, 1069-061 - Lisbon (Portugal), ³Laboratoire de Dynamique, Interaction et Réactivité, UMR7075 CNRS-Université Pierre-et-Marie-Curie, Paris 6, 4 Place Jussieu, C49 batF, 75252 Paris cedex 05 - Paris (France).

The Portuguese were the first Europeans to send merchant vessels regularly to China, bringing back, since the first half of the 16th century porcelains and other goods highly appreciated in Western Countries. Copies of those porcelains started to be produced in Lisbon, but in the form of faience, trying to imitate Chinese patterns [1]. There is now archaeological evidence that such production started in Lisbon at least in the middle of the 16th century [1 and references therein].

Common earthenware, however, was a much older production in the country, and there is archaeological evidence for its production at “Mata da Machada” and from Santo António da Charneca about 1480 to 1530, both South of Lisbon, and also in Lisbon at Santos o Velho at least from 1561 onwards [2].

In this study our first goal is the spectroscopic characterization of pigments, glazes and pastes of the 16th century Portuguese Faience, which still remains to be done. A comparison with Spanish production of Valencia and Seville was also performed. Raman micro spectroscopy was used as our main tool for such characterization [3 and references therein]. Ground state diffuse reflectance spectra (GSDR), with the use of the Kubelka-Munk treatment for colour evaluation were also obtained [3, 4] as well as FT-IR spectra obtained for the pigment, glaze and paste characterization [3]. A comparison of the spectroscopic data obtained from sherds from Mata da Machada and several other from an archaeological excavation on a small urban site in the city of Aveiro (late 15th century and 16th century) [5] was performed. Also sherds of

imported pottery from Valencia and Seville were studied, since it is well known that Portugal imported significant quantities of those goods from Spain at that time. The obtained results evidence a clear similarity in the micro-Raman spectrum in the white glaze and clays of Portuguese pottery produced at "Mata da Machada" and the sherds found at the medieval house of Aveiro. All these are quite different from the Spanish products under study, pointing to an earlier production of tin glaze earthenware in Portugal than the mid 16th century, commonly assumed.

Non destructive identification and diagnosis of natural organic substances in cultural heritage: insight from Raman and infrared signatures

T04 Cultural Heritage

#CH-1-Or-10

L. Bellot-Gurlet ¹, C. Daher ², C. Paris ¹.

¹Laboratoire de Dynamique, Interactions et Réactivité (LADIR), UMR 7075 UPMC/CNRS - Paris (France), ²Centre de Recherche et de Restauration des Musées de France (C2RMF) - Paris (France).

Natural organic substances are widely used in the history and constitute a precious testimony of human exploitation strategies, exchange networks and techniques for their implementation in numerous ancient objects. These materials have long been neglected because of their poor conservation or small quantities and some limits of analytical approaches. With the re-evaluation of vibrational spectroscopies (Raman and infrared) potentialities through spectral treatment procedures', these could offer alternatives or complements to the current analytical strategies based on separation methods. The use of FT-Raman is needed to avoid fluorescence and infrared measurements are performed using a micro-ATR configuration to eliminate sample preparation.

The identification of a broad range of natural organic substances: proteins (animal glues), triglycerides (oils), polysaccharides (gums) and terpenoids (resins from different geographical provenances), require specific strategies to differentiate vibrational signatures with close features. A methodology is proposed on spectral decomposition of CH stretching massif followed by Principal Component Analyses of extracted parameters. Applying PCA on the raw data, as commonly done, is indiscriminate. However, PCA of the fitting parameters becomes an efficient and powerful tool to cluster the different materials, because it is highly related to their molecular characteristics. This approach proved the possibility of identifying the natural organic substances, sometime at the scale of the tree species, and some alteration or ageing is not an issue to their recognition. This approach could find applications in various contexts (archaeology, museum context, conservation

purpose, but also present industrial application) and for a wide range of natural organic materials as varnishes, binders or adhesives.

The colour of gold and gildings can be influenced in many ways: the composition of the gold alloy or the nature of the substrate on which the gilding is applied [1] are two well known methods to obtain different colours of this metal. Nowadays, we are even able to change the colour of gold by playing with the size of gold nanoparticles or micropatterning pur gold. Several studies have shown an intentional change of the colour of gold over the history. Another less known technique to colour the gildings is the chemical treatment of the gilded surface itself, i.e. after the application and the burnishing of the gilding [2]. This chemical treatment might have been used on goldsmith pieces, such as Our Holy Lady Shrine of Huy (13th c. Mosan art, Belgium [3]) that motivated this study.

Several recipes that were able to give a warmer tone to gilding on a silver plate have been reproduced according to ancient writings. Nevertheless the physical chemistry of this coloration is not fully well understood. That is why we characterized the gilded surfaces before and after application of the re-created recipes. In order to do that, we used the tunability of the synchrotron source to probe the upper surface at two depths by X-ray Photoelectron Spectroscopy (SR-XPS) and we performed X-ray Absorption Near Edge Spectroscopy (XANES) to study elemental markers of the recipes (iron and copper). Thus, we attempted to identify the reagents required for the success of these recipes and to understand the reaction mechanisms occurring on the gilding during the treatment. Finally, we tried to discriminate recipes markers that remain on the coloured gilded surface after the treatment from residues of a modern cleaning product that is commonly used in goldsmith restoration, the « rouge à polir » [4].

The corrosion of ferrous objects can be influenced by the action of micro-organisms when they lay in a biologically active environment and the understanding of the corrosion mechanisms is important in two scientific domains: (1) the preservation of ferrous archaeological objects; (2) the French concept for geological disposal of nuclear waste based on a multi-barrier system including the metallic containers confined in natural clay. In both fields, the long term behavior of the metal has to be assessed in order to establish conservation treatment or prediction behavior models. One particularly crucial parameter is the influence of the presence of bacteria on the corrosion processes. The presence of iron sulphides and other iron/sulphur-containing compounds in the corrosion layers can be the fingerprint of the role of sulphate-reducing bacteria. Therefore, in this study, complementary imaging techniques were used to characterize the sulphur-bearing compounds in the corrosion products of archeological objects and of ferrous samples corroded in conditions relevant to a future geological disposal of nuclear waste: FEG-SEM for the bacteria images and the elemental mappings, μ -Raman for the identification of sulphur phases and ToF-SIMS for the determination of the $^{34}\text{S}/^{32}\text{S}$ ratio (as shown on figure 1). ToF-SIMS is particularly innovative in this scientific research and could permit to identify, from the $^{34}\text{S}/^{32}\text{S}$ ratio, how bacteria induce the formation of sulphur-bearing compounds in the iron corrosion process, as it has been reported that the bacterial culture medium shows sulphate aqueous specie depleted in ^{32}S and enriched in ^{34}S .

Figure 1: μ Raman image corresponding to iron sulphide border in the corrosion products of an archeological nail of the 16th century (Glinet, Seine-Maritime, France). Laser wavelength: 532 nm.

Figure 2: ToF-SIMS repartition in ^{32}S (left) and ^{34}S (right) of the iron sulphide border (Bi^+ ions, negative mode, image size: $242 \times 242 \mu\text{m}^2$).

Nanoparticles used to darken the patina of antic black bronze: TEM observations on new experimentations

T04 Cultural Heritage

#CH-1-Or-9

F. Mathis ¹, S. Tirat ¹, E. Grieten ², D. Robcis ³, M. Aucouturier ³, D. Schryvers ².

¹Centre Européen d'Archéométrie - Université de Liège - Liège (Belgium),

²Electron Microscopy for Materials Science - University of Antwerp - Antwerp (Belgium), ³Centre de Recherche et de Restauration des Musées de France - Paris (France).

Some studies that started in the nineties [1] proved that some antic artefacts or parts were intentionally patinated using a chemical treatment. In particular one type of patina was characterized on artefacts coming either from Egyptian civilization, Mycenaean period or Roman Empire. This patina has been identified as a precious material mentioned in ancient Egyptian and Roman texts. This particular material is named, depending on the artefacts' origin, black bronze (hnty km), or corinthium aes. This patina is made on copper alloys containing gold and/or silver and is composed mainly of cuprite. It was compared with a Japanese patina which appears in medieval times but which is still in use and known under the name of shakudo. Shakudo are copper gold alloys and they are treated chemically by means of different recipes named nikomi-chakushoku which developed a black layer of cuprite on the surface.

An important study of antic artefacts coming from the collections of French museums has been carried out since the beginning of the 2000's. An experimental protocol based on non-invasive analysis was developed to analyse these very precious objects and to identify and characterize this type of patina in function of the provenance and age of the artefacts [2, 3].

However, some questions about this particular surface layers could not be resolved using this experimental protocol due to the limitation of non-invasive analytical techniques: In particular the question of the formation of the oxide layer, the colouring mechanism of this black cuprite (copper oxide which is red under natural form) and the important adherence properties.

We developed a program of experimentation to make some black patina. These experimentations were based on the utilisation of the Japanese recipes, and we tried to differentiate the effect of the alloying element (Au, Ag, As) and the effects of the chemical treatment.

These patinas were studied by means of various analytical methods and in particular we used TEM to characterize the fine structure of the oxide layer.

The use of transmission electron microscopy (TEM) allows to evidence a hypothesis already mentioned in previous studies [4]: the presence of nanoparticles of gold in the cuprite layers and their role on the coloration of the patina making the black bronze the very first application of nanoparticles in technical history.

The DiffAbs beamline, at SOLEIL synchrotron, is located on a bending magnet and provides a monochromatic X-ray beam, tuneable in the 3-23 keV energy range. The multi-scale beam size, “standard” (300 µm) and microbeam (10µm) modes, can be used in conjunction with all the analysis techniques available at the beamline: X-Ray Diffraction, X-Ray Absorption and Fluorescence spectroscopies. The almost simultaneous combination of such techniques offers the possibility of complementing the local structure information by data on the long range order, which is essential for a full characterization of material. All the measurements are performed on the 6/8 circle kappa diffractometer using different well-adapted detectors, ensuring that all experiments are carried out on the same zone of the sample, in absolutely identical physico-chemical conditions (temperature, reactive solution, etc). Since its opening to users in 2008, DiffAbs beamline prove its competitiveness to study ancient materials (see references). Typical experiments will be presented.

For instance, a new specific set-up allowing in situ X-ray diffraction measurements was developed last two years using the XPAD, a new hybrid-pixel detector. The fast and well resolved diagrams acquired using mapping mode on an in-situ cell containing the archaeological sample, allow observing the transformation of the corrosion products of the marine iron artefact during its desalinisation.

BEYOND THE APPEARENCE OF WORKS OF ART

T04 Cultural Heritage

#CH-1-Kn-1

P. Walter.

**Laboratoire d'archéologie moléculaire et structurale, CNRS-UMR8220,
Université Pierre et Marie Curie (UPMC) - Ivry-Sur-Seine (France).**

The study of Cultural Heritage materials requires advanced techniques to shed new lights on ancient technologies and help in their preservation. The implementation of new analytical tools, including mobile laboratories or large/medium scale facilities such as synchrotron radiation, charge particle accelerators, neutron sources allows a deep insight on the archaeological and artistic materials, from the millimeter to the nanometer scales.

During this lecture, current applications and potential needs of multiscale imaging techniques will be presented to show the major role played by analytical techniques to characterize the nature and the mode of preparation of different pigments (origin of the minerals, chemical synthesis of new compounds, crushing of crystals, mixing of matters, etc.). The precious character of the most famous works of art and their uniqueness imply particular cautions and require methods which may give the maximum information with the minimum of sample, if any.

EMP-P3-01

Advanced structural characterisation of micro- and nano-electronics using neutrons and synchrotron X-rays

T05 Electronic Materials and Processes

#EMP-P3-01

E. Mitchell ¹, J. Beaucour ², J.C. Royer ³, P. Bordet ⁴.

¹European Synchrotron Radiation Facility and EPSAM, Keele University - Grenoble (France), ²Institut Laue-Langevin - Grenoble (France), ³LETI - Grenoble (France), ⁴Institut Neel - Grenoble (France).

Large-scale synchrotron and neutron research infrastructures offer unrivalled performance for the advanced characterisation of micro- and nano-electronic devices and systems. Examples include X-ray spectroscopy to study RRAM switching mechanisms, grazing incidence X-ray scattering and neutron reflectivity for structural data on materials for interconnections, hard X-ray PES to understand electronic properties of layered materials, and nano- and micro-X-ray-tomography for unprecedented non-destructive 3D imaging of packaging, vias, etc.

There is an increasing realisation worldwide that large-scale research infrastructures are a key component, not only of academic and fundamental research, but also of the innovation cycle and industrial research and development. However, working with industry has its own special requirements, and can bring to the fore mismatches and clashes between a traditional academic culture and the needs of the market driven commercial world: research infrastructures are often based on an academic modus operandi which can limit their industrial impact.

The IRT Nanoelec, a technological research institute for nanoelectronics, was founded in April 2012 through a joint venture between the French National Research Agency (ANR) and the French Atomic and Alternative Energy Commission (CEA). This public-private partnership comprises 17 public- and private-sector research

partners - including the European research infrastructures European Synchrotron Radiation Facility (ESRF) and Institut Laue Langevin (ILL) which provide world-leading synchrotron light and neutron facilities for both academic and industrial communities. **The IRT NanoElec research will be focused on a core technology programme encompassing 3D assembly integration, nanophotonics on silicon and via technologies, supported by technological infrastructure including a Micro- and Nano-Electronics Characterisation Platform. This platform, being created as a pathfinder project, will largely enhance the effectiveness and attractiveness of the Grenoble-based neutron and synchrotron light source facilities for European micro and nano-technological research.**

The NanoElec funding will provide staff to support electronics research at ESRF and ILL, as well as complementary facilities at the CEA Platform for Nano-Characterisation such as SEM, TEM and FIB. **Off-line sample preparation facilities and complete characterisation processes from industry device to on-line experiment design and performance with data analysis will be made available** as the large-scale facilities and industry learn how to work together. The experience gained and platform facilities will be available for European and international companies, as will opportunities for training in the synchrotron and neutron techniques.

This pathfinder project, together with other initiatives, will serve to highlight the impact that public large-scale facilities can and should have on the economic growth and international competitiveness of companies.

This work is supported by the French government within the Investissements d'Avenir programme with the reference ANR-10-AIRT-05.

Multilayer metal/ Polypyrrrole /Metal electrodes were fabricated providing better conductivity than that of Polypyrrrole (Ppy), and improving the flexibility and sensitivity compared to that of only metal electrodes. We report on the electrical and electrochemical properties of the electrodes, on the Ppy electro-polymerization process integration, and on the gold electroplating on the Ppy.

The Ppy was deposited by electrochemical polymerization using repetitive cyclic voltammetry (CV). The top metal was electrodeposited on the Ppy. The metal nucleation and growth on the Ppy were studied using HRSEM and FIB/SEM. The electrochemical behavior of the metal/Ppy/metal electrodes was tested by CV and impedance spectroscopy. The novel electrode system was tested for their application as whole cell biosensors using substrate - enzyme interaction by product electrochemical activity. We studied the response of the new electrode in biological solutions (PBS). We found that depositing Ppy on thin metal seed layer dramatically increases the measured current of the electrodes, as compared to Au electrode. This effect was also demonstrated by CV measurements as well as in amperometric detection of alkaline-phosphatase enzymatic activity using biological chips. This high current produces noise that interferes with the proper operation. However, when sufficient metal is electrodeposited on the Ppy, the behavior of the electrode becomes similar to that of a metal electrode, as demonstrated by CV and by amperometric detection of enzymatic activity. The CV curve has the same characteristics as that of the planar gold electrode, with a considerably higher current peak (Ip). More important, the new electrode demonstrated an improved ability of enzymatic activity amperometric detection.

The electrodeposition of Ppy followed by Au, on the surface of the biochip's Au seed layer, affected the electrocrystallization of the Au particles on the Ppy (Fig 1) resulting in a high surface area.

This electrode can serve as a highly sensitive, high surface area and flexible sensor for biological species.

HRSEM image of Gold/ Polypyrrole/Gold structure, on Biochip working electrode- Au deposition time- 10 minutes.

Amorphous indium-gallium-zinc-oxide (a-IGZO) thin-film transistor (TFT) has been investigated as a replacement for amorphous and polycrystalline silicon TFTs in active-matrix liquid-crystal display devices and active-matrix organic light-emitting displays [1]. In addition, rare-earth (RE) oxide films have been extensively studied to replace a traditional SiO₂ gate dielectric because of their probable thermal, physical, and electrical performance [2]. With its large dielectric constant, wide bandgap energy, and high transparency in the visible range [2], an Er₂O₃ film can be considered as a gate oxide for low-temperature TFT applications. The main issue is that using RE films is moisture absorption to degrade their permittivity due to the formation of low-permittivity hydroxides. To solve this issue, the addition of Ti or TiO_x into the RE dielectric films can cause improved physical and electrical properties [4]. In this study, we compared the physical and electrical properties of Er₂O₃ and Er₂TiO₅ a-IGZO TFT devices.

Fig. 1 displays the XRD patterns of the Er₂O₃ and Er₂TiO₅ thin films deposited on the TaN/SiO₂/Si substrate. A strong Er₂O₃ (400) and weak TaN (101) peaks appeared in the Er₂O₃ film, while only TaN (101) reflection peak was presented in the Er₂TiO₅ film, revealing that Er₂TiO₅ thin film was amorphous. The transfer characteristics of the a-IGZO TFT devices using Er₂O₃ and Er₂TiO₅ gate dielectrics were shown in Fig. 2. The V_{TH} value of the Er₂O₃ and Er₂TiO₅ a-IGZO TFT devices is 1.5 and 0.39 V, whereas the I_{on}/I_{off} ratio is 1.72×10⁶ and 4.23×10⁷, respectively. Furthermore, the μ_{FE} of the Er₂O₃ and Er₂TiO₅ TFT devices is 6.7 and 8.8 cm²/V-sec.

Charge transfer in molecules and ultrathin insulating films deposited on metal surfaces

T05 Electronic Materials and Processes

#EMP-1-Or-2

M. Robledo Relaño, S. Díaz-Tendero, F. Martín, M. Alcamí.

Universidad Autónoma de Madrid - Madrid (Spain).

The main feature behind photovoltaic devices, in the framework of organic electronics, is the presence of a stable molecular system in which solar radiation can easily induce electronic transfer. These systems can be constructed by deposition of organic molecules on metal surfaces as well as on metal surfaces covered by insulating layers, thus providing a donor-acceptor set with the possibility of charge transfer between them induced by light. Charge transfer processes lead to level alignment of the frontier orbitals but they may also induce structural transformations. Therefore, a first step towards the design of photovoltaic devices implies an accurate description of the structure and the charge transfer taking place on the ground state. In this communication we present the results obtained in a theoretical study on the interaction between different organic molecules, with potential photovoltaic activity, and clean metal surfaces or metal surfaces covered by ultrathin ionic layers. We have studied a wide range of organic molecules deposited on a metal surface (Cu(100) and Ag(111)). These systems cover from Van der Waals weak interactions (Benzene) to a strong covalent binding (TCNQ, tetracyanoquinodimethane). They also include the well known Fullerene, C₆₀, where not only the study of the system itself is interesting, but also dealing with the size of it is a demanding task. Further, we have chosen NaCl as the insulating film which, placed in between the organic molecules and the metal substrate, will decouple the former and induce changes in the work function of the latter [1]. Thus, we have studied C₆H₆/Cu(100), which is a prime example of the interaction between organic molecules, with π -delocalized electrons, and a metal surface. In order to check the effect of insulating films, we have also studied the following system: C₆H₆/nMLNaCl/Cu(100); (n = 1, 2 and 3), evaluating the geometry, the charge transfer, and the decoupling of the organic molecule. We have as well studied the structural rearrangement and the charge transfer in the system C₆₀/Cu(100) and C₆₀/nML NaCl/Cu(100) obtaining arresting results. Finally, we have studied the

interaction (self-assembled monolayers) of TCNQ on Ag(111) and TCNQ together with TTF on Ag(111). In these systems the geometry is affected after the adsorption on the surface due to the charge transfer. We will give prominence to these results by comparing them with experimental ones [2] and previous works [3]. All calculations have been performed with a plane wave, ultrasoft pseudopotential method as implemented in the VASP code [4]. The projector augmented wave method has been used together with the Perdew-Wang 91 functional. Dispersion forces (van der Waals) have been taken into account with the DFT-D2 Method of Grimme [5].

Abstract

Charge accumulation during electron beam exposure of insulating materials is a well-known artifact largely reported in literature [1,2]. To prevent charging effects, a metallic conductive layer is usually deposited either at the top of the resist or between the substrate and the resist [3]. For both methods, an additional etching step of the conductive layer is required giving rise to a complicated pattern transfer to the substrate and contamination issues. Another approach is to replace the metallic layer by a charge polymer dissipator [4]. Some of these dissipators have the advantage of being soluble in water which preserves the resist patterns and structures on the sample. However, these dissipators are generally corrosive and suffer from aging and poor high-resolution capability. The aim of this paper is to highlight a non destructive anti-charging process for electron beam lithography or for electron scanning imaging [5]. It is based on the use of inorganic layer soluble in water and achieves high resolution.

Ge-Sb-Te (GST) and nitrogen doped Ge-Sb-Te (N-GST) thin film layers for phase change random access memory (PRAM) applications were investigated by synchrotron-radiation-based x-ray photoelectron spectroscopy and absorption spectroscopy. The surface is readily oxidized by air exposure.[1] In-situ annealing of amorphous GST thin film resulted in changes in the Sb 3d orbital, indicating that not only Ge but also Sb involved in the phase changes, which was also justified by Stibnite model calculations.[2] Nitrogen doping in GST resulted in more favorable N atoms' bonding with Ge atoms rather than with Sb and Te atoms,[3,4] which explains the higher phase change transition temperature than that of undoped GST thin film. Surprisingly, it was noticed that N atoms also existed in the form of molecular nitrogen, N₂, which is detrimental to the stability of the GST performance.[5] N-doped GST experimental features were also supported by ab-initio molecular dynamic calculations.[4]

Ultrasound influence on the Si-SiO₂ system defects structure

T05 Electronic Materials and Processes

#EMP-P3-03

D. Kropman ¹, T. Kärner ², E. Daukšta ³.

¹Tallinn University of Technology - Tallinn (Estonia), ²Tartu University - Tartu (Estonia), ³Riga Technical University - Riga (Latvia).

The effect of ultrasonic treatment (UST) on the defect structure of the Si-SiO₂ system by means of electron spin resonance (ESR), metallography, MOS capacitance technique and secondary ions mass-spectroscopy is presented. The non-monotonous dependence of the point defect densities on the US wave intensity has been observed. The US frequency influence on the ESR signal intensity of the defect centres depended on the defects type and may be caused by vibrational energy dissipation which are a function of defect centre's type. The density of point defects and absorbed impurities at the Si-SiO₂ interface can be reduced by appropriate choice of UST. UST influence on the PD density (Fig. 1) shows the ESR spectra before and after UST. Before UST a signal with $g=1.9996$ (Pa centers) connected with vacancy complexes is observed. After UST appears another signal with $g=2.0055$ (broken bonds of Si atoms). Investigation of the dependence of the spin density on the US frequency of the UST in Si-SiO₂ samples with [111] and [100] crystallographic orientation was carried out. It has been shown that the influence of the US frequency and the sample orientation on the ESR signal intensity varies for different centres. The frequency and orientation dependence of the ESR signal with $g=1.9996$ and the lack of this dependence for the centres with $g=2.0055$ show that the vibrational energy dissipation depend on the type of defect centres and their orientation. Defect density grows with an increase of the US intensity or changes nonmonotonously depending on the oxides thickness (Fig. 2.) In the samples with thick oxide there is a maximum in the dependence of the life time on the US wave amplitude in samples with thick oxides and in the samples with thin oxides-a minimum. This shows that the structural defects form electrically active centres and their density can be varied by UST.

Fig.1. ESR spectra of the Si samples before (1) and after UST treatment (2).

Fig.2. Dependence of the density of structural defects at the Si-SiO₂ interface on the US wave amplitude. SiO₂ film thickness 0.4 (1) and 0.7 (2) μm.

Soft-X-Ray ARPES at Swiss Light Source: Electronic Structure of 3-Dimensional Systems and Buried Heterostructures

T05 Electronic Materials and Processes

#EMP-2-Or-2

V. Strocov¹, M. Shi¹, M. Kobayashi², C. Monney², X. Wang², J. Krempasky², T. Schmitt², L. Patthey², H. Berger³, P. Blaha⁴.

¹Swiss Light Source, Paul Scherrer Institute - Villigen (Switzerland), ²Swiss Light Source, Paul Scherrer Institute; - Villigen (Switzerland), ³Institut de Physique de la Matière Complexe, EPFL - Lausanne (Switzerland), ⁴Institut für Materialchemie, TU Wien - Wien (Austria).

A fundamental benefit of pushing ARPES into the soft-X-ray energy range is the increasing photoelectron escape depth λ . This boosts the bulk sensitivity as well as enables access to buried heterostructures. Furthermore, by the Heisenberg uncertainty principle, the increase of λ improves intrinsic resolution in surface-perpendicular momentum Δk_z . Combined with free-electron final states and atomic-like matrix elements, this enables exploration of the electronic structure 3-dimensional (3D) systems.

The soft-X-ray ARPES (SX-ARPES) facility at Swiss Light Source is installed at the ADDRESS beamline [1] which delivers soft-X-ray radiation with variable polarizations in a photon energy range from 300 to 1600 eV. High photon flux topping up 10^{13} photons/s/0.01%BW at 1 keV combined with small spot size and grazing X-ray incidence have allowed breakthrough of the notorious problem of small valence band cross-section in the soft-X-ray range. At energies around 900 eV, ARPES images are routinely acquired within 5 min at a combined energy resolution of 110 meV, and within 30 min at resolution of 60 meV.

We unfold on the pilot application of SX-ARPES to explore 3D band structure and Fermi surface (FS) of the paradigm transition metal dichalcogenide VSe_2 [2]. Unprecedented clarity of the experimental electronic structure illustrated in Fig. 1

demonstrates the 3D momentum definition achieved in the soft-X-ray energy range. Investigation of the experimental FS supported by autocorrelation analysis has revealed that the exotic 3D charge density waves in VSe₂ have their precursor in pronounced 3D nesting of the FS due to its out-of-plane warping. Other applications include polarization dependence and alternating FS shapes in pnictide HTSCs, demonstrating intra-cell interference effects; resonant spectroscopy Mn magnetic impurities in GaMnAs, revealing the energy position of the ferromagnetic impurity band and its hybridization with the 3D host GaAs bands, etc. Finally, we flash through the most important results achieved by external users, including topological surface state embedded in 3D valence band of PbBi₄Te₇; FS and depth localization of 2D electron gas in LaAlO₃/SrTiO₃ heterostructures; standing X-ray waves excited ARPES of multilayer heterostructures; etc. These unfolding results demonstrate an immense potential of SX-ARPES to deliver a clear view of the electronic structure of 3D systems and buried heterostructures.

EMP-P3-04

Air-Stable Organic Solar Cells with Ag/Pentacene Anode Buffer Layer

T05 Electronic Materials and Processes

#EMP-P3-04

K. Harafuji, Y. Omoto.

Department of Electrical and Electronic Engineering, Ritsumeikan University - Kusatsu, Shiga (Japan).

The effect of anode buffer layer on device performances is studied experimentally in small-molecule organic solar cells (OSCs). A proposed OSC (Device A) has the layered structure of indium-tin oxide (ITO, 14.5 nm, anode) on the glass substrate/ thin Ag (0.5 nm)/ pentacene (2 nm)/ copper phthalocyanine (CuPc, 20 nm, donor)/ fullerene (C60, 40 nm, acceptor)/ bathocuproine (BCP, 10 nm, cathode buffer)/ Ag (100 nm, cathode). Here, a combination of thin Ag and pentacene serves as the anode buffer [1, 2]. Following OSCs are also prepared to compare the device performance: (1) Device B with Ag anode buffer, (2) Device C with pentacene anode buffer, and (3) Device D without anode buffer.

Organic materials are evaporated on the ITO substrates at the rate of 0.5 \AA/s , under a pressure of less than $1.0 \times 10^{-3} \text{ Pa}$. The deposition rate is monitored by an oscillation quartz microbalance. All the devices are illuminated through the transparent ITO electrode. The photovoltaic current density-voltage (J-V) measurements are carried out in air at room temperature without any encapsulation. Xenon lamp illumination at an intensity of 100 mW/cm^2 is performed, and an air mass 1.5 global (AM1.5G) spectrum is obtained using a solar simulator. Repeated J-V measurement of 30 cycles is made. Here, the one cycle is composed of 3-second illumination and 27-second interval without illumination. The J-V measurement is made during the 3-second illumination.

Figure 1 shows the experimental result of normalized power conversion efficiency η as a function of the illumination cycle. It can be seen that efficiencies for Devices C and D are decreased greatly, whereas those for Devices A and B almost keep their initial values even after the 30th illumination. The S-shaped kink which indicates the device degradation appears in the J-V curves for Devices C and D as the illumination cycle proceeds. The decrease in η is dominated by the decrease in the fill factor of the J-V curve. Initial η for Devices A, B, C and D are 1.03, 0.71, 1.15 and 0.97%, respectively.

In summary, the thin Ag layer as an anode buffer plays an important role to protect

the device degradation. The thin pentacene layer as an anode buffer brings about the slight increase in η . The OSC with the anode buffer composed of the two thin layers is a promising candidate for OSCs with high η and long life time. The improvement is considered to be due to the hole-photocurrent multiplication originated from trapped electrons in the vicinity of the Ag /pentacene interface [2].

UV Raman and Multiwavelength Photoluminescence Characterization of Ultra-Shallow Implanted Junctions

T05 Electronic Materials and Processes

#EMP-2-Or-3

W. Yoo ¹, T. Ishigaki ¹, T. Ueda ¹, K. Kang ¹, N. Hasuike ², H. Harima ², M. Yoshimoto ².

¹WaferMasters, Inc. - San Jose (United states), ²Kyoto Institute of Technology - Kyoto (Japan).

For monitoring as-implanted dose and depth profiles, Thermo-Probe and SIMS have been widely used. Retained dose and dopant depth profiles are routinely monitored after dopant activation anneal. Sheet resistance measurements of activated implant layers are made using four point probes (FPP) to quantify electrical activation. For ultra-shallow junction (USJ) characterization, micro FPP are frequently used for improved spatial resolution and junction punch-through prevention. Rutherford backscattering spectroscopy (RBS) and transmission electron microscopy (TEM) are often used as complementary crystal quality and defect characterization techniques.^{1,2}

Conventional characterization techniques require either physical contact or time consuming destructive sample preparation. Development of suitable non-contact, non-destructive, comprehensive subsurface, in-line characterization techniques are strongly desired for fast feedback of implanted USJ characterization results.

Preliminary Raman and room temperature photoluminescence (RTPL) characterization of implanted Si has been demonstrated.^{3,4}

In this paper, UV Raman spectroscopy and multiwavelength RTPL are used for characterizing B⁺ (1 keV 1.0x10¹⁵cm⁻²) implanted p⁺/n USJs, These measurements are then contrasted with sheet resistance (Rs) measurement and SIMS analysis, before and after rapid thermal annealing (RTA) in N₂. The RTA temperature and residence time ranges were 850~1050°C and 35~140s, respectively. UV Raman characteristics, NIR RTPL intensities and junction depth of USJs showed very strong correlation with Rs. UV Raman and RTPL spectroscopy show promise as non-contact, in-line dopant activation characterization techniques.

Improvement of device performance by optimizing the Li/F8BT interface structures

T05 Electronic Materials and Processes

#EMP-1-Or-3

X. Feng ¹, X. Li ², H. Ju ¹, J. Guo ³, Y. Luo ², J. Zhu ¹.

¹University of Science and Technology of China - Hefei (China), ²Department of Theoretical Chemistry and Biology, School of Biotechnology, Royal Institute of Technology - Stockholm (Sweden), ³Advanced Light Source, Lawrence Berkeley National Laboratory - Berkeley (United states).

Interfaces between metals and conjugated polymers are important for the design of optoelectronic and electronic devices.[1,2] In this study, interface formation between Li and F8BT at 300 K was investigated by XPS, UPS and NEXAFS. With increasing Li thickness, a downward band bending is induced, resulting in a 1.4 eV reduction of electron injection barrier from Li to F8BT. Simultaneously, XPS and DFT calculation results indicate that Li react preferentially with S atoms whereas mildly with N atoms of F8BT. According to the evolution of UPS spectra, a significant decrease of interface work function is observed. Interestingly, after 2 nm Li absorbed on F8BT, an increase of the work function was found, implying the appearance of local electric field at the Li/F8BT interface. From the study on F8BT based light-emitting diode, this upward electric field is considered to improve the efficiency of the devices. Summarizing the XPS, UPS and NEXAFS results, the Li/F8BT interface model at 300 K is derived.

In comparison, the XPS and UPS evolution of Li/F8BT interface at 90 K indicate that the diffusion effects and chemical reactions are reduced. In addition, no S segregation or upward electric field is observed. Moreover, a downward interface dipole and the binding energy shift differences between C 1s, N 1s and S 2p are observed. No gap states appears at Li/F8BT interface, implying the possibility of improving device performance by building a "sharp" interface.

In the other hand, we developed a new method to get clean graphene/polymer interface without using PMMA or thermal release tape. NEXAFS and SRPES results

show that both the diffusion of metal atoms and the chemical reactions between metals and polymers can be reduced by a single layer graphene.

SiC Nanophotonic SiC multilayer filters for Bridging the Visible Spectrum to the Telecom Gap

T05 Electronic Materials and Processes

#EMP-2-Or-4

M.A. Vieira ¹, V. Silva ¹, P. Louro ², M. Vieira ².

¹DEETC-ISEL - Lisbon (Portugal), ²CTS-UNINOVA - Lisbon (Portugal).

Expanding far beyond traditional applications in optical interconnects at telecommunications wavelengths, the SiC nanophotonic integrated circuit platform has recently proven its merits for working with visible range optical signals. These systems are capable of addressing applications including industrial process, medical diagnostics, and free-space communication. Reconfigurable wavelength selectors that allow for operation on a large number of wavelength channels, with dynamic response, are essential sub-systems for implementing reconfigurable WDM networks and optical signal processing.

In this paper we demonstrate an add/drop filter based on SiC technology. Tailoring of the channel bandwidth and wavelength is experimentally demonstrated. The concept is extended to implement a 1 by 4 wavelength division multiplexer with channel separation in the visible range.

Experimental optoelectronic characterization of the fabricated devices is presented, Fig.1, and shows the feasibility of tailoring channel bandwidth and wavelength. The device consists of a p-i'(a-SiC:H)-n/p-i(a-Si:H)-n heterostructure with low conductivity doped layers [1]. Several monochromatic pulsed lights, separately (input channels) or in a polychromatic mixture (multiplexed signal) at bit rates between 500 bps and 12000 bps illuminated the device. Independent tuning of each channel is performed by steady state violet optical bias superimposed either from the front and back sides of the add/drop filter. Results show that, front background enhance the light-to-dark sensitivity of the long and medium wavelength channels and quench strongly the others. Back violet background has the opposite behavior; it enhances channel magnitude in short wavelength range and reduces it in the long ones. This nonlinearity provides the possibility for selective removal or addition of wavelengths. It provides a low-cost solution to many aspects of optical and optoelectronic interconnection technologies and architectures according to their suitability of use in optical cross connections (OXC), switches and routers.

Results show that the WDM demonstrated here is ideally suited for inter-chip level communications since it is implemented on a SiC platform. The large interference suppression also ensures minimal crosstalk between adjacent WDM channels. An optoelectronic model gives insight on the system physics. A numerical simulation, having as input parameters the experimental data, is presented and explains the light filtering properties of the add/drop filter, under different electrical and optical bias conditions.

EMP-P3-18

Hydrogen gas sensor based on metal insulator semiconductor fabricated with nanostructured porous silicon.

T05 Electronic Materials and Processes

#EMP-P3-18

H. Seba.

USTHB - Algiers (Algeria).

As a colourless, odourless flammable gas hydrogen cannot be detected by human senses, and other means are therefore required to detect its presence and quantify the concentration. Rapid and accurate hydrogen gas concentration measurement is essential to alert to the formation of potentially explosive mixtures with air. However, there is a continued need for faster, more accurate and more selective detection of hydrogen gas in various areas of industry for monitoring and controlling hydrogen concentration. Alternative hydrogen detection methods employ instruments such as gas chromatographs, mass spectrometers. These instruments are relatively large, expensive, high maintenance and slow in terms of their sampling and reaction times. Hydrogen sensors are transducer devices that detect hydrogen gas molecules and produce an electrical signal with a magnitude proportional to the hydrogen gas concentration. Hydrogen sensors have several advantages over the conventional hydrogen detection methods mentioned above, including their lower cost, smaller size and faster response. These advantages make them more suitable for portable and in situ hydrogen detection in a range of applications. Porous silicon (PS) can be used as an alternative material for hydrogen sensor, operating at relatively lower temperature including the room temperature. The interest in this material is mainly due to its extremely high surface to volume ratio, the ease of its formation and the compatibility with the silicon IC technology. This communication reports on the development of the hydrogen sensor based on the metal oxide semiconductors (Ag/SiO₂/PSi/c-Si) structure. The effect of porous silicon porosity on the I-V characteristics and the effect of hydrogen gas on the electrical properties (C-V characteristics) of a porous silicon sample are studied. The nano-porous layers for different porosities were prepared from p-type monocrystalline silicon (100) wafer of the resistivity (20–50 ohm.cm) by electrochemical etching in a solution of a hydrofluoric acid HF (48%) ethanol (99.9%) of 1:1 (by volume) and current density are varied from 10 to 100 mA/cm² for 15 minutes. After etching, the samples were

rinsed with deionised water and dried in air at room-temperature. The as prepared samples are annealed at the temperature of 150°C in oxygen atmosphere under vacuum (10^{-3} torr) in order to replace the unstable Si-H_x by stable Si-O bonds. Silver was thermally evaporated under vacuum (10^{-5} torr) for ohmic contact at the bottom of p-silicon surface and the metal-insulator-semiconductor MIS structure are formed by evaporation of Ag on the top of samples. Porous silicon layer morphology was observed by a Phillips X 30 scanning electron microscope (SEM). I-V measurements were carried out in a vacuum cryostat using a high precision Keithley 617 programmable electrometer. For C-V measurements the sensor was placed in a stainless-steel vacuum chamber kept at room temperature and connected by a valve gas bottles containing hydrogen this measurements were performed using an Hp 4192A LF impedance analyzer 5HZ-13Mhz. I-V measurements show an increase of the current values when the porosity of the layers increases. The characterisation of the sensor is undertaken at 1 MHz. We have found that the values of capacitance versus bias voltage (C-V) changes proportional to the hydrogen gas concentration.

EMP-P3-15

Nickel nano-particle synthesis by reactive RF thermal plasma

T05 Electronic Materials and Processes

#EMP-P3-15

H. Choi ¹, H. Na ¹, D. Kim ², W. Lee ¹.

¹Rare Metal R&D Group, Korea Institute of Industrial Technology (KITECH) - Incheon (Korea, republic of), ²Green Transformation Technology Center, Korea Institute of Industrial Technology (KITECH) - Daegu (Korea, republic of).

Metallic nano-particles have been extensively studied to utilize their superior electrical/thermal conductivity and size dependent properties for printable electronic components manufacturing. Nickel nano-particle is a representative example for multi-layered ceramic capacitor fabrication or magnetic applications. A complementary synthesis method needs to be developed to be compatible to size reduction and purity of Ni particle though most of Ni nano-particles have been synthesized by liquid base processes. In the present study, RF thermal plasma synthesis of Ni nano-particle was conducted and mass feeding rate of feedstock was considered as regards size manipulation.

Nickel hydroxide micro-powder was chosen for solid feedstock because of its favorable thermo-physical properties. Feedstock powder was fed into argon-hydrogen thermal plasma with mass feeding rate increasing at 1, 5 and 20 g·min⁻¹. After the process, as-synthesized particles were characterized.

As-synthesized nano-particle characteristics are shown in Fig. 1. Through the argon-hydrogen thermal plasma, β -Ni(OH)₂ micro-particle is fully transformed to γ -Ni nano-particle via dehydration, vaporization, reduction, and condensation reaction.

Considering sluggish heterogeneous reduction and bulk vaporization, vaporization rate may be faster than solid state reduction during the rapid heating reaction. Cooling vapor reaches a critical super-saturation state above which condensing matter is stably growing. Figure 1 (f) shows that mean particle size is increased as feed-rate increases. Within the scope of this study, most feedstock was vaporized regardless of mass feed-rate. Therefore, concentration of Ni gaseous species increases with mass feeding rate increasing. It results in the high temperature shift for starting condensation. Coalescence rate is increased as colliding particle temperature is higher. Accordingly, coarser nano-spheres are frequently observed as mass feeding rate increases.

W and Cu composite materials are used for thermal and electrical managements of electronic components owing to their high thermal/electrical conductivity and compatible thermal expansion coefficient to ceramic materials. While W-Cu composites are generally fabricated as bulk materials, thick film is deposited on alumina substrate by screen printing and sintering process in this study. To do this, W-Cu nano-particle was prepared by feeding a blended feedstock of tungsten trioxide micro-powder and cupric oxide micro-powder into argon-hydrogen thermal plasma. RF thermal plasma synthesis of nano-particle belongs to vapor phase condensation technology. Nano-particle is synthesized by condensation from cooling vaporized species. The weight fraction of cupric oxide is 20 wt.%. Using the synthesized nano-powder, paste for printing was prepared and thick film was deposited as shown in Figure. W-Cu composite nano-particle is composed of α -W, β -W, and Cu phase and nano-cube and nano-sphere are observed. Overall chemical composition was relatively consistent to the target chemistry. As-printed thick film was dried and binder was burned out before sintering. The pre-treated thick film was sintered at 1,000 °C, 1,200 °C, 1,300 °C, and 1,400 °C in a reducing environment. According to the sintering temperature, morphological changes and phase evolution were investigated by x-ray diffractometry and scanning electron microscopy. Furthermore, transmission electron microscopy was conducted for specimens that were sampled by focused ion beam method in order to verify interfacial features between tungsten and copper and between film and substrate.

Materials with a high on-off resistance ratio could become the basis for resistive random-access memory (RRAM). Such a “storage class memory” would revolutionize the information technology industry as outlined in [1-3]. One type of RRAM can be based on hybrid organic–inorganic systems, mainly consisting of inorganic nanoparticles (NP) blended into an organic matrix. The evolution of the morphology and the electronic properties of the hybrid organic-inorganic systems composed of Al, Ag and Au nanoparticles (NP’s) distributed in an organic matrix, copper phthalocyanine (CuPc), as a function of nominal metal content was studied by transmission electron microscopy and by surface- and bulk sensitive photoelectron spectroscopy. Gold atoms deposited onto the CuPc surface diffuse into the organic matrix and self-assemble to NP’s [4]. There is no formation of a continuous metallic Au film on top of the CuPc film up to large nominal coverages of about 130 Å. Gold atoms are assembled to well defined NP’s with metallic properties. Strong difference in morphology and electronic properties were observed for aluminum nanoparticles formation. E.g., on the very first stage of aluminum deposition, aluminum atoms show strong chemical interaction with substrate atoms. The properties of the nano-composite thin-film are supposed to be significantly dependent on their microstructure, i.e. the size, concentration, bulk- and size-distribution of

nanoparticles.

By using electric field induced optical second harmonic generation (EFISHG) is a method that allows electric field distributions in organic semiconductor devices to be directly probed. In this study, by using this system, we studied the rectifying property of organic double-layer diodes with a structure of indium-tin-oxide/polyimide/6,13-Bis(triisopropylsilylethynyl)-pentacene/gold (ITO/PI/TIPS-pentacene/Au). Before and after stress biasing the diodes, we measured the current-voltage and capacitance-voltage characteristics, and then the EFISHGs at various pulse voltages. Based on electrical measurements, these are difficult to discuss the physical meaning of these characteristics without knowledge of the electric field distributions in the diodes. However, results of EFISHG measurements probe the change of electric fields in the TIPS-pentacene layer. We can discuss the rectifying mechanism of organic double-layer diodes of electrode charging, carrier injection and carrier transport. These were well traced with time, depending on the d.c. biasing applied to the diodes. Accordingly the electric field distributions in the ITO/PI/TIPS-pentacene/Au diodes with accumulated charges at the PI/TIPS-pentacene interface were allowed to be determined. Analyzing the carrier behavior in ITO/PI/TIPS-pentacene/Au on the basis of the Maxwell-Wagner model, we discussed the rectifying property of the organic-double layer diodes in terms of d.c biasing effect, i.e., threshold voltage shift, and concluded that space charge limited current flowing across the PI layer governs the rectification of the diodes. Using the EFISHG measurement is an effective way to study the rectifying property of organic double-layer diodes.

EMP-P3-05

Structural and electrical characteristics of Ni/Lu₂O₃/TaN capacitors for analog IC applications

T05 Electronic Materials and Processes

#EMP-P3-05

C. Chuch, S. Mondal, T.M. Pan.

Chang Gung University - Taoyuan (Taiwan, republic of china).

Following the downscaling of the component size, a high density metal-insulator-metal (MIM) capacitors are needed for analog, radio-frequency, and mixed signal applications [1]. In addition, a small value of voltage coefficient of capacitance (VCC) is also required for this high precision semiconductor microelectronic circuit. Several high-k dielectrics, such as Sm₂O₃ [2], HfO₂ [3], and TiO₂ [4], have already been investigated to serve this goal. Unfortunately, increasing the k value usually decreases the conduction-band offset to the metal electrode, which arises problems of poor thermal leakage current, high VCC, and hence reliability issue. In Fig. 1, no Lu₂O₃ peak was found in the XRD patterns, suggesting that thin Lu₂O₃ film is amorphous. The insets of Figs. 1 show the core level O 1s and Lu 4d_{5/2} spectra with their appropriate peak curve-fitting lines of Lu₂O₃ thin film. Fig. 2 shows the capacitance–voltage (C–V) and current density–voltage (J–V) characteristics of the Ni/Lu₂O₃/TaN capacitors for different Lu₂O₃ film thicknesses. The k value of Lu₂O₃ dielectric was estimated to be ~12.8. The Ni/Lu₂O₃/TaN device for a 15 nm Lu₂O₃ film exhibits better electrical characteristics including a high capacitance density of 7.5 fF/μm² and a low leakage current density of 5×10⁻⁸ A/cm² at -1 V.

In this study, we report on the microstructural, morphological and electrical properties of (50 nm)Cr/Au(100 nm) contacts to p-GaN by electron microscopy, X-ray analysis and I-V measurements. Tested contacts were annealed at the temperature of 400, 600, 700 and 900 °C for 10 min in vacuum.

As shown by TEM studies the interface of the as-deposited sample is laterally homogeneous and sharp. 600 °C was the temperature at which we first observed large, but shallow grains grown into the GaN parallel to the interface. EDS analysis confirms the presence of a Cr-rich phase containing also a little amount of Au (twice more Cr than Au) in the ingrowth. Our analysis revealed that Cr and Au diffused into the p-GaN layer. After further annealing at 700 °C numerous grains had grown in the GaN. Crystalline grains developed in the ingrowths, revealed by dark field (DF) images. XTEM investigations of the p-GaN/Cr/Au contact revealed that some new crystalline phases developed in the mixed metal layers at 900 °C.

The surface showed a near featureless morphology up 600 °C, revealed by FESEM. The metal layer began to blister off and ball up during the heat treatment at 600 °C. Tiny grains (AuGa) – contained mainly Au and Ga – have arisen on the surface at 900 °C revealed by FESEM-EDS. Furthermore small metal free holes and voids have formed on the surface as well.

In the XRD plot of the sample annealed at 600 °C in addition to the peaks which were observed in the as-deposited and 400 °C annealed sample, there are little extra peaks which indicate the formation of new interfacial phases. These phases are identified as CrN phases. The first intermetallic phases were observed after

annealing at 600 °C, only. These CrN extra peaks became much bigger at 700 °C. Au₇Ga₂ phases appeared at 900 °C. The appearance of the Au₇Ga₂ phase is an indication that Au diffused to the GaN and reacted with it.

The as-deposited and heated up to 700 °C Cr/Au contacts on p-GaN exhibited nonlinear behaviour. Annealing at 900 °C degraded the electrical behaviour. Au metal layer is resistant to oxidation. However, diffusion of Au to the contact/nitride interface resulted in a degraded contact.

Previously examined as-deposited and annealed Cr/Au contacts on n-type GaN are rectifying up to 600 °C. After heat treatment in vacuum at 700 °C and 900 °C the Cr/Au contacts were linear. It is interesting, that in the case of Cr/Au contacts to n-type GaN the formation of CrN phase was not observed upon annealing.

The electrical properties of the contacts can be correlated to the solid phase reactions between the components.

Effects of Bi doping on the multi-phase changing properties of InSbTe

T05 Electronic Materials and Processes

#NST-2-Or-11

M. Choi ¹, J. Ahn ¹, Y.T. Kim ².

¹Hanyang University - Seoul (Korea, republic of), ²Korea Institute of Science and Technology - Seoul (Korea, republic of).

Phase change materials based on chalcogenide such as GST, GeTe, SbTe, and InSbTe have been extensively investigated for phase-change random access memory (PRAM). Among various chalcogenides, we have been investigating the InSbTe alloys as a most promising candidate for multi-level cell (MLC)[1]. According to our previous results, the InSbTe (IST) is more stable than the GST that is known as the best material for PRAM because the IST has high crystallization temperature (T_x) and activation energy (E_a). In this work, we have tried to improve the multi-phase changing properties of IST by doping Bi atom in the IST. The Bi doped IST shows 4 different crystallization temperatures. The T_x on the first crystallization point is lower than the T_x on the same point of the undoped IST, and other phase transformation temperatures become to be lower comparing the undoped IST. With increasing Bi content, the T_x becomes to be more reduced. Moreover, the E_a derived from Kissinger's formula[2] is also reduced along with T_x . We have fabricated PRAM cell devices to confirm the multi-level electrical properties of the Bi-doped IST. The resistance ratio between the amorphous and the crystalline state is more than three orders of magnitude, the Bi doped IST cells perform multi-level operating characteristics and the resistance difference derived from the I-V characteristics seems to be obviously distinguishable owing to the multi-level phase transformations. The threshold voltage (V_{th}) of the Bi-doped IST cell is clearly lower than that of the undoped IST, which means that the Bi-doped IST PRAM cells might be operated with lower power consumption. To confirm the endurance and reliability of test devices, we have measured the set/reset cycling by nanoscale electrical pulse and the endurance shows more than ~103 cycles. In this work, we will discuss the effects of Bi doping on the atomic structure of IST with high resolution TEM.

The opportunity to achieve high performance has become the motivation for extensive studies of solar cells with amorphous silicon/crystalline silicon (a-Si:H/c-Si) heterojunctions [1]. For outstanding performance, the quality of the a-Si:H/c-Si heterointerface and a-Si:H emitter have to be optimised. This paper focuses on the investigation of a-Si:H(n)/c-Si(p) structures with emitter prepared by ICP and PECVD deposition techniques. Prepared samples were investigated using SIMS, Raman spectroscopy and electrical C-V-F and C-T- ω diagnostic techniques. Results were completed by the dark and light I-V characterization and influence of post-annealing on the solar cell performance. Important information for post-deposition processing and applications in concentrator systems is the influence of the temperature treatment. To inspect this behavior, samples were annealed on the air at various temperatures in the range 160 - 400 °C for 30 minutes for each step and analyzed in term of the structure modification, interface quality and output performances. To get the full profile information about the structures they were analyzed using SIMS instrument (Ion-TOF, SIMS IV) with high-energy Bi⁺ primary source with combination of low energy Cs⁺ sputter gun as shown in Fig.1. The capacitance diagnostic results indicated superior heterointerface properties for ICP samples. Measured was also better output performance on these samples. Samples exhibited photovoltaic behavior even after high temperature treatment on the air (Fig. 2).

Electronic properties of metal/graphene/n-Silicon interfaces

T05 Electronic Materials and Processes

#EMP-1-Or-6

C. Troadec.

Institute of Materials Research and Engineering - Singapore (Singapore).

Graphene, a zero-band gap semiconductor consisting of a single layer of carbon atoms arranged in a honeycomb lattice, has been described as a “wonder material” for many applications due to its superior electronic properties[1], [2]. Most of the early research on graphene focused on the in-plane properties of graphene and only recently, vertically stacked graphene devices[3] were studied. Electronic properties of graphene are greatly influenced by external contacts and understanding the buried interface of metal/graphene/silicon is essential in the fabrication of graphene devices. We use Ballistic Electron Emission Microscopy (BEEM) [4], a variant of scanning tunnelling microscopy (STM), which is currently the only technique that is capable of measuring the electronic properties of buried interfaces with nanometer spatial resolution [5] to probe and measure the buried interface of metal/multilayer graphene/silicon.

We will present results including current-voltage (I-V) measurements [Fig1] and BEEM measurements of Schottky diodes of the form Metal/n-Si(111) and Metal/multilayer graphene/n-Si(111). By varying the thickness of multilayer graphene, significant differences can be observed in the device characteristics. Dual parameter BEEM[Fig2] measurements [5] is sensitive enough to detect the presence of graphene, unlike I-V. The BEEM spectra and images suggest that although multilayer graphene has a minimal impact on the barrier height, ballistic transmission properties of the device interface was reduced. The effect in the number of graphene layers on the transmission factor will also be presented.

In the early 1990s, the use of telecommunication services such as mobile phones and the Internet was marginal. The heterojunction component are well positioned to meet the demand for operating speed and low noise, among these components, the heterojunction bipolar transistor Si/ SiGe/Si [1].

The rate of Ge at the entrance of the base affects the height of the heterojunction, is therefore significantly change the characteristics of static and dynamic component [2]. A high rate of Ge in the base will provide greater value of f_T by increasing I_C , which in turn helps to increase the base doping to increase f_{max} [3].

This paper deals the impact of a gradual germanium SiGe HBT in the electrical characteristics of the dynamic characteristics especially the f_T and f_{max} determining the RF performance of the component. The rate of Ge at the entrance of the base has an influence on the bands gap, the intrinsic material density and height of the heterojunction. We present a numerical modeling of an NPN (SiGe) SiGe HBT realized in BiCMOS9G technology industrial: 0.13 μ m process, taking into account the gradual profile of germanium in the SiGe alloy 10-30%, 15-30%, and 20-30% (figure 1 and 2). We used our device simulator "SIBIDIF", two dimensional Drift-Diffusion Model (DDM) simulators. It solves the continuity equations for electrons and holes, coupled with the Poisson's equation.

In this work we investigate the transport and magnetic properties of a system constituted by two quantum dots with a local Coulomb interaction U which are interconnected through a chain of N non-interacting sites and individually coupled to two metallic leads. To perform the task we use two different approaches: the slave boson mean field approximation and a new method which is based on numerical diagonalizations of large clusters, using a multiconfigurational set of states constructed from Hartree Fock orbitals and enlarged properly by iterative application of the full Hamiltonian.

We studied the system in different regions of the parameter space for which we calculate many physical quantities, namely local density of states (LDOS), conductance, total spin and spin correlations. The results revealed a very rich physical scenario which is manifested by at least two types of Kondo regimes, corresponding to $s = 1/2$ and $s = 1$ respectively. We study the extension of the Kondo cloud in both regimes. Kondo

temperature depends on the parity of N . For odd N it is larger than for an even length. We provide an explanation of this fact, observed in recent experiments [1], in terms of a two temperatures Kondo regime.

Effect of periodic structure application on the light emitting diode (LED) surface is well known. Improvement of optical properties of LED such as directionality, far field profile or light extraction efficiency has been already demonstrated by implementation of periodic structures in LED surface [1-4].

The principle of LED light extraction efficiency improvement due to the planar structure introduced in the surface layer is twofold: it is based on the diffraction on the structure roughness [1, 2], or it is due to the photonic band gap effect generated by the structure [3, 4]. Although the effect of periodic structure on the light extraction efficiency is well documented, LEDs with predefined patterning have not been investigated yet. The predefined structure is arbitrary planar pattern prepared in the LED surface; therefore it is not necessarily periodic.

From the diffraction on roughness-based effect it can be suggested, that implementation of predefined planar structure allows local enhancement of light emitting from the LED surface. Application of such structures can be attractive for local enhancement of light from defined areas of the LED surface. Also predefined structure with specific properties is able to modify near- and far-field radiation characteristics [5].

We used optical and ion beam lithography techniques for patterning of the surface of GaAs/AlGaAs based LEDs. The structure was patterned in the upper confinement AlGaAs layer. Surface of the structures was analyzed by employment of scanning electron microscope and atomic force microscope. The overall emission properties of prepared LED with predefined structure in the emitting part were investigated by near- and far-analysis.

EMP-2-Or-10

Investigation on oxygen diffusion in a high-k metal-gate stack for advanced CMOS Technology by XPS

T05 Electronic Materials and Processes

#EMP-2-Or-10

A. Kechichian ¹, P. Barboux ¹, M. Gros-Jean ², F. Martin ³.

¹École Nationale Supérieure de Chimie de Paris, 11 rue Pierre et Marie Curie - Paris (France), ²STMicroelectronics, 850 rue Jean-Monnet - Crolles (France), ³CEA-Leti, 17 rue des Martyrs - Grenoble (France).

In the late 2000s' the 32nm Coupled Metal Oxide Semiconductor (CMOS) technology node required the use of a high-k dielectric with a metal gate instead of the historically used silicon dioxide and polysilicon. The aim was to reduce the leakage current between the gate and the channel which became critical for silicon-based gate stacks [1]. However using a high-k metal-gate architecture makes the control of the electrical properties of the transistor really challenging. Indeed the high-k material strongly interacts with its environment during the manufacturing process, which thoroughly changes the device properties.

Parameters such as the threshold voltage or the Equivalent Oxide Thickness are not only related to a material selection, but are also subject to modification due to the oxygen diffusion throughout the stack [1,2]. The understanding of the oxygen diffusion dynamics hence becomes mandatory.

Our work has been performed inside a cutting-edge STMicroelectronics cleanroom. It focuses on the annealing effects with regard to the oxygen diffusion throughout the stack TiN/HfO₂/SiO₂/Si. For that purpose, a blank 300mm Si (100) wafer undergoes an oxidizing wet treatment to create an 8Å chemical oxide on its surface. 2nm of HfO₂ are deposited onto this wafer by MOCVD with an Applied Material Centura. The annealing processes are made at low pressure (5 torr), with a N₂ saturated atmosphere containing 1ppm of O₂, at 450°C and 900°C for 60 seconds. The experiment is renewed with 2nm of TiN deposited on the top of the stack by RF-PVD with an Applied Material Endura tool at low temperature (< 50°C), in order to avoid any thermally activated parasitic reactions. All the samples are characterized with a ReVera VeraFlex II XPS tool as fast as possible after the annealing process.

The results show that the annealing without the TiN metal has no noticeable effect with regard to oxygen diffusion, especially at the HfO₂-substrate interface. However as soon as TiN is deposited, the Si2p spectra show an increase of the characteristic signature of SiO₂ after annealing at any temperature. This clearly indicates the diffusion of some oxygen towards the silicon substrate. Besides, Hf4f spectra show no major changes, but the Ti2p spectra decomposition reveals that the Ti-O component decreases with the annealing process for all the temperatures.

Our hypothesis is that an equilibrium exists between the reduction of the native TiO₂ oxide on top of the TiN by the substrate, and the oxidation of the TiN by the ambient O₂. The TiN splits up the ambient O₂ into a monoatomic oxygen, which will migrate across the HfO₂ layer towards the substrate. This effect is discussed as a function of the HfO₂ layer thickness.

We finally propose a discussion based on the existence of a battery-like system formed by electrochemical couples separated by a solid electrolyte (HfO₂). Electrodes are formed as a gas-metal electrode formed by the TiN-N₂: 1 ppm O₂ separated from the Si/SiO₂ redox system. This stack accelerates the oxidation of the silicon.

Silicon (Si) wafering is one of critical processes that determine production-cost of solar cell. Typically, wafering process accounts for more than 30 % of total production cost of Si solar cell. Thinner wafer results in lower wafering cost because the number of wafers produced from an ingot increases. Therefore, various processes have been developed to decrease a thickness of Si wafer. Multi-wire sawing is widely used process for wafering, but breakage of wafer during the process is serious problem when its thickness was lower than 150 μm . Multi-wire sawing system was set up and sawing process was researched to decrease the thickness without serious breakage. Single-crystalline Si wafer with thickness of 100 μm was successively sawn by using metal-coated wire (120 μm) and SiC abrasives (20 μm). Microstructures of sawn wafers were investigated to decrease the breakage. It was noticeable that breakage decreased from 54 % to 26.4 % by modifying the process and polishing ingot's surface, which prevents initial cracks formed on ingot's surface. Si-solar cell was fabricated using this wafer to evaluate the photoelectric conversion efficiency and efficiency of 17.8 % was obtained. Consequently, multi-wire sawing process in this study was effective for the thin single-crystalline Si solar cell with the thickness lower than 120 μm .

The growth of carbon nanotubes (CNTs) inside silicon vias has been investigated [1]. This pilot study is part of a larger project to demonstrate the feasibility of filling through silicon vias (TSVs) with a Cu/CNT matrix. The motivation for this work is in improving the electrical and mechanical reliability of TSVs. Currently, Cu filled TSVs have some limitations in terms of electromigration, areas of high stress in the via, and lack of mechanical compliance. The process flow for achieving CNTs in blind vias includes four main steps: 1) patterning the bare Si wafer by photolithography; 2) deep reactive ion etching (DRIE) to form the blind via; 3) depositing the catalyst layer; and 4) growing vertically oriented carbon nanotubes. The via diameter is in the range of 20-25 μm and the vias are etched to a depth of 100 μm resulting in aspect ratios of 4-5. This via diameter is somewhat larger than is currently used in interposer technology; however, these dimensions facilitate experimentation while investigating a new material system. We have used both Bosch DRIE etching and inductively coupled plasma (ICP) cryogenic etching to achieve a via profile which includes a tapered via sidewall. The tapered profile assists in deposition of conformal thin film layers inside the via. For the catalyst layer, 15 nm of Al_2O_3 is deposited by atomic layer deposition (ALD) and 2-4 nm of Fe is deposited by electron beam evaporation. Carbon nanotubes were grown using a thermal chemical vapor deposition (CVD) process at Argonne National Lab with $\text{Ar}/\text{H}_2/\text{C}_2\text{H}_4$ gases flowing through the quartz chamber. Previous to growth, annealing in a hydrogen ambient was found to be critical for achieving successful CNT growth. According to transmission electron microscopy (TEM), the CNTs are single walled and have some amorphous or graphitic carbon deposited on their sidewalls. Figure 1 shows CNTs growing out of

the top of a blind via in silicon. Once our process flow is optimized and process repeatability is observed, deposition of a seed layer and electroplating copper inside the via will complete the Cu/CNT matrix. The material system will then be ready for electrical and mechanical characterization.

This research was partially sponsored by ARL (Cooperative Agreement No. W911NF-10-2-0093) and NSF (CMMI-1234652). The Center for Nanoscale Materials at ANL was supported by the U. S. DOE, Office of Science, Office of Basic Energy Sciences, Contract No. DE-AC02-06CH11357.

Apart from other transparent conductive oxide (TCO) materials, Zinc Tin Oxide (ZTO) is a very promising candidate among the TCO. ZTO has the advantage of good stability at high temperature and unlike other popular TCOs such as ITO and Cd-Sn-O, ZTO films do not contain expensive or toxic elements. Another advantage of ZTO is its low sensitivity towards visible light. In many organic and hybrid devices ZTO thin films are used as the cathode or electron transport layer. So far, the etching of ZTO thin films is often done through wet chemical etching using hydrochloric acid (HCl). However, the wet etching process causes the problem of isotropy and selective-grain boundary etching [1]. For these reasons, stable dry etching process with high etch rate, selectivity is needed. Therefore, stable dry etching process with high etch rate and selectivity of ZTO thin films in chlorine-based plasma is studied for the organic and hybrid devices. Chemical reaction of the etched ZTO surface has been studied by x-ray photoelectron spectroscopy measurement (XPS). Surface morphology of the etched ZTO thin films was characterized using atomic force microscope(AFM).

First principle study of structural, electronic and optical properties of $\text{InS}(1-x)\text{Se}(x)$ alloy

T05 Electronic Materials and Processes

#EMP-2-Or-5

I. Ben Amara, R. Bennaceur.

faculté des sciences Tunis El Manar, Campus universitaire - Tunis (Tunisia).

III-VI compounds become an area of great technological activity, and attracted attention on account of their semiconducting nature and applications in optoelectronic devices, in non linear optic devices such infrared detectors and as electron exchange electrodes in solid-state batteries, and in photovoltaic domain as solar cells compounds. In the recent years, there is strong interest on the III-VI family related to the success of I-III-VI laser semi-conductors which allow the construction a variety of a solar cell used as optic windows. It is known that the major goal in materials engineering is the ability to change artificially the electronic and optical properties of semiconductors and this is assured by forming their alloys. Thus, it appears very interesting to combine two different III-VI compounds with different optical band gaps in the aim to produce novel materials, with intermediate physical properties, used in the future scientific investigations.

Keeping this in mind, we are motivated to study the ground-state properties of the ternary alloy $\text{InS}(1-x)\text{Se}_x$, for several Selenium compositions. We have investigated their structural, electronic and optical properties within a framework of density functional theory (DFT) [1]. We have performed our calculations using Full-Potential linearized augmented plane wave plus local orbital (FP-LAPW+lo)[2] embedded in WIEN2k package .The exchange-correlation potential is treated by generalized gradient approximation (GGA) [3] for the optimized structures. Whereas the Engel-Vosko GGA [4] is applied to approximate the corresponding potential for bands structure calculations. Our investigations on the effect of Se concentration on lattice constants, ionicity factor, band gap, and some optical constants for ternary alloys shows non-linear dependence on the composition x . Deviation of the lattice parameters from Vegard's law is explained and the microscopic origin of gap bowing are identified and calculated by Zunger approximation [5]. We have also calculated the total and partial densities (DOS and PDOS) for every molar fraction x .The imaginary and real dielectric function are determined and the optical constants such

as refractive index $n(\omega)$, absorption coefficient $\alpha(\omega)$ and electron energy-loss function $L(\omega)$ are interpreted. Our results are compared with previous works.

Complementary hole-transporting (p-channel) and electron-transporting (n-channel) materials are both needed to achieve all-organic circuits. Only a few examples of robust n-channel materials are known, and most suffer from threshold voltage shifts due to charge trapping. Unlike hole-transporting materials, for which oxidation of the bulk is key to performance degradation, the concern for electron-transporting materials is the radical anion reactivity.

If the n-channel material's LUMO level is above -4.0 to -4.3 eV, then the radical anion is susceptible to reaction with O₂; the long-term stability of the resulting reaction products is still unclear [1]. Similarly, for high-LUMO n-channel materials deposited on untreated silicon dioxide, the radical anion is expected to react with dangling Si-OH groups to yield long-lived traps on the dielectric surface [2]. Other trapping mechanisms, such as traps at chemical impurities or physical defects, are plausible for any LUMO level.

Here we report studies of charge trapping in several perylene diimide derivatives by time- and wavelength-resolved electric force microscopy (EFM). The spatial distribution and kinetics of trapped charge measured by EFM can identify the trapping mechanisms at play. We moreover use EFM coupled with wavelength-resolved illumination to measure the first-ever trap-clearing spectra in perylene diimides (PDIs) (Fig. 1). Such spectra have been shown to offer insight into which chemical species are involved in neutralizing traps [3].

Thin films of NKN (Na_{0.5}K_{0.5}NbO₃), produced by laser ablation of stoichiometric ceramic targets, have shown an increase of polycrystalline structure and increase in ferroelectric quality, when the substrate temperature is raised from room temperature up to 600 °C. However, increasing loss of Na and K can occur. Alkali deficiency, a common problem in different deposition methods of NKN thin films, has been quantified by several methods. XPS analysis, using Mg K α line, confirmed the loss of alkali atoms at deposition temperatures beyond 400 °C. The analysis takes the intensities of the Na 1s peak at 1071.0 eV, the K 2p doublet with the -2p_{3/2} peak at 293.4 eV, and the Nb 3d doublet with -3d_{5/2} peak at 206.0 eV into account. Considering the charge states, we suggest that excess of Nb and O might be present in the form of NbO₂.

Detailed information of the morphology and structure of the films was obtained from confocal Raman spectroscopy. The lateral resolution allowed us to scan domains with submicron precision. The change in film structure observed by SEM is accompanied by a shift of the Nb-O-octaeder stretching mode at an energy of 615 cm⁻¹, suggesting a change in internal stress of the films. Two further strong peaks [1] present in the ceramic NKN targets at 260 cm⁻¹ and 852 cm⁻¹, are either low in intensity in the films or they do not change position. These results are correlated with XRD diffraction data to identify the possible content of non-stoichiometric NKN components.

Interface between organic semiconductor and dielectric is an important key requirement to survey the mechanism of carrier transport properties, because only few molecular layers at the interface govern the intrinsic feature in organic field effect transistors (OFETs). In spite of their technological importance, the fundamental questions, which are to be revealed, still remain. We investigated the origin of nonlinear transport in a highly ordered regioregular poly(3-hexylthiophene-2,5-diyl) (P3HT) monolayer.

P3HT monolayer prepared by liquid crystal hybridized Langmuir-Blodgett method [1] was deposited on flattened metal electrodes [2]. Titanium-gold with sub-micro channel width of 0.5-2 μ m and length of 0.1-0.5 μ m was embedded in 100nm thick SiO₂ grown on a highly doped Si substrate. The height difference between the metal and SiO₂, less than 1 nm, minimizes the deformation of deposited molecular layer. The devices work as OFETs with typical mobility of 0.002–0.2cm²V⁻¹s⁻¹ at 300K. The contact resistance (R_c) of a device at was very small as compared to film resistance.

We investigated the temperature and voltage dependence of the charge transport through the P3HT monolayer. The current decreased as temperature decreases. The mobilities decrease following a straight line with an activation energy of 110 meV in an Arrhenius plot. Although, at lower temperatures, 4K-150K, the current characteristics exhibit significant nonlinear response to the voltage increase. What is origin of the nonlinearity? We confirmed that our data never agreed with a conventional exponential expression, which includes " $k_B T$ " in the exponential factor. We founded that the nonlinear currents have voltage threshold (V_t) and obey a power law of $I \propto (V - V_t)^\xi$, where typical gradient ξ was 3.9. Respective V_t were in inverse proportion on temperature increase. These characteristics are consistent with a Coulomb-blockade charge transport model in a two-dimensionally (2D) quantum dot array system [3]. We propose an isotropic extended-charged state, which can form a 2D quantum dot array, in P3HT monolayer based on our DFT calculation results.

Estimated self- and mutual-capacitances in the model are roughly but quantitatively consistent with our experimental data.

We conclude and strongly suggest that the Coulomb blockade effect is one of the origins of nonlinear charge transport, which is frequently observed in organic conductors.

Segregation, oxygen vacancies and waterfall behaviour in SrTiO₃ : A complete synchrotron radiation study

T05 Electronic Materials and Processes

#EMP-P3-13

A. Levy, J. Avila, E. Frantzeskakis, S. Lorcy, M.C. Asensio.

Synchrotron SOLEIL - Gif Sur Yvette (France).

The development of all-oxide electronic devices presents a quickly advancing technological field where SrTiO₃ (STO) plays a key role. An important step for oxide electronics was the discovery of a high mobility 2D electron gas (2DEG) on the LaAlO₃/SrTiO₃ interface, two otherwise insulating oxides. On the other hand, a similar 2DEG has been recently reported on the bare STO (001) surface. Among other explanations, the physical origin of the aforementioned confined electron gases has been attributed to surface oxygen vacancies.

In this communication we report on the structural and electronic properties of thermally reduced STO single crystals. We have investigated these systems using a probe with real- and reciprocal-space sensitivity: a synchrotron radiation microscopic setup which offers the possibility of Scanning Photoemission Microscopy and Angle Resolved Photoelectron Spectroscopy (ARPES) down to the nanometric scale. For the first time, we have spectroscopically imaged the chemical composition of samples presenting reproducible and suitable low-energy diffraction patterns after following well-established thermal reduction protocols. At the micrometric scale, Ca-rich areas have been directly imaged using high-energy resolution core level photoemission. Moreover, we have monitored the effect of Ca segregation on different features of the STO (100) electronic band structure, measuring ARPES inside, outside and at the interface of the Ca-rich identified areas. In particular, the interaction of Ca with the well-known intra-gap localized state, previously attributed to oxygen vacancies, has been investigated. Most importantly, the combination of direct imaging and spectroscopic techniques with high spatial resolution has clarified the long-standing dilemma related to the bulk or surface character of Ca segregation in STO. Moreover, new data will be discussed on the light of the calcium segregation, oxygen vacancies and waterfall 2DEG states.

EMP-2-In-2 VISUALIZATION AND MODELING OF CARRIER MOTION IN ORGANIC DEVICES BY ELECTRIC FIELD INDUCED OPTICAL SECOND HARMONIC GENERATION

T05 Electronic Materials and Processes

#EMP-2-In-2

M. Iwamoto.

**Department of Physical Electronics, Tokyo Institute of Technology - Tokyo
(Japan).**

Probing and modeling of carrier motion in organic materials is a fundamental research subject in science and electronics. By detecting nonlinear dielectric polarization induced in organic materials by moving carriers (electrons and holes), we can visualize and model the carrier motion. The method developed here is a novel optical method based on electric field induced optical second harmonic generation (EFISHG) measurement. In this presentation, basic concept for probing dynamical carrier motions by using EFISHG is discussed briefly, and the visualized carrier motion in organic field transistors, organic ELs, and organic solar cells are presented. After that the carrier motion is discussed based on the Maxwell-Wagener effect model analysis.

EMP-1-In-1 PLASMA ASSISTED MOLECULAR BEAM EPITAXY OF III-NITRIDE SEMICONDUCTOR HETEROSTRUCTURES AND NANOSTRUCTURES

#EMP-1-In-1

A. Georgakilas.

Microelectronics Research Group (MRG), Department of Physics, University of Crete and Institute of Electronic Structure and Laser (IESL), Foundation for Research and Technology-Hellas (FORTH) - Heraklion, Crete (Greece).

Molecular beam epitaxy employing a nitrogen plasma source is successfully used in the research and development of III-nitride semiconductor heterostructures-nanostructures. A significant advantage of the method is the supply of reactive nitrogen species independently of the used substrate temperature, which facilitates the growth of thermally unstable In-containing compounds and of far from equilibrium III-nitride heterostructures. Four important cases which will be discussed concern: (1) the growth of advanced High Electron Mobility Transistor structures, (2) the heteroepitaxy on very dissimilar substrate materials such as single crystal and polycrystalline diamond, (3) the heteroepitaxy of high quality InN layers and InGaN and InAlN alloys spanning the entire composition range, and (4) the catalyst-free spontaneous growth of III-nitride nanopillars as a bottom-up nanofabrication approach.

Atomic layer etching for next generation nanoscale device processing

T05 Electronic Materials and Processes

#EMP-2-In-1

G.Y. Yeom.

SUNGKYUNKWAN UNIVERSITY - Seoul (Korea, republic of).

Atomic layer etching is a technique that can etch materials layer by layer in an atomic layer scale. It can be applied to various materials not only the crystalline materials such as Si, GaAs, etc. but also amorphous materials such as SiO₂, HfO₂, etc. In addition, it also can be applied to the removal of 2-D materials such as graphene, etc. layer by layer. It is believed that for the next generation nanoscale device fabrication, the control of the material processing with atomic scale precision without forming any damage to the material is very important. Therefore, in this presentation, the results of atomic layer etching carried out various materials will be reported and the characteristics of the devices fabricated with atomic layer etching will be also reported.

EMP-P3-14

Attempt to manufacture a solar cell by using a simple method of n-type doping of monocrystalline silicon

T05 Electronic Materials and Processes

#EMP-P3-14

R. Ndioukane, M. Biagui, M. Tine, L.G. Ndiaye, K. Kobor.

Laboratoire de Chimie et de Physique des Matériaux (LCPM), Assane Seck
University of Ziguinchor (UAS) - Ziguinchor (Senegal).

The electrical behavior of a semiconductor device depends strongly on the dopants distribution within the structure. To make solar cells from monocrystalline silicon, it is necessary to realize a pn junction by implanting phosphorus atoms mainly on a given thickness of the p-type. Different liquid, solid, or gaseous methods are used. These methods often require equipment not available for underdeveloped countries.

In this work, we try to make mono-Si solar cells using an easier doping method. We combined spin-coating thin film deposition method and solid doping technique. This technique can be considered as the SOD method. The difference between these methods is the use of an phosphorus oxide

There are many ways of making thin films that can be classified into physical and chemical ways. The best known methods as regards the physical ways are sputtering, thermal evaporation, etc.. These methods require expensive equipment. In our study, two phosphorous-based gel compounds are prepared and deposited by spin coating. Heat treatment would thus, after deposition of thin layer, diffuse phosphorus atoms into the substrate to obtain a pn diode. I-V measurements characteristics in dark and under illumination of 1000 W give curves close to a pn diode behavior.

Keywords : Monocrystalline silicon, doping, spin coating, thin film, solar cell.

Figure 1: The SIMS profile versus time for p-type Si doped by the phosphorus oxide gel.

Effects of adding silica fume on the properties of high performance concretes subjected to high temperatures

T06 Energy and Sustainable Development

#ESD/ASS-P3-01

B. Chemani.

M'Hamed Bougara University of Boumerdes - Boumerdes (Algeria).

In this study, the compressive strengths and weight losses of the High Performance Concretes (HPC) containing Silica Fume (SF) and superplasticizer (SP) at high temperatures were investigated in comparison to Ordinary Portland Cement (OPC). For many years, the mineral admixtures have been used in Portland cement. As the silica fume is a very reactive pozzolan, it is used in the concrete because of its fine particles, large surface and high percentage SiO₂ content.

Its addition to the HPC causes significant effects on the properties of the products obtained. This paper presents the results of experimental work on physical-mechanical behavior of HPC containing different levels of silica fume after being exposed to high temperatures (100, 200, 400, 800, 900° C), without intermediate steps for a ripening cycle of 24 hours.

To achieve these objectives, different types of concrete mixtures were produced. In producing the mixtures, silica fume (SF) was used to replace the Portland cement in the ratios of 0%, 5% and 10% by weight. Half of the mixtures were obtained by adding superplasticizers (SP) to mixtures in the ratio of 1.5 and 2% by weight to OPC.

Weight losses increased from 3% to 12% following exposure to temperatures of 200 ° C and 900 ° C.

A 4% decrease in the compressive strength of concrete was recorded at 200 ° C
At 900 °C it was observed a resistance fall and a concrete spalling with adjuvants

1.5% and 2% respectively

These results show that adding the Silica Fume and the superplastizer to concrete, decreases both unit weight and compressive strength. Additionally, elevating the temperature above 600 °C affects the compressive strength such that the weight loss of concrete is more pronounced for concrete mixtures containing both SP and SF.

The optimization of water flow in the photovoltaic pumping system

T06 Energy and Sustainable Development

#ESD/ASS-2-Or-8

M. Chergui ¹, M. Bourahla ².

¹University of Mascara-Algeria - Mascara (Algeria), ²University of Oran-Algeria - Oran (Algeria).

The present work aims to achieve a better strategy for a photovoltaic pumping system using different types of solar cell technology and techniques to control induction motor for maximum optimization of the amount of water pumped operate over the sun that draws water from a well and pumped into a reservoir.

As the rapid development of semiconductor and digital technology, mainly in the control devices and power electronics, slightly improved the performance of photovoltaic systems and reduces its cost. The optimization of our system elements is based on: The design and simulation of a adequate tracking system maximum power point to extract the maximum power irrespective of the generator photovoltaic atmospheric variations (temperature and irradiation); design and simulation of a convenient inverter reliable and high performance by applying the best technique of PWM, the application of the technique uncomplicated and effective control of induction motor coupled to a centrifugal pump.

We present the essential information about solar energy, its current and future use in the world, and its impact on environmental and sustainable development, in particular the strategy photovoltaic pumping in scattered areas. We have developed several methods vector control which optimizes not only the efficiency of the photovoltaic conversion, but also, the losses in the induction motor and the optimization of the quantity of water flow.

Electrochemical performance of pre-lithiated graphite as negative electrode in lithium-ion capacitors

T06 Energy and Sustainable Development

#ESD/ASS-2-Or-9

M. Yuan ¹, W. Liu ¹, Y. Zhu ², Y. Xu ¹.

¹Research Institute of Tsinghua University in Shenzhen - Shenzhen (China),

²Tsinghua University - Beijing (China).

Recently, a relatively new type asymmetric capacitor called lithium-ion capacitor (LIC) was reported, which has storing about 5-10 times more energy than EDLC and having similar levels of high power and long cycle life[1-11]. Electrochemical performance of the pre-lithiated graphite and the as-assembled lithium ion capacitors were investigated within the Li/graphite two-electrode cell. By short circuiting technique, the Li/graphite two-electrode showed a three-stage during the Li-ion intercalation (Fig.1). The EIS spectra included only one semi-circle and a inconspicuous slash during the Li pre-doping at 1-30 h (Fig.2). The values of the ohmic resistance (R_s) and SEI layer (R_1) increased with the increasing doping time (Table 1). The cell of 8 h pre-doping time have the best cycle performance at high C rates compared with that of 1 h, 2 h, 24h and 30 h doping time (Fig.3), which showed the capacity degradation with less than 2% after 600 cycles at 10 C. Within the galvanostatic charging technique, the smaller C rate for Li intercalation gave more discharge capacity (Fig.4), which is favor to improve the electrochemical performance of the as-assembled LICs, the cycle performance of which was slightly inferior to that with 8 h pre-doping time (Fig.5). The present work provided enough information about the pre-lithiated of graphite and the electrochemical performance for the as-assembled LICs.

BLACK SILICON: MICROFABRICATION TECHNIQUES AND CHARACTERIZATION FOR SOLAR CELLS APPLICATIONS

T06 Energy and Sustainable Development

#ESD/ASS-2-Or-11

A. Deraoui.

Université Hassan 1er - Settat (Morocco).

The properties of black silicon are well suited for use in photovoltaics. We plan to use the advantages of black silicon to format new types of solar cells that will be able to capture solar energy across a wider range, thereby realizing greater efficiency in future photovoltaic cells [1–4]. The method of production has brought the use of black silicon in photovoltaic arrays closer to commercial realisation, as it will reduce the cost of black silicon production, minimize reflectivity and maximize the absorbance . The basic objective of this paper is to create black silicon by chemical wet etching techniques using Au nano particles directly formed on silicon substrates. We further decided to try to optimize this material using non-heavily photolithographic methods, such as etching. The morphology of Black Si was characterized by Scanning Electron Microscopy (SEM) and the optical properties were given thanks to Cary Spectrometer.

Low temperature stable delta Bi₂O₃ thin films grown by reactive RF sputtering

T06 Energy and Sustainable Development

#ESD/ASS-1-Or-7

P. Lunca Popa ¹, S. Sonderby ², S. Kerdsonpanya ², J. Lu ², P. Eklund ².

¹ISMO -CNRS, CNRS/Université Paris-Sud Bat.351, Université Paris-Sud F-91405 Orsay Cedex - Paris (France), ²Thin Film Division, Department of Physics, IFM, Linköping University, SE-581 83 Linköping, Sweden - Linköping (Sweden).

In recent years bismuth oxide systems have received an increased attention due to their interesting properties, particularly excellent ionic conductivity, an important asset in various technological fields as gas sensors, oxygen pumps, Solid Oxide Fuel Cells (SOFCs) and other applications where conduction by oxygen vacancies is required. SOFCs represents a valuable alternative source of energy providing large fuel adaptability and high efficiency. Current SOFCs operate at high temperatures, (800°C). Current research in the field is focused in decreasing the operating temperature to an intermediate range without affecting the efficiency. Herein we report the synthesis by reactive magnetron sputtering and structural characterization of highly (111)-oriented thin films of δ -Bi₂O₃, the best ionic conductor. Amorphous films, α , β , γ , δ phase films, metallic bismuth films or mixtures of phases were obtained depending on the deposition parameters. For a narrow window in deposition parameters with respect to deposition temperature (150-200 C) and oxygen flow (15-20% of total gas flow) values the obtained films consist in a highly oriented phase-pure δ -Bi₂O₃. Small modifications (higher temperature or oxygen flow) on the values of deposition parameters result in α -Bi₂O₃ or phase mixtures formation. Transmission electron microscopy and x-ray diffraction reveal a polycrystalline columnar structure with [111] texture. The delta films are stable from room temperature up to 250° C in vacuum and 350° C in ambient air, when an irreversible transition to monoclinic α -Bi₂O₃ crystal occurs. This low-temperature stability opens new perspectives for use as ionic conductor at low temperature in e.g. SOFCs.

Hybrid MnO₂ nanowires /Carbon Fiber Paper Electrodes in Urea-Li Salt Molten Complexes: an Outstanding Pseudocapacitive Material

T06 Energy and Sustainable Development

#ESD/ASS-P3-02

J. Chen, M.J. Deng, K.T. Lu.

National Synchrotron Radiation Research Center - Hsinchu (Taiwan, republic of china).

A simple and general approach effected the synthesis of MnO₂ nanowires /carbon-fiber paper (CFP) of Birnessite type as electrodes coupled with a Li-ion melt as electrolytes for supercapacitor applications. A unique mesoporous and nanostructured MNCFP in an urea-LiPF₆ ion liquid electrolyte-based EC can be cycled reversibly across voltage 3 V, and exhibits a great energy density 330 W h kg⁻¹. This cell exhibits a greater energy density of 50 W h kg⁻¹ even at power density 104 kW kg⁻¹. XPS and in-situ XAS spectra elucidated the mechanism of charge storage in the ion liquid The analytical results indicate that the Mn³⁺/Mn⁴⁺ transition during charge and discharge cycling was compensated by the reversible insertion of Li(urea)_n⁺ cations into, and their withdrawal from, the tunnels between the MnO₆ octahedral units. In contrast, the BMP⁺ and Li⁺ cations merely adsorbed on the electrode surface, and did not penetrate into the oxide. This work might not only provide an effective method to understand the electrochemical mechanism involving an ion liquid electrolyte but also open a new route for the development of efficient systems to store energy using metal-oxide electrodes deposited on macroporous carbon materials with ion liquid electrolytes.

Design and Fabrication of Nano-array Architecture for Supercapacitor and Electro-catalytic Reaction

T06 Energy and Sustainable Development

#ESD/ASS-P3-03

Z. Lu, X. Liu, X. Yu, X. Sun.

State Key Laboratory of Chemical Resource Engineering, P.O. Box 98, Beijing University of Chemical Technology - Beijing (China).

Nanostructure arrays, offering uniformed size, ordered structure, lower agglomeration and good connection with the substrate, have been proved as advanced and efficient electrodes in electrochemistry. Through a lot of research, our group has found that the specific capacitance, rate capability and cycling life of the electroactive material could be improved significantly by constructing the materials into nano-array structures. 1-2 Hierarchical structure nano-array can provide even higher porosity and loaded mass which lead to the enhancement of areal capacitance ($\sim 25 \text{ F/cm}^2$) and rate capability, while the specific capacitance and cycling stability can be preserved. 3-4

More importantly, nano-array architecture also are effective to gas evolution reaction (e.g. oxygen evolution reaction and hydrogen evolution reaction). Besides the above advantages, nano-array architecture can promote the bubble evolution process because of the low adhesion of the surface to the gas bubbles. This observation should be generally applicable for gas evolution reaction.

Generally PEDOT:PSS conductivity polymers are used as buffer layer for organic based solar cells. It is important that improvement of the PEDOT:PSS electro-properties for high Power Conversion Efficiency(PCE) of solar cells. Furthermore, by getting a high conductivity of PEDOT:PSS films use as electrode for flexible device. In this work, we study on the the morphology and electro-properties of POEDOT:PSS thin films through spray method. PEDOT:PSS thin films are prepared with spin coating method. Then co-solvents are sprayed on the thin-films. To comparatively study the structural effects on the resulted electrical properties, the films are spin-coated on glasses and treated with sry method. At the same time, a contact angle goniometer is used for clarifying a mechanism of wettability of PEDOT (hydrophobic) and PSS (hydrophilic) on the observed conductivity. The structures and electrical properties are investigated by FE-SEM (Field Emission Scanning Electron Microscopy), AFM (Atomic Force Microscopy), and 4-point probe, respectively.

High-resolution imaging of lithium intercalation in graphite particles in a Li-ion battery

T06 Energy and Sustainable Development

#ESD/ASS-1-Or-2

K. Takata.

Kansai university, Faculty of Engineering Science - Osaka (Japan).

Lithium ion batteries are one of the most interesting power storage devices, and have attracted attentions of many researchers. The main elements to develop are positive electrodes, negative electrodes, separators and electrolytes. Since the report of the electrochemical reactions of lithium intercalation in graphite, the lithium ion batteries have been achieved in great advances though some problems to overcome still exist in the development. The application of the graphite to the anode overcame the dendrite problems, and the lithium ion batteries have been widely used as the most important power storage devices. Intercalation and deintercalation that lithium ions move into and back out the graphite or the layered oxides are interesting phenomena to observe using microscopic techniques. The phenomena are exactly the battery operation, charging and discharging. We focused on the changes in volume due to lithium intercalation. Insertion of lithium ions into graphite leads to expansion, and extraction leads to contraction. We can observe movement of lithium ions by imaging the changes in volume, for example, as follows.

We have studied on imaging of fine strains using SPM since 1993. Basically, SPM is microscopy capable of very high-sensitive detection of changes in the gap between the tip and sample, with high spatial resolutions in the lateral directions. Ordinary topographic SPM images are obtained by detecting the changes in the gap caused by raster scanning of either the tip or the sample, that is, the changes caused by the modulation of the tip position along the sample surface. SPMs can also detect changes in the gap induced by other modulations, with high sensitivities and high spatial resolution. Strain imaging we have proposed is based upon the detection and imaging of changes in the gap caused by surface displacements induced by strains generated by any modulation different from scanning of the tip. Strain imaging was first used for observing piezoelectric/ferroelectric properties. , Subsequently, magnetic strain imaging, thermal strain imaging, and electrochemical imaging have been done.

Variations of the images of volume changes depending on modulation frequencies clearly represented lithium intercalation. A linear relationship between the amplitudes of volume changes and the products of the diffusion elements and the reciprocals of the frequencies has been proven. Thus, the detected signals well quantitatively corresponded to the lithium ion movements.

ESD/ASS-P3-04

Molecular H₂ chemisorption by Kubas interaction onto Ti ion coordinated to methyl aluminum oxane/silica

T06 Energy and Sustainable Development

#ESD/ASS-P3-04

J. Lee.

Seoul National University - Seoul (Korea, republic of).

In the last decade, a number of theoretical investigations [1] by DFT calculations have predicted that 3-5 hydrogen molecules chemisorb onto early transition metals such as Sc, Ti, and V atomically decorated onto various substrates by the Kubas interaction with an adsorption energy of 0.25-0.35 eV suitable for reversible hydrogen storage. A new type of hydrogen storage based on this finding may have a great potential but experimental pursuit [3] along this direction is rare so far. We report here the preliminary results of our experimental investigation on the chemisorption of H₂ molecule by the Kubas interaction onto Ti ions coordinated to methyl aluminum oxane (MAO) oligomers attached to the surface of hydroxylated porous silica (3nm pores) powder of 60 μm size. The coupling reaction of MAO with silica was carried in pentane as solvent at room temperature and then TiCl₄ was added at 150 C under H₂ flow, which we believe to result in Ti⁺H₃ coordinated to the Al⁺ site. Elemental analysis by EDX revealed that Ti of 1.0 wt.% or 4.3 wt. % was coordinated onto the MAO/silica and no Cl was left over. 200 mg of the synthesized sample was loaded in an adsorption cell and thoroughly evacuated at 150 C with a turbomolecular pump to remove solvent molecules which may remain in the pores of the sample. After D₂ adsorption to saturation at 80 K by filling with 5000 Torr of D₂, the cell was again evacuated to 10⁻⁸ Torr to pump out all D₂ which is not permanently adsorbed at 80 K. Then, temperature-programmed desorption (TPD) was performed in the closed cell by heating at an average rate of ~ 1K/s while monitoring the pressure increase in the cell. From the total pressure increase we estimate that ~ 0.26 D₂ molecules adsorbed per Ti. Differentiation of the measured P-T curve yields TPD spectrum showing a sharp peak centered at T_p~110 K with a long tail. The peak temperature corresponds to D₂ adsorption energy of E_{ad}~ 28.3 kJ/mol according to the Redhead relation E_{ad}~ 31kT_p [3]. This value is much larger than that of ~10 kJ/mol or less typically measured for H₂ physisorbed on various carbonaceous materials and molecular organic frames. Thus, one has to attribute the desorption peak to

molecularly chemisorbed D_2 by Kubas interaction onto Ti^+ ions coordinated to Al^- sites. The small amount of D_2 continuously desorbing at $T > 130$ K is due to diffusion-limited desorption from deep in the pores. The same measurement with 4.3 wt.% Ti sample resulted in ~4 times larger amount of D_2 adsorption than that of 1.3 wt.% Ti. Repeated adsorption measurements with the same sample gave almost the same result, indicating that the sample is not degraded. Although the total amount of adsorbed D_2 is very small, the results suggest that hydrogen storage based on Kubas interaction may provide a viable solution, if a better system can be designed.

ESD/ASS-1-Or-3

Reactive sputter deposition and characterization of K_2NiF_4 coatings for Intermediate Temperature - Solid Oxide Fuel Cell (IT-SOFC)

T06 Energy and Sustainable Development

#ESD/ASS-1-Or-3

J. Fondard ¹, A. Billard ¹, G. Bertrand ², P. Bertrand ¹, P. Briois ¹.

¹IRTES-LERMPS, UTBM - Belfort (France), ²CIRIMAT UMR CNRS-INPT-UPS 5085, ENSIACET - Toulouse (France).

Intermediate Temperature-Solid Oxide Fuel Cell (IT-SOFC) produces energy from the reaction between oxygen and hydrogen at 600-800°C. Its core, where the reaction takes place, is composed of three different solid oxide layers, cathode, anode and electrolyte. One of a major obstacle to the development of IT-SOFC is the large cathode overpotential at these temperatures. One solution is to improve SOFC's electrocatalytic properties by the use of mixed ionic and electronic conductors (MIECs) as cathode material. Rare-earth nickelates with K_2NiF_4 structure, namely Ln_2NiO_4 ($Ln = La, Nd, Pr$) are assumed to be promising cathode materials for IT-SOFC. Such MIEC materials exhibit both high values of oxygen adsorption and diffusion, and high electronic conductivity. Moreover, their thermal expansion coefficient is close to that of electrolyte materials ($CeO_2-Gd_2O_3$ (CGO) and $ZrO_2-Y_2O_3$ (YSZ)). Interesting electrochemical performance of the nickelates have already been demonstrated on $La_2NiO_{4+\delta}$ /YSZ [1], $Nd_2NiO_{4+\delta}$ /YSZ [2] and $Pr_2NiO_{4+\delta}$ /CGO/YSZ [3] symmetric half-cells by Electrochemical Impedance Spectroscopy (EIS). Ni-YSZ /Ni-YSZ /YSZ /CGO / Pr_2NiO_4 [3] and $Nd_{1.95}NiO_{4+\delta}$ /YSZ /Ni-YSZ [4] complete cells were also tested under operating conditions and show promising results.

In this study, we investigate the feasibility of Ni-YSZ /YSZ / Ln_2NiO_4 cells ($Ln = La, Nd, Pr$) and compare the performance of the different cathode materials. Thin and dense Ln_2NiO_4 coatings were deposited by reactive magnetron sputtering under unstable conditions using Plasma Emission Monitoring (PEM) on an anode/electrolyte half-cell support. This support is composed of dense sputtered YSZ electrolyte layer deposited on porous plasma sprayed anode NiO-YSZ. For cathode deposition, the

discharge current on the Ln target is fixed at 2.5 A and that on the Ni target is adjusted to obtain the convenient composition for nickelate compound. The as-deposited coatings are amorphous and crystallize under K_2NiF_4 structure with appropriate annealing temperature. The structural and chemical features of nickelate coatings and also their compatibility with electrolyte material have been determined by X-Ray Diffraction and Scanning Electron Microscopy. Their electrical properties were evaluated using EIS on YSZ/ Ln_2NiO_4 half cells and Ni-YSZ /YSZ / Ln_2NiO_4 complete cells under air and hydrogen.

Microscopic Measurements of Photovoltaic Energy Conversion

T06 Energy and Sustainable Development

#ESD/ASS-1-Or-6

A. Fejfar, M. Ledinsky, M. Hyvl, A. Vetushka, J. Kocka.

Institute of Physics, Academy of Sciences of the Czech Republic - Prague (Czech republic).

Modern nanostructured solar cells can be described as parallel arrays of random photodiode elements [1]. The elements typically have mesoscopic size (well below 1 micrometer). Examples of such structures are silicon nanowires, silicon nanodomains and many others. We need to point out that even common thin films based cells using geometric light trapping structures (for example Si thin films folded on ZnO nanorods) will exhibit same features.

Nanostructuring the cells helps to achieve excellent light trapping and enables collection of photogenerated carriers at short distance, providing optically thick and geometrically thin structures.

However, no information is available about the distribution of the local efficiencies at different positions of the solar cell. Yet the combination of the diodes may severely limit the open circuit voltage and fill factor of the elements array [1].

We have developed several approaches using the atomic force microscopy with conductive cantilever to measure the local photoresponse (see experimental scheme at Fig. 1) [2]. Measuring local I-V characteristics at each scan point could in principle provide local conversion efficiency, in practice problems with noise, reproducibility and oxidation have to be dealt with. Alternatively, Kelvin force microscopy can provide local photovoltage. We shall illustrate the approach by results obtained on solar cells based on microcrystalline grains in mixed phase Si thin films or on Si nanowires obtained by plasma enhanced vapour-liquid-solid growth catalyzed by metal nanoparticles (see Fig. 2).

Finally, we address the reference for the illumination absorbed power which is needed to assess the local photoconversion efficiency.

Eindhoven (Netherlands).**

The unique features of atomic layer deposition (ALD) can be employed to face processing challenges for various types of next-generation solar cells. Hence, ALD for photovoltaics (ALD4PV) has attracted great interest in academic and industrial research in recent years. In this presentation, the recent progress of ALD nanolayers applied to various solar cell technologies (c-Si, CIGS, DSSC, and OPV) will be reviewed and their future prospects will be discussed [1]. The presentation will focus particularly on the application of ALD oxides (Al_2O_3 , SiO_2 , $\text{SiO}_2/\text{Al}_2\text{O}_3$ stacks, $\text{Al}_2\text{O}_3/\text{ZnO}:\text{Al}$ stacks) for the passivation of surfaces of high-efficiency silicon solar cells [2]. Moreover, the upscaling of ALD to high-throughput solar cell production will be addressed [3].

ESD/ASS-1-In-1 DYNAMIC ATOMIC SCALE SOLUTIONS TOWARDS SUSTAINABLE ENERGY AND CLEANER ENVIRONMENT: INSIGHTS INTO BIOMASS TRANSFORMATION DYNAMICS USING IN-SITU E(S)TEM AT THE SINGLE ATOM LEVEL

T06 Energy and Sustainable Development

#ESD/ASS-1-In-1

P. Gai, E.D. Boyes.

The York JEOL Nanocentre and Departments of Chemistry, Physics and Electronics, University of York - York (United kingdom).

Considerable efforts are in progress worldwide to secure sustainable energy sources and cleaner environment. Superior catalysts are required for the efficient transformation of biomass and to optimise fuel cells for energy solutions, and for the reduction of emission of pollutants from automobiles. The latter is crucial to minimising the damage to the environment and to improve the air quality. We have directly visualised atomic scale interactions at the environment-catalyst interface in biomass transformation, fuel cells and in environmental control using our novel development of environmental (scanning) transmission electron microscopy (E(S)TEM) at the sub-Angstrom level and have complemented the studies by chemical methods. The studies provide insights into atomic scale active sites for the reactions.

Spectroscopic X-ray Photoelectron Emission Microscopy (XPEEM) has come to maturity over the past ten years with the advent of advanced instruments exploiting both synchrotron and laboratory excitation sources [1-2]. It is a powerful tool for studying the correlations at the microscopic level between electronic and chemical states in epitaxial graphene systems, because it allows to cross-check direct space (work function, core level shifts) and reciprocal space (band structure) information [3]. With laboratory excitation sources, routine analyses at the photoemission threshold can be performed to provide useful information regarding work function heterogeneities, local variations of charge transfer at the graphene/substrate interface (Fig. 1). In the reciprocal space (kPEEM), band structure information is provided at the micron scale, either for providing estimates on the shift of the Dirac point relative to the Fermi level or for fingerprinting graphene after plasma cleaning (Fig. 2). This contribution will provide an overview of XPEEM results regarding graphene/SiC and graphene/metal systems obtained with laboratory excitation sources, with emphasis for the case of growth on metallic substrates and effect of doping/intercalation.

Direct observation of local redox-processes on resistively switching SrTiO₃ with spatially resolved spectroscopy

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-1-Or-1

A. Koehl, C. Lenser, M. Patt, V. Feyer, C.M. Schneider, R. Dittmann, R. Waser.

Research Center Juelich - Juelich (Germany).

The effect of resistive switching in transition metal oxides is a currently very active field due to the possible applications for non-volatile memory applications. In this work we directly monitor the local redox-process during resistive switching in the valence change material SrTiO₃. Epitaxial Fe-doped SrTiO₃ thin films were grown on conducting, single-crystalline Nb:SrTiO₃ substrates by pulsed laser deposition. After an initial forming sweep bipolar resistive switching is enabled and several pads were programmed to different resistive states. After removal of the top electrode spatially resolved X-ray photoelectron spectroscopy (XPS) and X-ray absorption spectroscopy (XAS) are employed in order to investigate the influence of the resistive switching process onto the electronic structure and chemical composition of the sample. The measurements have been performed with the NanoEsca at Elettra, Trieste, where spectroscopic information with a lateral resolution down to 100nm can be gained. We compared the Sr-XPS, Ti-XAS and O-XAS signal of a virgin pad with "On" and "Off" pads, which have been set to low and high resistive state respectively. On all electrically treated pads several spots with a Sr-O rich surface component are found, which display a characteristic shift of the Sr 3d spectra to lower binding energies. As this effect is independent of the resistance state the evolution of this new component is assigned to the forming process which involves high voltages and currents. Due to Joule heating during the forming process Sr-diffusion might be enabled allowing the formation of a new Sr phase. Exclusively on the pad in low-resistive state a small feature of 300nm diameter with a Ti³⁺ contribution is found. This is interpreted as a signature of a reduced and therefore conducting filament giving rise to the decreased

resistance. Based on our spectroscopic studies we discuss redox-processes and phase formation on the nanoscale, which are relevant for the resistive switching effect.

Microscopy image at $E_{\text{Bind}}=132.5\text{eV}$ of formed pad and corresponding Sr 3d spectra.

FPFI-3-Or-9

A new challenge of energy-filtered x-ray photoemmission electron microscopy (EXPEEM) with a Wien filter

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-9

K. Miyazaki¹, T. Kitayama¹, T. Iwai², K. Tsuno¹, M. Kudo², H. Hiraiwa², K. Asakura¹.

¹Hokkaido University - Sapporo-Shi (Japan), ²Suga Co.Ltd - Hokuto-Shi (Japan).

PEEM with an energy analyzer is called as EXPEEM(energy filtered x-ray photoemission electron microscopy) and is a useful tool for chemical mapping of surface with high spatial and energy resolution.[1] The energy selection of photoelectron is usually fulfilled by a hemispherical energy analyzer where an optical axis of photoelectron should be bent and not good for the optical axis adjustment in microscopy.[1,2] We used a Wien filter to keep the straight optical axis even in the energy selection mode. We have developed 12 pole Wien filter to reduce the aberration in the Wien filter and increase the energy resolution and/or sensitivity[1]. The next challenge in this paper is to reduce the cost and increase the maneuverability. One is to decrease the number of poles in Wien filter. We now report a possibility of EXPEEM with 8 pole Wien filter with sufficient energy resolution and sensitivity.[3,4] The other is the perfect alignment of straight optical axis as shown in Fig. 1 by the coincidence of the radii of electrodes and coils. Figure 1 shows the schematic design of the newly built EXPEEM. The sample is grounded and photoelectron is collected by a combination electrostatic-electromagnetic objective lens (immersion cathode lens). Electrons are running through liner tubes in magnetic lenses. The accelerating voltage of 10kV is retarded to 100V at the Wien filter. The Wien filter consists of 8 poles of air-core coil electromagnets and electrodes, both of which are inside the vacuum. Finally the electron is projected on a screen with a four-stage lens. We can obtain the 100 meV resolution at the slit set after the transfer lens(TL2) followed by the Wien filter at pass

energy =100 eV.

Consequently, we can reduce the cost down to less than half that of the previous EXPEEM and can be improved the maneuverability by using less electric and magnetic poles in the Wien filter and easy alignment of the beam.

Spin resolved momentum microscopy is an efficient tool to study the band structure of ferromagnets. A spin polarizing electron mirror, i.e. a W(100) crystal, allows the measurement of the spin polarization in the whole momentum image, simultaneously. Thus, spin resolved 3D band structures as function of (k_x, k_y, E) can be measured with unprecedented efficiency, for the first time. We present comprehensive maps of the spin resolved band structure of cobalt grown on Cu(100), measured at the NanoESCA beamline [1] of the Elettra synchrotron. This instrument, consisting of a photoemission electron microscope (PEEM) and an electrostatic energy analyzer directly records the parallel momentum, $k_{||}$, of photoelectrons emitted from the sample. For these measurements, the imaging spin filter [2] was installed temporarily at the exit of the energy analyzer. A series of momentum images gives direct access to the electronic structure of the Co-film. Using 40eV to 200 eV photons, several constant-energy cuts in the 3D Brillouin zone are selected. Figures 1 and 2 show electronic states in the majority- and minority- spin-channel at the Fermi surface and their dispersion towards larger binding energies. At E_F , intensity is dominated by minority features, while at 300meV below E_F we observe a change of the spin-polarization to positive sign, attributed to the flat dispersing Co d-bands. At larger binding energies sharp bands are only observed in the minority channel. The comprehensive data sets can serve as valuable input for advanced concepts in theory for the refined treatment of spin-dependent electron correlation.

Epitaxial, metastable fcc Fe₅₀Cu₅₀ alloy films are grown by Fe and Cu codeposition with the aid of a surfactant Pb monolayer pre-deposited on a Cu(111) surface. During codeposition, Pb atoms segregate to the surface and at the same time reduce the lateral mobility of the deposited atoms [1], preventing phase separation of both elements that are immiscible in bulk. Metastable FeCu alloys are known to display Invar properties as a result of the competition between two structural phases with different atomic volume [2]. Due to the Stranski-Krastanov growth mode of Pb on Cu(111) 3D islands of relaxed Pb are formed for coverages beyond 1 ML. XMCD-PEEM and LEEM experiments allow us to compare the structure and magnetic behavior of the FeCu alloy films grown simultaneously on two different substrates, the Cu(111) crystal and the Pb(111) islands. These measurements reveal a completely different magnetic character for both systems: an 11 ML film of Fe₅₀Cu₅₀ (Fig. 1) imaged using circularly polarized x rays at the Fe L₃ absorption edge show that the alloy grown on the Cu(111) substrate is paramagnetic; no dichroic contrast is visible, whereas the same alloy displays an intense in-plane dichroic contrast when lying atop the Pb islands. Micro-LEED measurements demonstrate that all alloy films are fcc with equivalent crystallographic structure and lattice parameter irrespective of the supporting substrate (on the islands and out of the islands), and micro-XPS shows that they also have the same chemical composition and stoichiometry. The origin of the different magnetic behavior it is ascribed to electronic effects at the interface between the alloy and the substrate, as revealed by magnetic circular

dichroism data obtained at synchrotron MAX IV in Lund. These alloy films also constitute a privileged playground to investigate the effect of magnetic order on adsorption phenomena: chiral molecules have recently been proposed as a candidate to spin filter after the observation of intense spin polarization in electron currents transmitted through them. For this purpose we have deposited films of chiral Diphenyl-ethanediol on the alloy and performed a selective dichroic study, exciting electrons from the underlying, ferro- or paramagnetic FeCu film to measure the spin-selective transmission through the molecules.

Multiferroic domain imaging by linear and circular dichroism in threshold photoemission microscopy

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-2-Or-5

A. Hofer, W. Widdra.

Institute of Physics, Martin-Luther-Universität Halle-Wittenberg - Halle (Germany).

Threshold photoemission microscopy (PEEM) is an excellent technique to image the ferroelectric domain structure of sample surfaces by using work function differences [1]. For $\text{BaTiO}_3(001)$ it has been demonstrated that three different ferroelectric domain types are discriminable with significant contrast in Laser-excited PEEM. The observed domain pattern preserves even at temperatures above the Curie point which is explicable by a remaining tetragonal distortion of the topmost unit cells as supported by first principle calculations [2]. So far, the domain patterns of multiferroic surfaces have been imaged by complementary techniques only. Typically, X-ray PEEM has been used to investigate the magnetic and piezoresponse force microscopy the ferroelectric domain structure. Laser-excited threshold PEEM as a lab-based experiment is capable to be sensitive to the ferroelectric as well as the magnetic signal, since also the photoemission from the valence band depends on the magnetization direction. Here, we demonstrate for magnetoelectric $\text{BiFeO}_3(001)$ that threshold PEEM allows for the separation of different multiferroic domain structures in a single experiment. There, the imaging is based on work function contrast, linear and circular dichroism. In Laser-PEEM (Fig. 1(a)) two ferroelectric domains can be discriminated by their photoemission yields. Additionally, the contrast observed in PEEM severely depends on the linear or circular polarization of the exciting light, respectively. The normalized difference of two images measured for two different linear polarizations of light or measured with left and right circularly polarized light shows clear domain structures (Fig. 1(b) and (c), respectively). The comparison of these patterns among each other and with the ferroelectric domains reveals in each case additional domain states. With the aid of the ferroelastic domain structure we are able to discriminate all eight

multiferroic domains. The observation of a varying linear dichroism for different ferroelectric domains is explicable by the coupled ferroelectric-antiferromagnetic order in BiFeO_3 .

Quantum well states (QWS) can be formed when electrons are confined in ultrathin films due to a projected bulk band gap of the substrate for wavevectors perpendicular to the film surface. In the surface parallel directions, the electron still experiences the periodic potential of an infinite crystal and therefore reflects the bulk band dispersion. In Co thin films on Cu(001) substrate, such QWS are located in the unoccupied part of the band structure. Two-photon photoemission with the second harmonic of a Ti:Sa laser yielding 3.0-eV-photons enables us to observe resonant transitions via the QWS. This approach has been previously employed to study spin-selective electron excitation in normal emission [1]. In this study, we have used an energy-filtered momentum-imaging PEEM [2] that detects photoelectrons of all emission angles in one shot. The $E(k_{\parallel})$ -dispersion (Figure 1) of the QWS in 6 ML Co/Cu(001), which is shown in Figure 1, is consistent with the sp-type character of the relevant Co bands. Using a recently developed 2-dimensional spin filter [3], we have measured momentum maps of the partial intensities for both spin channels (Figure 2). The direct comparison of resonant and non-resonant two-photon transitions reveals that the resonant two-photon excitation via the quantum well leads to nearly 100% spin polarization which mixes with less strongly polarized electrons from non-resonant excitation.

Photoelectron emission microscopy (PEEM) combines high lateral resolution with the capability to monitor processes on the surface in real-time. For experiments in the lab, unpolarized light of a Hg lamp is commonly used to excite the photoelectrons. In this case, valuable information about the optical anisotropy of the surface under investigation is lost. On the other hand, techniques like reflectance difference spectroscopy (RDS) which are focussed on this anisotropy have proven to be useful tools to study thin adsorbate films of organic molecules. So why not combining both in a single experiment? In this presentation we will show, how polarized light can be used to study the growth of α -sexithiophene on silver and nickel oxide surfaces. As the ionization potential of the molecules is higher than the photon energy, the light of the Hg lamp only excites electrons from the metal-organic interface. In this case, no direct response of the molecules to the polarized light can be expected in the PEEM image. Nevertheless, the molecules are optical anisotropic and act as dichroic filters for the incident light. This effect can actually be used, e.g., to probe the orientation of the molecules even during growth. [1]

Combined surface-sensitive microscopies for the study of surface modifications of micro-switches upon cycling

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-P3-01

O. Renault, E. Martinez, D. Mariolle, B. Reig.

LETI, MINATEC - Grenoble (France).

For the optimization of micro-switching systems with Ru-based active components (Fig.1) , a key parameter to be controlled is the stability of the switching resistance over time upon many cycling processes of the devices. We have implemented in a complementary way different surface-sensitive microscopies to contribute to the understanding of the anomalous cycling effects on such devices. Fig. 2 shows results of core-level spectromicroscopy performed with XPEEM on the gold/ruthenium active part of the switch. It shows that upon cycling, additional core-level components (visible on the micro-spectra of Fig. 1) and shifted to lower binding energies appear on both Ru3d and Au4f images, with a clear localization in the switching region. This cannot be explained by a different surface potential which is shown constant by Kelvin Force Microscopy. This region happens to be over-contaminated in carbon and contains sulphur traces, as shown by scanning Auger nanoprobe. We interpret the spectromicroscopic results in terms of formation of nano-clusters, possibly inducing negative binding energy shift due to final state effects.

Surface magnetic domain imaging of antiferromagnetic (AFM) materials has been a challenge to most magnetic microscopies due to the absence of a net magnetic moment. X-ray Magnetic Linear Dichroism (XMLD) based techniques are primarily used nowadays for surface AFM domain imaging, requiring access to dedicated synchrotron beamlines. Thus, there is a strong demand for a laboratory-based imaging technique offering high spatial resolution as well as enhanced sensitivity to surface AFM order enabling routine surface magnetism studies. Here we present an electron microscopic approach for imaging surface AFM domains using coherently exchange-scattered unpolarized electrons in a laboratory-based Low Energy Electron Microscope (LEEM) [1]. Coherent exchange scattering of electrons from AFM surface of NiO(100) are visible at low electron energies (< 100 eV) due to the enhanced exchange scattering cross-section for slow electrons [2]. We employed such exchange-scattered half-order diffraction beams in the dark-field operation mode in LEEM (shortly, AFM-LEEM) to directly image AFM surface domains. Figure 1 sketches the general concept behind this AFM-LEEM experiment; single half-order diffraction beam is selected so that the LEEM image will show only the sample regions that contribute to the selected half-order diffraction spot. The small probing depth (~ 0.2 - 0.5 nm) of the low energy electrons enables to explore mostly the top-layer magnetic information. Along with the spatial resolution (~ 10 nm) this makes AFM-LEEM complementary to XMLD-PEEM techniques. This method has been successfully applied to resolve the surface AFM domains on prototypical systems;

single crystal NiO(100) surface and epitaxial thin films of NiO(100) grown on Ag(100) and are directly compared with XMLD-PEEM experiments demonstrating their complimentary nature. In case of the NiO model system, we have demonstrated that AFM-LEEM provides sufficient intensity to be exploited in realistic imaging experiments, providing valuable information on the AFM state at lateral resolution better than 10 nm with fast acquisition times. High surface sensitivity combined with improved spatial resolution of this technique will open up new route for studying surface magnetism and can grant access to finer details of the AFM domain structures that are still unexplored.

PIC-mapping of biomineral crystals by PEEM

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-1-in-1

P. Gilbert.

University of Wisconsin - Madison (United states).

Biominerals include teeth, bone, mollusk shells and the skeletons of algae, sponges, corals, sea urchins and most other animals. The function of biominerals are diverse: mechanical support, attack, defense, grinding, biting, and chewing, gravity and magnetic field sensing, light focusing, and many others. Organisms have evolved to master mineralization, and the nanostructure of their biominerals. We harness x-ray linear dichroism to produce Polarization-dependent Imaging Contrast (PIC) mapping using PEEM (1-10), and reveal the complex architecture of mollusk shell nacre, or mother-of-pearl, and how it is formed by animal-controlled self-assembly (1-3, 9-10).

Mapping the interplays of organic semiconductor and ferromagnetic layers in vertical organic spin-valve structures

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-1-Or-6

D. Wei, Y.L. Chan, Y.J. Hsu.

National Synchrotron Radiation Research Center - Hsinchu (Taiwan, republic of china).

A key issue in constructing layered electronic devices is the control of nanoscale interfaces. This is because the electric current is sensitive to the variation of electric/magnetic field, and interfaces are where the potential energy surfaces experience an abrupt change. For devices aiming to manipulate electrons' spin degree of freedom, the interfaces are even more important - they need to regulate not only the charge flow but also the coherence of spin polarization among carriers. For this regard, the magnetization at interfaces is recognized as a key parameter in GMR showing the GMR effect [1]. In this presentation, I would like to address a concern wondering if the lessons given by inorganic structures can be readily applied to metal-organic hybrid structures [2,3]. I will discuss the magnetic behavior of cobalt-pentacene (Co-Pn) interface from the perspective of X-ray imaging, and its possible correlation with the diminished room temperature magnetoresistance found at hybrid spin-valve structures. In brief, through element-specific X-ray magnetic images acquired from Pn/Co structures, the development of ferromagnetism in Co layer grown on Pn film was found somehow retarded (as shown in figures). X-ray images and micro-spectroscopic evidences indicated that this magnetic retardation is associated with both chemical reaction and metal penetration [4,5]. Our experiments indicate that the magnetism at hybrid structure's interfaces is affected by the order of layer deposition.

IRAMIS/SPCSI/LENSIS - Saclay (France).**

We present dark field Photoelectron Emission Microscopy and energy filtered electron emission spectromicroscopy with high spatial and wave-vector resolution on few-layer epitaxial graphene on SiC(000-1) grown by furnace annealing.

Conventional electron spectroscopy methods are limited in providing simultaneous real and reciprocal or k-space information from small areas under laboratory conditions. Therefore, the characterization of materials with only micron scale sample homogeneity such as epitaxially grown graphene requires new instrumentation. Recent improvements in aberration compensated energy-filtered photoelectron emission microscopy (PEEM) can overcome the known limitations in both synchrotron and laboratory environments.

Energy-filtered, threshold PEEM is used to locate distinct zones of FLG graphene. In each region, selected by a field aperture, the k-space information is imaged using appropriate transfer optics. By selecting the photoelectron intensity at a given wave vector and using the inverse transfer optics, dark field PEEM gives a spatial distribution of the angular photoelectron emission. Only the combination of high lateral, high energy, high k-resolution and controlled switching between real space and k-space allows detailed understanding of micron size sample sites with 1–3 layers graphene.

Development of breakthrough stainless steel materials via spectromicroscopy

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-P3-02

M. Hannula, K. Lahtonen, M. Valden.

Surface Science Laboratory, Tampere University of Technology - Tampere (Finland).

Stainless steels are versatile materials due to the excellent thermal properties, mechanical strength and corrosion resistance. The enhanced properties of advanced ferritic grades are often achieved through optimization of the alloy composition. Addition of Nb and Ti e.g. is used to prevent precipitation of Cr with C or N and induce formation of nanodispersed NbC that enhance the strength of steel.¹ The role of minor alloying elements is crucial at surface and interfaces where the enrichment and segregation of alloy elements under corrosive or high-temperature conditions play an important role.

Our earlier work has focused on the oxidation of stainless steels, segregation phenomena and, in particular, on the role of alloying elements.^{2,3} Here we report results obtained from microalloyed ferritic stainless steel with a newly commissioned NanoESCA (Omicron GmbH) spectromicroscopy system. Its sub-micrometer resolution and *in situ* sample preparation facilities allow us to oxidize steel in a controlled fashion and conduct spectromicroscopy experiments to observe segregation phenomena, precipitate formation, surface chemical composition, enrichment phenomena at grain boundaries and passive oxide film formation in general. Figures 1 and 2 present the work function and chemical contrast images of Fe on ferritic stainless steel, demonstrating how the grain structure can be readily correlated with the surface chemical composition. This information is the key to developing new stainless steel materials, since it allows us to understand how alloy constituents, grain boundaries, precipitate formation and segregation phenomena influence surface passivation under oxidative conditions.

Photoemission electron microscopy using high intensity ultrashort laser pulses

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-1

E. Mårzell, C.L. Arnold, A. L' Huillier, A. Mikkelsen.

Lund University - Lund (Sweden).

Photoemission electron microscopy (PEEM) together with advanced laser sources has during recent years emerged as a powerful tool to study phenomena such as surface plasmons or magnetization dynamics on surfaces. Most studies have been performed using femtosecond pulses from a Ti:Sapphire oscillator. By instead using intense femtosecond pulses from laser amplifiers, possibilities open up for a variety of non-linear processes. One such process is high-order harmonic generation (HHG), which can produce coherent attosecond extreme ultraviolet (XUV) pulses. The use of such pulses for PEEM studies with unprecedented spatiotemporal resolution was suggested by Stockman et al. in 2007 [1], and some experiments have since then been performed on PEEM imaging using XUV radiation from HHG sources [2-4]. A spectrum of the radiation we have used for the experiments is shown in figure 1. It is, however, a challenging experiment to realize in practice, mainly due to space charge effects and chromatic aberration. We present ways of optimizing imaging conditions, and discuss what improvements are needed to realize PEEM with attosecond temporal resolution.

Multiphoton PEEM using infrared pulses has been shown to be a powerful way of mapping out localized field enhancements at surfaces, and we show results on both semiconductor and metal nanostructures excited by infrared pulses. By optical frequency mixing in non-linear crystals, we can produce femtosecond laser pulses ranging from 400 nm to 2000 nm, and we demonstrate 6-photon PEEM at the important telecommunication wavelength of 1550 nm.

Finally, we present first results from a new HHG setup using femtosecond pulses from a non-collinear optical parametric amplifier (NOPA), which works at repetition rates of hundreds of kHz up to one MHz. Such a high-repetition rate system allows us to decrease the individual pulse energy while keeping high enough average

photoelectron flux for imaging, which will significantly reduce space charge effects. A high enough photoelectron flux also opens up possibilities for energy filtering, thus reducing chromatic aberration.

Graphene on metals has evolved into a paradigm for understanding how the substrate interactions influence the electronic properties of two-dimensional sp^2 hybridized atomic networks [1]. Aiming at characterizing its band structure, research has recently focused on high-quality epitaxial films grown on transition metals, investigating a variety of extrinsic, substrate-induced effects. Known since the early days of surface science [2], the growth of few-layer graphene can nowadays be accurately controlled on most fcc(111) or hcp(0001) transition metal surfaces. Epitaxial graphene on metals shows a great variety of rotational structures and moiré patterns originating from the small lattice mismatch with the substrate, often accompanied by the formation of regular corrugations in the film [3]. Despite the huge number of studies that the rise of graphene has triggered, the properties of graphene on crystal faces showing different symmetry than the threefold are still largely unexplored [4,5]. We report here on the structure and electronic properties of graphene grown on Iridium (100), a square symmetry substrate. By combining advanced microscopy methods (spectroscopic photoemission and low energy electron microscopy, microprobe angle-resolved photoelectron spectroscopy, scanning tunneling microscopy) and *ab initio* calculations, we characterize a new commensurate graphene phase that displays exceptionally regular one-dimensional ripples with nm-periodicity and extends over microscopic length scales. A unique

feature of this system is that the buckled graphene phase can be reversibly transformed into flat physisorbed graphene by simple control on the temperature. We demonstrate that this process, which effectively relieves the strain that builds up with temperature variations, involves the formation and rupture of a just few interfacial C-Ir bonds. Our results illustrate how the substrate symmetry can be exploited to control the morphology, bonding and electronic structure of graphene, opening further possibilities for tuning adhesion and charge transport in this material.

In the last years much work has been devoted to find the best strategy to apply *tensile* strain to Ge structures in order to reduce the energy difference between the direct and indirect band-gaps favoring population inversion and lasing.[1] According to recent *k*·*p* calculations,[2] the direct gap condition is dominated by the hydrostatic strain component. Several strained configurations have been explored so far, especially using external stressors.[3] However, high tensile strain has been reached only using thick stressor layers and for large structures (> 1 μm). This reduces their scalability and prevents the applicability of these methods to the design of nanoscale optoelectronic devices.

In this work, we explore a strategy to obtain nanoscale structures with a high gap narrowing, avoiding the use of external stressors. We created Ge-rich SiGe *embedded* nano-stripes (Fig. 1a) with a microscopic strain state maximizing the hydrostatic component. Nanoscale resolved spectroscopies, strain simulations and electronic-structure calculations have been used to map the strain field and the strain-induced band gap variation at the surface of the nano-stripes.

Strain is measured by Tip Enhanced Raman Spectroscopy (TERS) with a lateral resolution of 30 nm (Fig. 1b). A large tensile hydrostatic strain is found in the nano-stripes, as a result of the out-of-plane frustrated relaxation due to the constrained geometry, combined with a plastic relaxation in the (001) plane. The strain-induced variation of the surface electronic structure is studied by valence band and work function mapping using X-Ray Photoelectron Emission Microscopy (X-PEEM) with a resolution better than 100 nm (Fig. 1c-d). A positive work-function shift and a broader dispersion at the valence band edge are found for the nano-stripes with respect to the bulk case. We attribute these findings to the narrowing of the direct band gap induced by the tensile strain. Fitting the experimental results by *ab initio* calculations, the reduction of the energy difference between the direct and indirect band gaps is estimated to be ~ 100-120 meV, larger than that of strained structures reported so far in literature. The present results have a potential impact on the design of optoelectronic devices at nanometer-length scale and on the achievement of the population inversion and lasing by SiGe technology.

Shanghai Synchrotron Radiation Facility (SSRF) is a third-generation of synchrotron radiation light source with an electron energy of 3.5 GeV. An advanced angle-resolved photoemission spectroscopy system (ARPES) and an aberration corrected photoemission microscope (ACPEEM) are installed at a soft X-ray beamline named Shanghai Dreamline. The soft X-ray energy ranges from 20 eV to 2000 eV, covering the K edges of elements C, N, and O, L edges of 3d transition metal elements, and M edges of 4f rare earth elements. The polarization can be set as linear or circular. The focusing beam size is down to 14 μm x 5 μm . The typical photon flux is $4 \times 10^{12} \text{ s}^{-1}$. The ARPES-PEEM facility is designed for a high energy resolution of ~ 10 meV at a photon energy of 1000 eV for ARPES, and a high lateral spatial resolution of ~ 10 nm and an energy resolution better than 0.15 eV for PEEM. The current setup is well suited for XMCD-XMLD, nano-XPS, and k-space PEEM studies. The ACPEEM is further improved with a fs-laser to study time-resolved dynamics. The Shanghai Dreamline at SSRF is scheduled to be available from July, 2013. More details will be described in this presentation.

Photoemission electron microscopy (PEEM) is a well-established technique for high-resolution imaging using x-ray excitation. A number of different contrast mechanisms has been exploited to gain valuable insight into electronic and magnetic properties of microstructured systems, among them elemental contrast due to absorption at element-specific absorption edges, magnetic contrast due to magnetic dichroism, and spectroscopic imaging using energy-selected photoelectrons from specific core levels [1]. On the other hand, photoelectron spectroscopy using hard x-rays as excitation (HAXPES) has proven to be a valuable tool to retrieve spectroscopic information from deep bulk regions and from regions buried under surface layers [2]. Recently, we could show that the combination of both methods is feasible using a NanoESCA-type photoemission electron microscope with double hemisphere energy filter [3]. Energy-filtered imaging is possible even at kinetic energies as high as 6.4 keV, where the electron inelastic mean free path reaches values of several 10 Å in most materials. This method is particularly useful to investigate changes in the electronic structure of novel integrated devices. Examples from the class of resistive switching devices (Memristors) will be shown in this contribution (see figure). Here, HAXPES is employed to retrieve spectroscopic information from the active region of the device which is hidden underneath a metal top electrode, while the lateral resolution of PEEM helps to pinpoint changes that occur only in well-defined regions of small extent (like e.g. conductive filaments). In principle, one could even think of observing devices in operando using this method [4].

Surface, Interface and Thin Film Processes in Organic Materials Investigated by Photoemission Electron Microscopy and Low Energy Electron Microscopy

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-1-Or-4

M. Casu.

Institute of Physical and Theoretical Chemistry University of Tuebingen - Tuebingen (Germany).

By using a combination of microscopic imaging and diffraction techniques with structural and chemical sensitivity, we studied the growth of diindenoperylene (DIP) on gold single crystals. Growth and structure of DIP films of different thickness were monitored in situ including real time PEEM and LEEM performed at the aberration-corrected SMART spectromicroscope, installed at the synchrotron radiation source BESSY (Berlin) and at the SPELEEM, installed at the Nanospectroscopy beamline at Elettra (Trieste). DIP thin films were grown by organic molecular beam deposition at room temperature and at very low evaporation rate. A layer-by-layer mechanism characterizes the initial growth followed by island nucleation, i.e., the growth follows the Stranki-Krastanov mode. The effect of the Ehrlich-Schowebel barrier was also directly observed at the substrate and in the film morphology, in particular inside the islands that show a non-homogenous thickness due to a rough front growth, because of the additional energy required for the diffusing molecules to surmount a downward step [1]. Highly resolved spectromicroscopy reveals that electronic structure, core-hole screening, and molecular orientation depend on the local morphology of thin films. These phenomena, like different screening of the core hole, or different FWHM of the XPS lines, have been previously shown comparing different samples consisting of monolayers and multilayers. In our work we show their occurrence comparing islands versus monolayers in the same film [2]. We also find that island shapes and aggregation in diindenoperylene deposited on Au(100), Au(110), and

Au(111) single crystals are steered by the anisotropy due to the lattice geometry of the substrate [3]. Finally, first preliminary results of our investigations on organic radicals will be shown. This represents the first PEEM/LEEM experiment on this class of materials.

Momentum microscopy [1] is a novel approach to study the electronic structure of surfaces using the cathode-lens technique, well-known from PEEM. Whereas a PEEM is optimized for best resolution in real space, momentum microscopy aims at an ultimate resolution in k-space (reciprocal space). Up to now, dispersive spectrometers have been used as energy filter and an imaging spin filter of W(001) type was employed [2]. In this contribution we present first results using *time-of-flight* (ToF) energy dispersion using a delayline detector, adopting concepts of ToF-PEEM [3]. By setting a ToF condition in the 3D (x,y,t) data sets, we define sections in k-space. In extended simulations we optimized the electron optical design such that for start energies up to 80eV the full half space above the sample surface (more than the first Brillouin zone) is imaged with high k-resolution. Starting from the imaging Ir(001)-type reflection spin filter [4], we were able to extend the lifetime of the surface by orders of magnitude via coating with a thin, pseudomorphic Au(001) overlayer that also stabilizes the surface in the non-reconstructed 1x1 phase. The instrument allows simultaneous spin filtering of many energy sections through momentum space. TOF filtering bears the potential of very high energy resolution. It can be selected via the drift energy and length of drift space. Aberrations are very small because a linear electron-optical column is retained. The instrument is operated using pulsed laser sources and will be installed at BESSY II (beamline RGBL-PGM).

Gutenberg-Universität Mainz - Mainz (Germany).

We present an innovative twin photoemission electron microscope (Twin-PEEM), which consists of two fully functionally PEEMs crossed in the shared low-energy zone (20-100 eV), see Fig. 1a. The desire to analyze the spin of the photoelectrons forming the image in UV-PEEM experiment bring us about to design this multifunctional Twin-PEEM with high transmission properties. In our design we have used only electrostatic lenses. Due to the combination of a cathode lens and different asymmetric immersion lenses we have achieved performance, which allows to place a single crystalline target directly into the electron optical path after the cathode lens of the microscope (Fig. 1a) and use it as an active electron mirror. In this way it is possible to realize different operating modes of the Twin-PEEM. If the crystal is extracted from the optical axis of microscope (Fig. 1b), then the direct spatial image can be obtained on the multichannel plate of a position sensitive detector (Fig. 1c). If the crystal is inserted into the optical axis of microscope, see Fig. 1(d), then the low energy electrons diffracted from the single crystal can be imaged in a 90° mirror-like geometry (Fig. 1e). As was recently shown [1,2], the W(100) target can be used as a highly efficient spin-filter for 2D PEEM images. In this case Twin-PEEM can be used as Spin Polarised Photoemission Electron Microscope (SP-PEEM) which is able to map magnetic sample by illumination with unpolarised deep ultraviolet light.

Current induced domain wall motion is a key phenomenon to realize novel spintronic devices such as a race-track memory (IBM) and a domain wall motion magneto-resistive random access memory (NEC). It has been indicated that domain walls in nanowires with perpendicular magnetic anisotropy can move with lower current density than those with in-plane magnetic anisotropy. Multilayer [CoNi₂] multi-layer is known to exhibit perpendicular magnetic anisotropy and is expected as a material for the devices with low operation current [1,2]. We investigated magnetization during growth of the [CoNi₂] multi-layer with our high brightness and highly spin-polarized SPLEEM [3-5]. We will also reproduce the magnetic domain pattern formation of the surface of Co/Ni multilayers by numerical simulations, based on the Landau-Lifshitz-Gilbert (LLG) equation, which describes the dynamics of local magnetization. Fig. 1 shows experimental and simulation results of magnetic domain images of multilayers of pairs of [CoNi₂] on W(110). The numerical simulations well reproduce the magnetic domain patterns observed in the experiments.

We investigate by spectroscopic XPEEM the doping signature of intentionally n-doped GaN microwires. We present spectromicroscopic results at threshold and Ga3d core-level emission excited with soft x-ray radiation (Nanospectroscopy Beamline, Sincrotrone Trieste, Italy, NanoESCA MkII instrument [1]). Figure 1 shows the threshold spectra of the Si-doped and non-intentionally doped (NID) regions of the wire. These regions present a 134meV work function difference. The doped region presents the lowest work function, consistent with a n-doping. Moreover, Ga3d binding energy peak maximum presents a shift as a function of its position along the wire. This positive binding energy shift (160 meV) in the doped region is qualitatively and quantitatively in agreement with n-doping and a lower work function. The work function changes are thus, dominated by shift of the Fermi level upon doping. Scanning Auger (SAM) measurements were also performed to confirm the presence of silicon in the wire. Figure 2 highlights the drop of Si concentration along the wire, dropping from 7% to reach a stable 3.5%. This profile is coherent with the growth method, and an expected N.I.D. [2]. Based on complementary laboratory experiments, we will discuss the influence of band bending effect and surface photovoltage [3] on the measured energy level shifts.

The work was supported by the French National Research Agency through the Recherche Technologique de Base program and was performed in the

Nanocharacterization Centre of MINATEC and Sincrotrone Trieste acknowledged for providing beamtime.

FPFI-3-Or-7

New developments and future trends in high-resolution LEEM and PEEM

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-7

A. Kaiser, S. Bahr, O. Schaff, A. Pioda.

SPECS Surface Nano Analysis GmbH - Berlin (Germany).

Eighty years ago, Ernst Brüche developed the first photoemission electron microscope (PEEM) in the AEG laboratories in Berlin. Today, the state-of-the-art Low Energy Electron Microscope (LEEM) is produced just a few kilometers away from Brüche's former laboratory carrying forward this groundbreaking developments into the SPECS FE-LEEM P90.

This instrument - based on the sophisticated electron-optical design by Ruud Tromp [1-4] - combines user friendly operation with highest stability and ultimate resolution measurements. For this, the integrated cold field-emission electron gun provides a high-brightness electron beam with low energy spread. Already equipped with an in-line energy filter with high energy resolution [3] it can be upgraded with an optional aberration corrector [3, 4] improving the lateral resolution of the instrument from 5 nm to better than 2 nm by correcting spherical and chromatic aberrations.

For PEEM measurements, various light sources can be employed far beyond the standard of a Mercury discharge source, such as an optional Deuterium source or spectroscopic sources, like Helium discharge lamps, various laser sources or synchrotron sources. For experiments with laser excitation, the excitation source can be fed into the system under different incidence angles ranging between 0° and 90° relative to the sample surface.

Surface preparation techniques, such as ion or evaporation sources can be installed within the sample chamber for in-situ sample preparation or in an additional preparation chamber mounted on the same system frame. For a thorough characterization of the sample surface, the LEEM/PEEM system can be combined with other analysis methods, such as the SPECS Aarhus STM 150 HT for highest stability Scanning Tunneling Microscopy with atomic resolution.

The instrument's development is continuously driven forward. In this presentation, new developments and future trends in LEEM and PEEM will be presented, resulting in new applications of the available operation modes, like NanoARPES. Furthermore, various upgrade capabilities, like the new integrated sample stage will be presented allowing sample positioning with highest precision and stability with up to six computer-controlled degrees of freedom and an optional sample cooling.

Photoelectron Emission Microscopy in combination with high brilliance synchrotron radiation (XPEEM) is known to be an appropriate method for studying surface properties with chemical selectivity. The use of an additional transfer lens in the optical path of such an energy-filtering XPEEM installation allows us to take an angular/momentum resolved image of the excited electrons at a well-defined kinetic energy. Varying this kinetic energy gives access to a robust band structure imaging. With our NanoESCA at the synchrotron Elettra (Italy) [1] in combination with a micro spot refocused synchrotron beam we measure one full momentum distribution with an angular resolution smaller than 0.09 \AA^{-1} .

We use this method to investigate the topological insulators (TI) Bi_2Te_3 and Sb_2Te_3 grown as epitaxial thin films [2], which are highly interesting future materials regarding their special electronic properties (high mobility and dissipationless spin-locked transport). The excitation of photoelectrons with right and left circular polarized synchrotron light (RCP, LCP) gives access to a strong circular dichroism (CD) contrast [3], which is related to the spin texture of the Dirac state in a TI [4]. We show our CD results for the aforementioned TI's and discuss them with the help of relativistic first-principal photoemission calculations.

As Stern-Gerlach type spin filters do not work with electrons, spin analysis of electron beams is accomplished by spin-orbit or exchange scattering processes [1]. Existing single-channel devices are not compatible with parallel imaging microscopes and also not with modern electron spectrometers that simultaneously acquire a certain energy and angular interval. Recently, a novel method was developed that can transport a spin filtered 2D image utilizing k-parallel conservation in LEED [2,3]. In this contribution we present a major enhancement of this imaging spin filter by using an iridium (001) scattering target. The lifetime of this surface in UHV is one day, an order of magnitude higher than for the W(001) target used in our previous work. The inset in Fig. 1 illustrates the operation principle for the ideal case of an incoming parallel beam. The measured spin asymmetry for specular reflection from Ir(001) at 45° impact angle for energies up to 50eV is shown in (b). The experimental curve shows reasonable agreement with a relativistic SPLEED calculation (a), in particular for the leading signal A as well as several characteristic features (B-D). Signal G was not accessible because of too low energy, features E and F are missing in experiment, possibly because the measurement was performed for the 5x1 reconstructed surface, whereas the calculation assumed 1x1. The imaging spin filter allows to resolve the spatial coordinates (x,y) in *high-contrast spinfiltered PEEM images*, e.g. of ferromagnetic domains [2]. Resolving the energy- and angle-coordinates (E,θ) behind an electron spectrometer establishes *multichannel spin polarimetry* [3]. Finally, imaging the transversal components of the momentum vector (k_x,k_y) constitutes *spin-filtered momentum microscopy* [4].

Sources of inherently cold electrons extracted from laser cooled atoms have the potential to transform electron imaging. These new sources promise high current, high coherence electron bunches suitable for both conventional and ultrafast electron imaging. Here, we describe two instances of the cold atom electron source (CAES). Firstly, a source aiming to realise ultrafast diffraction from biological targets with atomic resolution. Secondly, a low energy source capable of triggering targeted surface chemical reactions, whilst simultaneously collecting a high resolution electron energy loss spectrum to identify the reaction pathways.

The cold atom source is a new source of charged particles, based on the extraction of electrons and ions from cold atoms [1]. The produced beam displays high coherence, high brightness and an intrinsically small energy spread. The internal structure of the atoms that form the underlying electron source provides a unique tool for three dimensional control over the density distribution of the electron beam [2]. This shaping provides a method for the realisation of beams which display minimal emittance growth (uniformly distributed ellipsoidal bunches), allows novel methods of beam characterisation and real-time optimisation of the electron beam properties.

Ultrafast electron diffraction (UED) of nanoscale objects such as biological molecules and nanoscale defects in solid state devices provides crucial information of dynamic processes [3]. Progress with UED is currently limited by the brightness of sources with su

ciently high temporal resolution. Cold Atom Electron Sources have been shown to be bright, but with pulse lengths too long for UED. We demonstrate the production of simultaneously cold and short duration electron pulses from a cold atom electron source by incorporating an ultrafast laser into a two-colour below threshold photoionisation scheme. Counter-intuitively, the large bandwidth of the ultrafast laser pulse does not adversely affect the electron energy spread. Electron bunch shaping is used to characterise the beam and current experiments aim to demonstrate diffraction.

The chemistry of surface compounds can drastically alter the material properties. To probe structure and identify reaction pathways, targeted reactions can be induced with low energy electron beams, usually a few eV. Techniques such as high resolution energy loss spectroscopy (HREELS) allow for the determination of chemical changes, but conventional HREELS sources/detectors require long times to produce high resolution spectra. We report on the assembly and testing of a continuous beam CAES, to be used for both inducing chemical reactions and as the source for producing HREELS spectra. A continuous beam is produced from the fi

eld-ionisation of a transversely cooled cesium beam, producing a highly monochromatic electron beam. The beam is coupled to a high resolution microscope column and the sample is biased to achieve low electron energies.

Strongly coupled plasmons are induced in a system of individual gold nanoparticles placed at sub-nanometer distance to a gold film (nanoparticle-on-plane, NPOP) via a monolayer of cysteamine (0.8 nm) as spacer layer. This results in a plasmonic resonator with high quality where two types of modes can be excited: A particle plasmon mode close to the resonance frequency of single, free Au nanoparticles and a so-called gap resonance mode which is strongly red shifted in comparison with the particle plasmon. For the gap resonance our calculations revealed a near-field enhancement in the gap region of 1000. In the first experiment we investigated the system using two complementary *single-particle spectroscopy techniques*. Optical scattering spectroscopy exclusively detects plasmon modes that couple to the far field via their dipole moment (bright modes). Using photoemission electron microscopy (PEEM), we detected in the identical NPOPs near-field modes that do not couple to the scattered far field. These so-called dark modes are characterized by a strongly enhanced nonlinear electron emission process. This is the first time that both far- and near-field spectroscopy were carried out for identical individual nanostructures interacting via a sub-nanometer gap. Strongly resonant electron emission occurs at excitation wavelengths far off-resonant in the scattering spectra [1]. In a second experiment we performed *electron spectroscopy* using an imaging energy analyzer, in order to elucidate the origin of strongly enhanced emission in the region of the gap resonance. Strongly coupled plasmons are excited in the NPOPs by femtosecond laser pulses. Field-emitted electrons from individual nanoparticles are detected by means of photoelectron emission microscopy and spectroscopy. We

propose optical field emission of electrons as major emission channel [2]. It is generated by the ultra-strong near field of strongly coupled plasmons without the help of a noticeable dc field. The dependence of total electron yield and kinetic energy on the laser power proves that field emission is the underlying emission process. We derived a dynamic version of the Fowler–Nordheim equation that yields perfect agreement with the experiment.

Iron oxide, widely used as a catalyst and as a support for catalytically active systems, has been intensively studied with various techniques [1]. However, controversies in the literature regarding the surface termination and structural inhomogeneities hinder the direct linking of surface electronic and structural properties to chemical properties. Our aim is therefore a comprehensive and consistent characterization of the Fe₃O₄ and Fe₂O₃ film growth on Pt(111) and Ag(111) substrates by using the SMART instrument [2], operating at BESSY-2, the soft x-ray light source of the Helmholtz Center in Berlin. This energy-filtered LEEM/PEEM instrument is specially designed to obtain chemical and structural information with high lateral resolution in-situ and in real time. It is the first instrument achieving 2.6 nm in LEEM [3] and 18 nm in energy filtered XPEEM [4], which was only possible by simultaneous correction of spherical and chromatic aberrations.

The combined LEEM/LEED and XPEEM study shows that the oxide thin film reveals defects depending on different preparation conditions, for example. a coexistence of different stoichiometric phases (Fe₃O₄, Fe₂O₃ and FeO), rotational domains and domains of different surface terminations [5]. We found that the substrate influences the quality of the supported oxide surface and its thermodynamics; e.g. the phase diagram of co-existing Fe₃O₄ and Fe₂O₃ phases can differentiate significantly from that calculated for bulk materials. We systematically characterized the conditions to reversibly transform alpha-Fe₂O₃ to Fe₃O₄ thin films on Pt(111) and on Ag(111). A comprehensive characterization of oxidation and reduction of mixed-phase films, the various defects in the film, as well as the substrate role in such reactions, will be discussed.

Typical resistive switching (RS) systems are capacitor-like devices, where the electrode is an ordinary metal and the functional material a dielectric transition metal oxide or a telluride phase change material. Recent studies indicate that a thermal or electrochemical redox reaction in the vicinity of the metal-oxide interface is possibly the mechanism responsible for RS. This results in an altered local electronic structure and local stoichiometry during and after switching. These changes are confined to nanoscale areas such as contacts, filaments, grain boundaries, or defects. Synchrotron-based techniques (UPS, XPS and XAS) are sensitive to changes in the electronic structure and chemical states of the studied system. Thus, combining photoemission electron microscopy (PEEM) with synchrotron radiation provides a unique tool to study these phenomena

In the present study, several RS materials have been investigated using PEEM at NanoESCA beamline of Elettra [1]. The observed energy shift of 0.3 eV of the valence band maximum of crystalline AgInSbTe compared to the amorphous phase correlates well with a resistance change during heating to 160°C [2]. The analysis of Te, Sb, In and Ag 3d XPS spectra of both phases shows that crystalline AgInSbTe forms, while Ag diffuses into the bulk and the top surface layer is enriched with In and Sb elements. Using micro-probe UPS and XPS we also demonstrate that GaO_x thin films exhibit analog memristive switching based on the bulk diffusion of donor ions (oxide ion vacancies or interstitial gallium ions). The drift of the vacancies creates a nonuniform donor concentration profile across the film and induces a change in the density of states in the valence band top near the Schottky barrier interface between

Pt electrode and GaO_x. In the third case, micro-XAS was used to study a 20nm Fe:SrTiO₃ film deposited on the conducting Nb:SrTiO₃ substrate. The Fe:SrTiO₃ pad was resistively switched by applying bipolar voltage sweeps [3]. The spectra were measured at Ti L-edge (Fig.1a) on areas marked on Fig. 1b. The spectra of resistively switched area "Set" show some difference compared to the spectra measured on the two others. This may indicate a lowering of the symmetry around Ti atom, which is likely related to the creating an oxygen vacancies [3,4].

In order to observe surface plasmon polaritons (SPPs) in a photoemission electron microscopy (PEEM) experiment, ultrashort (15 fs) laserpulses of 800nm wavelength are directed onto a surface with plasmonic Ag or Au nanostructures. In the past, non-linear photoemission under grazing incidence was used to obtain a Moiré type contrast of propagating SPPs waves. If the light impinges perpendicular onto the surface (normal incidence) a direct imaging of the plasmon is possible, as the observed fringes resemble the SPP wave fronts. In time-resolved experiments under normal incidence conditions, propagation of isolated SPP wave packets can be observed. In this manner the direct measurement of group velocity and also the in-situ visualization of the propagation length become possible.

Non-linear photoemission microscopy has in the last years been shown to be a successful method for the imaging of surface plasmon polaritons (SPPs) and for the observation of the time-dependent propagation of SPPs across a surface. Using femtosecond laser pulses of a photon energy that is smaller than the work function of the plasmonic material of interest, SPPs are imaged via a plasmon-enhanced two-photon photoemission process in which a part of the laser pulse is used to excite SPPs, while the remaining part of the laser pulse is used to generate photoelectrons and probe the SPP state with spatial resolution. 2PPE PEEM then detects the temporal integral of the fourth power of the superposition of all electric fields at the surface.

So far, almost all experimental 2 PPE PEEM setups have exploited a grazing incidence geometry in which the fs laser pulses impinge on the surface under an angle of $\sim 70^\circ$ relative to the surface normal. A moiré pattern can then be used to describe the contrast in two-dimensional plasmonic structures. The periodicity of the observed moiré pattern, however, is different from the wavelength of the SPP. For the moiré contrast the projection of the exciting light field into the surface plane is relevant, and accordingly, the spacing of the moiré maxima depends on the angle of incidence of the laser pulses on the surface. In particular, with decreasing incidence angle the moiré pattern is expected to converge into the SPP wavelength until under normal incidence a “direct imaging” of SPP wave packets becomes possible. At the same time the propagation direction of the SPP changes. We present 2PPE PEEM results for Grazing Incidence (GI) and Normal Incidence (NI) 2PPE PEEM and discuss the differences between the two situations. The interpretation will be backed up by a simple plane-wave model for the superposition of the plasmon’s electrical field and

the femtosecond laser pulse.

FeRh is a unique material that undergoes a first order antiferromagnetic (AF) to ferromagnetic (FM) transition above room temperature (near 350 K) [1]. This phase transition, which is coupled to a lattice expansion, can be driven by temperature or magnetic field. FeRh in thin film form is therefore a promising candidate for heat-assisted magnetic recording in an exchange-spring system with a hard magnetic layer (for example FePt) [2,3]. Upon application of heat, FeRh becomes FM and lowers the switching field by a spring exchange mechanism. At room temperature, the AF phase does not alter the coercive field of the hard layer, hence the magnetic information stored in the hard layer is stabilized. Interfacial effects are highly relevant to the understanding of the coupling mechanisms between FeRh and adjacent layers and to the use of FeRh for technological applications.

Here we report on the use of photoemission electron microscopy (PEEM) to investigate the influence of interfaces on nucleation and growth of FM domains in FeRh. Imaging the magnetic contrast at different temperatures via x-ray magnetic circular dichroism (XMCD), we directly observe the nucleation and growth of the FM domains. In epitaxially FeRh thin films (grown on (001) MgO substrates) we find nucleation growth, and coalescence stages of FM domains characteristic for the first order AF to FM phase transition (Fig. 1). Comparing results for samples with different capping layers we find that in some cases an additional capping layer can lead to the formation of interface induced FM domains persisting even at room temperature[4].

Magnetic nanoparticles show a rich variety of new properties when compared to the respective bulk materials, mostly due to the effect of the surface and interface on the magnetic interactions and to critical magnetic length scales such as domain wall width and exchange length. Tuning these properties requires precise control over their size, shape, and composition. For instance the size may determine whether a particle is in a single domain state or whether it will show a non-collinear spin structure [1]. The search for ever smaller nanomagnets being switchable between two states (bistability) at room temperature and sizes which are technologically relevant is a growing area of research due to their potential for applications in fields such as information storage media, biology and medicine. It is therefore important to further develop methods which give insight in the magnetic anisotropy energy and the magnetic reversal of individual nanomagnets [2].

We have used photoemission electron microscopy (PEEM) together with x-ray magnetic circular dichroism (XMCD) to investigate size-dependent magnetic properties of Fe, Co, and Ni nanoparticles.. We observe that a sizeable fraction of Fe and Co nanoparticles with a mean size of about 12 nm is magnetically stable at room temperature. However, Ni particles show no magnetic contrast (cf. Fig. 1). Combining the PEEM data with complementary atomic force microscopy and scanning electron

microscopy data, we will give a detailed comparison of the different systems and discuss the origin of their properties.

⁵Australian Synchrotron - Clayton (Australia).

Low work function surfaces on diamond that are chemically stable and can be operated at elevated temperatures are of great technological interest. Not only do they offer a means to make high brightness, low 'noise' electron sources, but also energy conversion devices and radiation detectors. This is due to the high electron yields often observed when the work function of diamond is significantly lowered. Usually, this is achieved by treating the diamond surface with atomic hydrogen to terminate all the available carbon dangling bonds with hydrogen atoms. Since carbon is more electronegative than hydrogen, each carbon-hydrogen bond is polarised creating a surface dipole with the positive charge on the hydrogen atom. Collectively the dipoles disposed on a diamond surface form a double layer that pulls down the vacuum energy barrier for electron emission (lowering the work function) to such an extent that electrons at the bottom of the diamond conduction band are at a higher potential than the vacuum level. Under these conditions the diamond surface exhibits a Negative Electron Affinity (NEA). For the fully hydrogenated C(100)-(2 x 1):2H surface each surface carbon has two dangling bonds available to bond to hydrogen. The value measured by He I, Ultra violet Photoemission Spectroscopy (UPS) for this NEA on p-type (NA ≈ 10¹⁶ cm⁻³), diamond is typically -1.3 eV. This compares favourably with the predicted value of -1.95 and gives a minimum work function for this surface of 3.9 eV. But recently we have found that for an oxygen-terminated, p-type diamond surface with a single monolayer (1ML) of lithium absorbed on it, the NEA is much larger. Our model calculations suggest that Li adsorption leads to partial delocalization of charges that would otherwise be bound tightly to the surface, leading to a large effective dipole. The predicted value for an energetically stable NEA on the C(100)-(1 x 1):O,Li surface being -3.9 eV. The experimental value that we

deduce from UPS measurements is -2.1eV , which is substantially smaller than the theoretical value. Spectroscopic photoelectron emission microscopy provides image contrast influenced by changes in work function induced by crystallinity, crystal orientation, and the nature of atoms absorbed onto a surface. Using this technique, the addition of oxygen and lithium atom layers, and their controlled desorption from polycrystalline diamond surfaces has been studied in order to gain further insight into the distribution and the values of work functions attainable on degenerately doped ($N_A, N_D \approx 10^{20}\text{cm}^{-3}$), p- and n-type diamond films. In this report we demonstrate the use of UHV Scanning Kelvin Probe Microscopy to interpret energy filtered photoemission images of lithiated diamond obtained by NanoESCA.

Ultrafast magnetization control by femtosecond laser pulses is an intensively developing technique in recent spintronics researches. In GdFeCo ferrimagnetic thin films having perpendicular magnetizations, unusual phenomena beyond the description of conventional magnetism such as deterministic magnetization reversal which is unable to explain by simple recovery process from heat demagnetization state[1], helicity-dependent magnetization switching[2] and transient breaking of ferrimagnetic coupling state[3] have been reported.

From the viewpoint of practical application, it is also an important issue to optimize the performance of magnetization reversal by controlling compensation of angular momentum and its temperature dependence. Figure 1(a) shows Kerr microscope images of three kinds of [Glass (sub)/Ta(5 nm)/Ru(20 nm)/Si₃N₄(5 nm)/Gd_xFe_{92-x}Co₈(20 nm)/Ru(1 nm)/Ta(1 nm)] films (x=22, 24, 26) after applying a circularly polarized laser pulse ($\lambda=800$ nm, $\tau\sim 120$ fs, ~ 12 mJ/cm²) at room temperature. By varying only the composition of the GdFeCo alloy layer, the shape of the produced magnetic domains is drastically changed and helicity dependent switching is clearly observed in the sample containing 26% of Gd. It has also been acknowledged that the shape of modified magnetic domain is changed by omitting a Si₃N₄ heat blocking layer or by applying a pulse in different environments (air/vacuum). The results show the importance of controlling the macroscopic heat diffusion by designing optimum multilayer structure as well as the microscopic gyrotropic motion in the process of laser heating. Figure 1(b) shows time-resolved magnetic domain images of

Gd₂₆Fe₆₆Co₈ thin film after a laser pulse fluence observed by a photoemission electron microscope (PEEM). In this talk, dynamic behavior of laser induced magnetization reversal and spatial distribution of magnetization in its process will be discussed, showing the results on a variety of GdFeCo films.

High resolution band structure imaging with a new photoelectron emission microscope

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-8

N. Barrett, C. Mathieu.

DSM, IRAMIS, SPCSI, LENSIS - Gif-Sur-Yvette (France).

The analysis of chemical and electronic states in complex and nanostructured material systems requires electron spectroscopy to be carried out with nanometer lateral resolution, i.e. nanospectroscopy. This goal can be achieved by combining a parallel imaging photoelectron emission microscope (PEEM) with a bandpass energy filter. The decisive advantage of energy filtered, photoelectron emission microscopy is the simultaneous combination of high spatial and energy or wave vector resolution. Using an appropriate PEEM system, correlations may be made on the micron or sub-micron scale between chemical and electronic structure. Typical synchrotron beam spots are several tens of microns in width and cannot provide the same spatial resolution unless used in scanning mode with zone plates. On the other hand, their energy resolution is very good, typically better than 50 meV and band structure studies of highly correlated materials require such a spectroscopic resolution. Until now this was not possible in PEEM. Therefore, the challenge for PEEM based chemical and band structure imaging is to approach this figure in order to provide a decisive new tool to study spatially resolved electronic structure.

Here we present some first results using the "MesoXcope", an energy filtered PEEM with target spectroscopic resolution of 50 meV. The initial improvements over existing PEEMs will be discussed in terms of the extra degrees of freedom available for sample alignment, the sample temperature and the use of micro-apertures in an intermediate image plane. Reciprocal space imaging of the band structure with a high intensity, focussed He I/II laboratory source will be shown with a view to its application to graphene and 2D functional oxides.

RESONANT 2PPE-PEEM FOR ORGANIC FILMS

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-3

T. Munakata, C. Udhardt, T. Ueba, R. Terawaki, T. Yamada, H. Kato.

Osaka University - Toyonaka (Japan).

The interplay between the electronic structure and the molecular arrangement is one of the hot topics of surface science. Because the electronic structure of organic films is sensitive to intermolecular interaction as well as to substrate-molecule interaction, the electronic structures are frequently spatially inhomogeneous even on well prepared films. In order to control and improve the functionalities of organic films, the electronic structure should be measured with high lateral resolution. We report lateral distribution of unoccupied electronic states of organic thin films studied by combined use of two-photon photoemission (2PPE) spectroscopy and 2PPE-PEEM.

The light source is the third harmonic output of a titanium sapphire laser operated at the photon energy region between 3.9 and 4.6 eV, a repetition rate of 76 MHz, and a pulse width of 100 fs. The unique feature of our PEEM is the high-precision stage [1]; The step resolution is 10 nm, and the absolute accuracy is better than 100nm. The size of the PEEM image is accurately determined by the translation of the sample. When one-photon photoemission (1PPE) PEEM images are measured for lead phthalocyanine (PbPc) films on HOPG, several islands of different brightness are observed. Photoemission yield curves are obtained for different islands by plotting the brightness as a function of the photon energy. Comparison with the micro-spot photoemission spectroscopy of 0.3 μm resolution clarifies the origin of the islands [2]. 1PPE-PEEM image of sub-ML rubrene on HOPG shows only very weak contrast, because the work function of the film is close to that of HOPG. On the other hand, 2PPE-PEEM images show high-contrast at the pump photon energy of 4.40 eV as shown in Fig.1. The images of the bright islands originate from a resonant excitation to a specific unoccupied molecular orbital (labeled as L_n). Resonant excitation to the L_n level is strongly enhanced by mixing of L_n with the image potential state on HOPG [3]. The bright area is composed of small fine-structures with large boundary. The unoccupied states are more sensitive than occupied ones to the environment around

the molecules [4].

Time resolved XMCD-PEEM measurements have been developed by our group at ESRF, SOLEIL and ELETTRA to allow the direct observation of magnetisation dynamics induced by nanosecond current pulses in magnetic nanostructures.

Manipulation of magnetic domain walls (DW) in these nanostructures, through the spin transfer torque effect, has been extensively studied in the last years [1]. These studies are motivated by potential applications to spintronic devices and memories, but also by the wealth of interesting physical phenomena associated to the interactions between conduction electron spins and local magnetisation. The dynamics of DW under the action of spin polarised current is complex and implies a modification of the internal domain wall structure. A full understanding of it relies on the observation of DW during the application of the current pulse.

We carried out time-resolved XMCD-PEEM measurements for two types of nanostructures: i) trilayers and bilayers containing Py, in which the magnetisation lies in the plane of the layers and DW are relatively wide (a few 100nm); ii) asymmetric structures containing ultrathin Co, where the magnetisation is out of plane and DWs are narrow (some nanometers).

In Py-based trilayers and bilayers, we found that the DW mobility is much larger than in single Py layers, thanks to the action of a non vanishing Oersted field on the Py magnetisation. This field, transverse to the current direction, stabilises the internal DW structure, preventing the periodic transformation that in single Py layers reduces

the average DW speed for large current densities. XMCD-PEEM measurements carried out during the current pulse using our Focus IS-PEEM, allowed us to give clear evidence of the effect of such an Oersted field, which leads to a tilt of the Py magnetisation in the transverse direction [2]. More recent measurements still under development on the Elmitec PEEM in Elettra also show that the DW internal structure is modified during the pulse but that the periodic transformation is suppressed by the presence of the Oersted field.

Time-resolved XMCD-PEEM measurements on Pt/Co/AlO_x nanostructures allowed us to study the long distance motion of the DWs during the current pulses, and to show that the domain walls in this system present a very weak inertia. This means that the temporal response of DW to the current pulse is instantaneous: DW start moving as soon as the driving force is applied. This behaviour - different from that found in DW in Py where the inertial effects are very important - is connected with the presence of narrow domain walls (Bloch or possibly Néel) whose internal structure is only weakly modified during the pulse [3]. Our measurements show that these systems are clearly better suited for applications to magnetic memories, where the frequency at which information can be transferred would suffer from the presence of strong inertial effects.

These measurements show that the high spatial and time resolutions obtainable with XMCD-PEEM make this technique a tool of choice for the study of magnetisation dynamics in nanostructures.

Nanoscale control of plasmon dipolar and quadrupolar resonances in Au triangles using polarization- and energy-dependent light excitation

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-2

L. Douillard ¹, T. Popescu ¹, C. Awada ¹, F. Charra ¹, A. Perron ², H. Yockell-Lelièvre ², A.L. Baudrion ², P.M. Adam ², R. Bachelot ².

¹CEA - Gif Sur Yvette (France), ²UT Troyes LNIO - Troyes (France).

Localized surface plasmon resonances (LSPR) are coherent charge oscillations within metallic particles offering a way to concentrate and manipulate light on the nanoscale. Aside from size, shape and dielectric environment, the effect of directionality upon the light-plasmon coupling is crucial for applications, including directional nano-antennas, selective control of single molecule fluorescence [1] and surface-enhanced Raman spectroscopy (SERS) [2]. We study this directional aspect here by obtaining qualitative and quantitative measurements of the plasmon resonances in dipolar and quadrupolar modes as a function of the polarization and wavelength of the incident light [3].

We are able to lift the degeneracy between orthogonal plasmonic resonances by varying the linear polarization of the incident light. The experimental results are obtained using photoemission electron microscopy (PEEM), an optical excitation scheme (photon-in, electron out) that allows control over the polarization and energy of the exciting field. We obtain full field images of the plasmon resonance “hot spots” via photoelectrons collected using traditional electron optics. Nanometer scale spatial resolution (20 nm lateral resolution) and a spectral resolution of < 5 meV at 800 nm are achievable.

In the present study, we analyze regular gold triangles with in-plane altitudes spanning the range [100, 300] nm and a thickness of 50 nm, fabricated by electron beam lithography (EBL) and deposited on a 0.5 nm titanium oxide (TiO₂) adhesion

layer and 5 nm of ITO.

According to group theory calculations [4], an isolated triangular prism of group D_{3h} has three dipolar modes that can couple to the linearly-polarized incident field: one inaccessible high-energy out of plane mode, and two degenerate in-plane modes. By varying the polarization between orthogonal p- and s-modes, we are able to excite these two degenerate modes independently. A similar analysis yields the quadrupolar modes, which we observe experimentally. Finally, PEEM results correspond well to simulations using finite difference time domain (FDTD) simulations and the wavelength dependence of the dipolar and quadrupolar modes can be correlated to measurements obtained using extinction spectrometry.

Spectroscopic XPEEM at ALBA: first results

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-P3-12

L. Aballe¹, M. Foerster¹, J. Fontcuberta², C. Ocal², E. Barrena², S. Matencio².

¹ALBA Synchrotron Light Facility - Barcelona (Spain), ²Institut C. Materials Barcelona - Barcelona (Spain).

The spectroscopic XPEEM station at the CIRCE beamline in ALBA started user operation in late 2012. The beamline provides variable polarization photons with high flux and resolution in the energy range 100 – 2000 eV, and the spot at the microscope sample position can be focalized down to a size of $\sim 12 \times 36 \text{ m m}^2 \sqrt{xH}$. The XPEEM electron optical system including an energy analyzer offers many complementary techniques for the advanced characterization of surfaces, thin films and nanostructures by combining different working modes (spectromicroscopy, microspot, diffraction) with either absorption, dichroic and/or photoemission contrast mechanisms. The experimental station permits in situ sample preparation and fast sample transfer. A brief review of the beamline and microscope performance will be given and first results on self-organized oxide surfaces and thin films will be presented.

FPFI-3-Or-6

PEEM3: An aberration-corrected PEEM at the Advanced Light Source

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-3-Or-6

M. Marcus, A. Scholl, A. Doran.

Advanced Light Source, Lawrence Berkeley National Laboratory - Berkeley, Ca (United states).

PEEM3 is a photoemission electron microscope (PEEM) at the Advanced Light Source (Lawrence Berkeley Laboratory). It is fed by an elliptically-polarizing undulator, allowing the use of polarization for imaging of ferroelectric, ferromagnetic and antiferromagnetic domains, as well as crystal orientation. The PEEM also provides the option of using an aberration corrector for high spatial resolution, and a wide-field mode with a 100 μ m field of view. The sample manipulator provides translation over millimeters and temperatures ranging from 30-800K. This variable-temperature option makes possible a wide range of experiments not possible in most PEEMs. In addition, it is possible to make electrical connections to the sample from electronics on a floating "hot deck", which allows time-resolved measurements using on-sample generation of pulsed electric and/or magnetic fields in a pump-probe mode. An in-situ strain sample holder is also available. The range of incident X-ray energies is 150-1600eV, covering the CNO K-edges, 3d-metal L-edges and lanthanide M-edges. In addition to simple imaging, it is possible to take "stacks" at sequences of energy and, optionally, polarization, thus allowing element specificity. PEEM3 is thus a versatile tool for materials science, especially in the areas of magnetics and multiferroics.

In this presentation, we will show the electron-optical layout of PEEM3, discuss strategies for tuning the instrument, and present examples of a diverse collection of work which has been performed there.

FPFI-P3-14

Soft X-ray Spectromicroscopic Studies of Graphene Nanomaterials by X-ray Photoemission Electron Microscopy (X-PEEM)

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-P3-14

J. Wang ¹, J. Zhou ¹, C. Karunakaran ¹, C. Wright ¹, S. Urquhart ².

¹Canadian Light Source Inc. - Saskatoon (Canada), ²University of Saskatchewan - Saskatoon (Canada).

Graphene nanomaterials have been attracting enormous attentions in many fields and technological applications for their unique structures and outstanding physicochemical properties. A thorough understanding and analysis of the graphene nanomaterials not only requires nanoscaled spatial resolution for morphology, but also demands the elucidation of the chemical and electronic structure of the systems. The X-ray Photoemission Electron Microscope (X-PEEM) at the Canadian Light Source (covering 130 - 2500 eV) is well suited to these requirements through its powerful spectromicroscopic capabilities. Particularly, X-PEEM provides the X-ray absorption contrast images via total electron yield, the quantitative distributions (maps) of chemical components through spatially-resolved X-ray Absorption Near Edge Structures (XANES) spectroscopy, and the molecular orientation with the help from arbitrarily-controlled polarized X-ray beam, at high spatial resolution (< 50 nm) and high energy resolution (< 0.05 eV). In this poster, selected examples of X-PEEM analysis of graphene nanomaterials, such as reduced graphene oxide (rGO), i.e. graphene, and graphene nanocomposites will be presented. One of the major challenges for X-PEEM measurements of ultra-thin graphene samples is the normalization in the low energy regime, particularly the C and N K-edges, which is due to the incident X-ray beam having significant absorption dips in these energy edges caused by the absorption of the ubiquitous beamline contaminants. To overcome this problem, a few approaches have been explored, such as normalization to clean Si wafer, to Si photodiode and to fresh gold mesh etc. With successful normalization our spectromicroscopic findings reveal the morphological,

chemical and electronic structure information and variations, as well as the defects and contaminants associated with the individual graphene nanomaterials.

FPFI-P3-13

The wide application range of the NanoESCA: From micro-ARPES to HAXPEEM

T07 Frontiers in Photoelectron Full-field Imaging and Spectromicroscopy

#FPFI-P3-13

N. Weber ¹, M. Escher ¹, T. Kühn ¹, M. Merkel ¹, C. Wiemann ², M.C. Patt ², C.M. Schneider ².

¹FOCUS GmbH - Hünstetten (Germany), ²Peter Grünberg Institute (PGI-6) and JARA-FIT, Research Centre Jülich - Jülich (Germany).

The NanoESCA is a photo electron microscope (PEEM) equipped with a band pass filter. Its capabilities in imaging x-ray photoemission (iXPS) and k-space imaging have been well proven in the past [1, 2]. We now present a modified electron optics, which allows for imaging hard x-ray photoemission spectroscopy (HAXPES) up to 10keV [3]. The newly designed optics simultaneously allows higher transmission and a larger range in imaging k-space.

HAXPES is a well established technique for bulk sensitive photoemission [4]. In order to extend this technique to laterally structured samples, the NanoESCA has been upgraded to be used for hard x-ray photoemission electron microscopy (HAXPEEM). One key feature of this upgrade is the high extraction voltage, which has been raised to 24keV, to enable an easy sample biasing scheme.

HAXPEEM results were obtained at PETRA III [3]. The inset in figure 1 shows the image of a checkerboard-patterned Au/Si sample, using Au4f_{7/2} core level electrons. Bulk sensitivity is demonstrated at the Si2p peak. Whereas the spectrum taken at hv=4.9keV (Fig. 1) shows predominantly the elemental silicon signal, the spectrum at hv=400eV (not shown, Elettra [5]) is dominated by a mixture of different oxidation states of silicon.

The modified electron optics enables the NanoESCA instrument allows to image a larger k-space of 8 Å⁻¹. With Hell excitation we can demonstrate a k-space of 6 Å⁻¹, limited by the takeoff angle of the photoelectrons (Fig. 2).

Functional Proline—Based Chiral Ionic Liquids : Catalysts for Chiral Synthesis

T08 Functional Molecules and Molecular Machines

#FMMM/NST-P3-01

K. Nobuoka ¹, S. Kitaoka ², Y. Yamamoto ¹, Y. Ishikawa ¹.

¹Oita University - Oita (Japan), ²Kinki University - Higashihiroshima (Japan).

Ionic liquids have various properties that make them attractive for application. The high designability of the ionic liquids gives various functional possibilities. Among the functional ionic liquids, the chiral ionic liquids have received considerable attention as an enantioselective catalyst and a medium for chiral synthesis or chiral extraction. Therefore, we designed and synthesized novel functional chiral ionic liquids starting from L-proline which is a natural chiral amino acid.

First, we synthesized the chiral ionic liquids which consist of a pyrrolidine ring from L-proline and a bulky quaternized five-membered unsaturated aza-hetero cycle with a simple methyl group (Figure 1(a)). The ionic liquids (a) have low viscosity (124 cP at 25 °C) and very low glass transition temperature ($T_g = -73$ °C) which are suitable for reactions over a wide temperature range. Thus, we investigated the catalytic ability of the chiral ionic liquids (a) for asymmetric reactions. In Michael reaction of β -nitrostyrene and cyclohexanone, the ionic liquids catalyst (a) gives relatively high stereo- and enantio- selectivities (syn/anti = 92/8, 85% ee(syn)), whereas in moderate yield (52 %). Brønsted acids additives improve the yields without lowering the selectivities (88%: TFA, 93%: salicylic acid). In addition, the chiral ionic liquids (a) could be reused at least three times without significant loss of activity.

The result of Michael reactions revealed that the chiral ionic liquids (a) works well as a chiral catalyst. Subsequently, we designed the ionic liquids (Figure 1(b)) with a hydroxyl ethyl group instead of the methyl group of the ionic liquids (a) in order to improve its reactivity and enable to use the wide range of the asymmetric reactions and the substrates. Its hydroxyl group can form hydrogen bond with the substrates

such as, the nitro group of β -nitrostyrene, in the transition state. Although the presence of a hydroxyl group increases its viscosity somewhat (1024 cP at 25 °C), the glass transition temperature ($T_g = -53$ °C) is low enough which are suitable for reactions. In the presence of 15 mol % of the ionic liquids (b), the Michael adducts were formed with relatively high yield (76%). Adding *p*-nitrophenol can further improve the yield (86%) and the selectivities (syn/anti = 98/2, 95% ee(syn)). Besides, both chiral ionic liquids could be reused at least three times without significant loss of activity.

These proline-based chiral ionic liquids and their derivatives would be one of the powerful tools for various enantioselective reactions via chiral enamine intermediates. Therefore, we now investigate enantioselective reaction except for Michael reaction.

Fig1. Structures of proline-based chiral ionic liquids

The Anion effect of Functional Ionic Liquids for Porphyrin Preparation

T08 Functional Molecules and Molecular Machines

#FMMM/NST-P3-02

S. Kitaoka ¹, K. Nobuoka ², T. Matsufuji ², Y. Ishikawa ².

¹Kinki University - Higashi-Hiroshima (Japan), ²Oita University - Oita (Japan).

Because of their green properties, ionic liquids are widely used for various reactions. We have already reported the porphyrin preparation using acidic ionic liquids as a phase separated catalysis ([1, 2]). The porphyrin preparations in the conventional ionic liquids also have been already reported by us ([2]). However, there is no study about the porphyrin preparation in the functional ionic liquids such as acidic ionic liquids. Herein, we report the tetraphenylporphyrin, TPP preparation in the acidic ionic liquids, [HC₄mim][X] (**Figure 1**).

[HC₄mim][CF₃CO₂], [HC₄mim][BF₄] and [HC₄mim][Cl] produced TPP at 15%, 9% and 5% in yield, respectively (**Table 1**). The yield in [HC₄mim][CF₃CO₂] is the same level as the reaction in the propionic acid (15%). These results suggested that the yields of TPP is affected by the anion of ionic liquids. The efficacy of the ionic liquids to promote these cyclization reactions was correlated to the basicity of the anions of ionic liquids. It was observed that with increasing basicity of the anion (increasing *pK_a* of the corresponding acid) there is a progressive increase in yield (**Table 1**).

In addition, [HC₄mim][CF₃CO₂] could be reused at least 2 times without any loss of its catalytic activity. This porphyrin synthesis in the acidic ionic liquids enabled to suppress the acid waste.

Observation of Cross-over of Vibration and Kondo Resonance Excitation at Single Molecule Magnet TbPc₂ complex

T08 Functional Molecules and Molecular Machines

#FMMM/NST-1-Or-1

T. Komeda, H. Isshiki, J. Liu, K. Katoh, M. Yamashita.

Tohoku University - Sendai (Japan).

There are rising interests of the application of the spin to the quantum information process. Organic molecules have unique capabilities for such applications, and a single-molecule-magnet (SMM) molecule is one of best candidates for them. The analysis of vibrational and spin information are indispensable techniques to characterize a single molecule devices. In addition the interaction of vibrational mode and spin states are of great interest for an advanced control of the molecule conductance.

In this study we want to investigate the interference between the vibrational mode and Kondo resonance in the film of TbPc₂ molecule, [1-3] which is a phthalocyanine double decker molecule and shows the SMM property. To obtain higher resolution, we employed low temperature STM in a part of the experiment whose head is cooled by a dilution refrigerator operated at 600 mK, at which temperature we expect the resolution of ~500 μ eV.

We show the d^2I/dV^2 spectrum obtained for the centre of the TbPc₂ molecule adsorbed on the Au(111) surface in Fig. 1. We can observe peaks at 53, 75 and 95 meV at symmetric positions which are originated from vibrational excitations. Tip position dependence is shown in Fig. 2. At the lobe position we see a derivative like feature at around the Fermi level. This is originated from the Kondo resonance formed by an unpaired π orbital of the Pc ligand. When the tip was moved to the center, only vibrational nature were observed. We confirmed two distinct molecular orbitals on the molecule from DFT calculation. Depending on which orbital the tunneling electron injected, the cross-over between vibration and Kondo excitations occurs.

that the spin and electronic states of the organic molecules are strongly correlated with their structures.[1]R. Robles et al., Nano Lett. 12, 3609 (2012). [2]T. Komeda et al., Nat Commun 2, 217 (2011). [3] K. Kato et al., Coord. Chem. Rev. 255, 2124 (2011).

Understanding of molecular switching between different charge states is crucial to further progress in molecule-based nano-electronic devices. Scanning tunneling microscopy (STM) is one of the most promising techniques for imaging of prototype molecular devices and testing their properties. We employed scanning tunnelling microscopy to reveal a correlation between charge state of a individual C₆₀ molecule and its orientation within a molecular layer grown on the WO₂/W(110) surface. Tunnelling junction based on individual C₆₀ molecule is stable below temperature of kinetic rotational transition of 220K [1] when all molecules are static. However, in the temperature range of 220–260 K some isolated molecules switch between high-, and normal- conductance states. At high temperatures the molecules rotate continuously so fast that no “blinking” is observed and all molecules appear as perfect spheres [2]. High- conductance state arises due to charging of the C₆₀, which causes changes in the local density of electron states near Fermi level and consequently a variation in tunnelling current. Using density functional theory calculations, these states were suggested to be: charge-neutral C₆₀; negatively charged C₆₀⁻, which has accepted an electron. Such molecules appear in STM topography as flashing nano-bulbs on the surface. Switching of the molecule conductance state is accompanied by change of molecule orbital structure detected in STM topography that proves change of

orientation of the molecule during switching. Molecular movement accompanies the molecule's switching between these states; as the molecule rotates, it exchanges charge with the substrate, gaining or losing an electron.

Responsive organic monolayers have found application as smart systems – enabling reversible control of surface properties such as wetting, adhesion, catalytic activity, or serve as molecular memory devices or platforms for nano-engineering. In this contribution the functionality of several molecular switches in solution and in monolayers is discussed. The first example is a remarkably robust self-assembled monolayer (SAM) of a bithioxanthylidene redox switch (**1**, Fig. 1) that shows excellent bistability, manifested in reversible changes in spectroscopic and electrochemical properties and in physical properties such as water contact angle (a ca. 30° difference in water contact angle between the two redox states of a bithioxanthylidene monolayer) [1]. The effect of surface immobilization of the bithioxanthylidene on its photochromic, thermal and electrochemical properties is described. Raman, SERS and XPS spectra provide essential information on molecular transformations in SAMs. As a result, a combination of light and potential allows accessing four distinct conformational and redox states in monolayer. The second example is a photochromic and redox active spiropyran SAMs (**2**, Fig. 1) that undergo substantial changes in polarity and dipole moment upon switching and have found numerous applications in a wide range of novel smart materials, photonic devices and logic units. Under ambient conditions spiropyrans are in the ring-closed form (SP) and ring-open merocyanine (MC) form can be generated photochemically [2].

We prepared self-assembled monolayers of spiropyran on gold for further utilization of its photochromism and redox activity. Ring open MC form can be successfully

induced in monolayers with UV light, as evidenced with UV/Vis absorption, XPS and SERS spectroscopies. On the other hand, application of electrochemical potential induces oxidation and irreversible chemical reaction in spiropyran. In contrast to earlier reports, we show a spectroscopic evidence for the mechanism of this oxidation in SAMs and identify products of the oxidation cycle in spiropyrans. Thus, the combination of light and redox potential in spiropyrans provides access to six unique states in monolayers of a spiropyran, which represents a versatile system, where it is possible to store information both temporary and permanently.

Among several new concepts in electronic technology, the one based on utilization of single organic molecules, acting as active blocks performing logic operations, appears as one of the most appealing and is based on the state-of-the-art use of modern nanotechnology tools, such as scanning tunneling microscopy (STM) and non-contact atomic force microscopy (NC-AFM). In order to facilitate molecular orbital imaging and spectroscopy, electronic decoupling of the molecule in question from the underlying substrate is required. It is expected that proper isolation of such molecular entities could be achieved by application of passivated semiconductor surfaces, e.g., Si(001):H and Ge(001):H.

Following the first experiments with pentacene molecules on the Si(001):H surface we performed measurements of trinaphthylene molecules (Y molecules) on the hydrogenated Ge(001):H substrate with the application of low temperature scanning tunneling microscopy/spectroscopy (STM/STS) supported by the advanced theoretical modeling. In the presentation we will discuss the influence of the substrate on the electronic properties of adsorbed molecules and the role of surface dangling bonds (DBs) on the adsorption, immobilization and molecule imaging. We will show that HOMO states of the molecule physisorbed on the hydrogenated surface are hidden for STM measurements due to filtering by the substrate. These states could be directly accessed only if the molecule is laterally manipulated and connected to surface DBs, that leads to increased coupling. Reversibility of the manipulation processes gives perspectives for practical implementations as molecular switches. Finally, perspectives for tip induced molecule manipulation on passivated

semiconductors leading to further integration of nanoscale circuits based on molecules and DB structures created with atomic precision will be demonstrated.

Molecular recognition at interfaces is a key aspect in several important present and perspective applications, leading to nanomaterials with new, tunable and improved properties, in the field of sensing, drug-delivery and molecular electronics.[1] Previous studies have pointed out the importance of calix[4,6]arenes in the production and reactivity of supramolecular architectures based on rotaxanes.[2,3,4] Extending molecular recognition to the surface reactivity of calixarenes may develop additional and more attractive properties, allowing for potential use of the resulting hybrids.

Gold nanoparticles (AuNPs) have been anchored on Si(100) surface through a complex rotaxane-based system, using wet-chemistry procedures and extra-mild Si activation. The resulting samples have been characterized through surface (XPS, AFM and SEM) and electrochemical techniques. Molecular adhesion on the specific binding sites has been demonstrated by the presence and quantitation of XPS signals from specific elements in the molecules. AFM and FESEM measurements have revealed morphology consistent with the presence of AuNPs. Functionalized Si surfaces have been successfully used as electrodes for a controlled release of AuNPs in solution after an electrochemical treatment.

FMMM/NST-1-In-1 FUNCTIONALITIES FROM CORRUGATED SP²-BONDED MONOLAYERS

T08 Functional Molecules and Molecular Machines

#FMMM/NST-1-In-1

J. Osterwalder.

Physik-Institut, Universität Zürich - Zurich (Switzerland).

Single layers of hexagonal boron nitride (h-BN) or graphene exhibit strong corrugations with periodicities in the few nanometer range when grown on transition metal surfaces with a large lattice mismatch. The geometrical corrugation is accompanied by a corrugation of the electrostatic potential, which provides these surfaces with certain functionalities, e.g. for the trapping of molecules. The corrugation can be lifted by the intercalation of hydrogen atoms underneath the monolayer, leading to effects observable also on the macroscopic scale. In my presentation I will give an overview on recent results on these nanomaterials obtained in our research group.

Identification of macroscopic solid-like correlations from RT-Ionic Liquids to Liquid Water

T09 Ionic liquids surfaces and interfaces

#ILS-2-Or-4

L. Noirez.

Laboratoire Léon Brillouin - Gif-Sur-Yvette (France).

At a macroscopic scale, normal liquids (i.e above the melting temperature of the crystal), are typically and empirically defined by the absence of shear elasticity by opposition to solids or plastic fluids that require a stress threshold for flowing. A novel method optimising the transmission of the shear stress to the sample enables to probe the true mechanical response of liquids. It reveals that glass formers and viscous alkanes exhibit actually finite macroscopic shear elasticity away from any phase transition. This study is for the first time extended to molecular liquids as simple liquids (Heptadecane), room temperature ionic liquids ([emim][Tf2N]) and water, confirming the generic character of the elastic properties governing the sub-millimeter properties of liquids, even away from any phase transition[1,2].

Surface structure of binary mixtures of ionic liquids using high-resolution Rutherford backscattering spectroscopy

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-5

K. Kimura, K. Nakajima, S. Oshima, M. Suzuki.

Kyoto University - Kyoto (Japan).

Ionic liquids (ILs) are known as “designer solvents” because their properties can be tuned by appropriate combination of a wide range of anions and cations. The tuning can be also done by mixing different ILs. Recently, surface composition of binary mixtures of ILs was investigated using TOF-SIMS [1]. Although the charge neutrality holds at the surface, remarkable surface segregation of larger cations and/or anions was observed. This suggests the possibility that the bulk and surface properties can be designed separately by mixing appropriate ILs. There are, however, a couple of reports conflicting with the TOF-SIMS result, which shows no surface enrichment of particular molecules in IL mixtures [2, 3]. Thus, the surface segregation of particular molecules in IL mixtures is still the subject of debate. In the present work, the surface structures of equimolar binary mixtures of ILs, which have different anions and a common cation, were systematically studied using HRBS. The chosen substances are imidazolium based ILs, namely [C₆MIM] [TFSI], [C₆MIM] [PF₆], [C₆MIM] Cl, [C₄MIM] [TFSI] and [C₄MIM] [PF₆]. The surface structures of the mixtures of these ILs were observed using HRBS as well as the pure ILs. For pure ILs, the alkyl chains of the cations protrude to the vacuum and the anions are located at almost the same depth as the imidazolium rings of the cations. The [TFSI] anion also shows a preferential orientation at the surface with CF₃ groups pointing toward the vacuum. For the mixtures, the molecules have the same preferential orientations at the surface as in the pure ILs. There is a tendency that larger anions are located at shallower depths than smaller anions in the mixture. In addition, the [TFSI] anion is found to be slightly enriched at the surface relative to [PF₆] with coverage of 60% for [C₄₍₆₎MIM] [TFSI]_{0.5}[PF₆]_{0.5} although no surface segregation is observed for other mixtures. These results can be roughly explained in terms of the surface tension.

IONIC LIQUID SURFACE SCIENCE: INTERFACE PROPERTIES AND CHEMICAL REACTIONS

T09 Ionic liquids surfaces and interfaces

#ILS-1-In-1

H.P. Steinrück.

Physikalische Chemie II, Universität Erlangen-Nürnberg - Erlangen (Germany).

An overview is given on the potential of X-ray photoelectron spectroscopy to investigate ionic liquid (IL) interfaces. The IL/vacuum interface of various imidazolium-based ILs is systematically studied by variation of alkyl chain lengths, by investigation of different anions, and by introduction of functional groups; detailed information on surface orientation, enrichment effects and the correlation to macroscopic surface tension of ILs is derived. The IL/solid interface between ultrathin ionic liquid layers on various substrates is studied with emphasis on the molecular arrangement and growth behaviour. Furthermore, we demonstrate the application of in situ XPS to monitor organic, liquid-phase reactions.

Metallic nanocolloids prepared by magnetron sputtering on the surface of an ionic liquid

T09 Ionic liquids surfaces and interfaces

#ILS-2-Or-3

P. Lobotka ¹, I. Vávra ¹, P. Kunzo ¹, G. Radnóczy ², Z. Czigány ², M. Držík ³.

¹IEE SAS - Bratislava (Slovakia), ²MFA KFKI - Budapest (Hungary), ³ILC - Bratislava (Slovakia).

Similarly to the pioneer work by Torimoto et al. [1], who exploited remarkable property of room temperature ionic liquids (RTILs) – very low vapour pressure of about 10^{-11} mbar – and prepared by sputtering colloids containing Au nanoparticles about 6 nm in size, we used the same procedure in preparation of non-magnetic (Ag-Cu) and magnetic nanoparticles of Ni and Ni-Fe in several RTILs (consisting of EMIM or BMIM cations and BF_4 or PF_6 anions, and BMIM-Tf2N). The main motivation is to prepare colloids with magnetic nanoparticles to be used later in sensorics. A further goal is to deposit proper nanoparticles from the nanocolloid on the surface of planar thin-film gas sensor [2] in order to increase its sensitivity and/or selectivity.

The metals were deposited in UHV sputtering machine from two magnetrons onto RTIL poured in a Petri dish. The nominal composition of Ni-Fe alloy was 80:20 which corresponds to that of permalloy. The presence of the nanoparticles in colloids was revealed by TEM, XRD, and UV-vis spectrometry (using localized surface plasmon resonance effect). We found the size of nanoparticles to be RTIL-dependent. For example, the nanoparticles formed by sputtering of Ni-Fe or Ag-Cu alloys on the surface of the 1-Butyl-3-methylimidazolium bis (trifluoromethylsulfonyl) imide are several times larger than those formed by sputtering on the surface of other RTILs used in the experiments. Even the nanoparticles of the size of ~ 40 nm show faceting which is a property so important for enhanced sensing and catalysis.

In our opinion, this technique provides an elegant way for preparation of nanoparticles with narrow size distribution and of different complex composite materials (metallic, semiconducting or insulating) that cannot be prepared by

chemical means. The nanocolloids are stable for many months; the nanoparticles are protected against oxidation, etc. Recently, we succeeded in deposition of Ni-Fe nanoparticles on a substrate by electrophoresis.

The authors P. L., I. V., and P. K. acknowledge the financial support by the APVV grant agency under the number APVV-0593-11.

TEM micrograph of Ni-Fe (80:20) nanoparticles obtained by simultaneous sputtering of Ni and Fe on the surface of the ionic liquid 1-Butyl-3-methylimidazolium bis (trifluoromethylsulfonyl)imide. The average size of faceted nanoparticles is about 12 nm. Please note the self-assembling effect.

ILS-P3-01

Electroplating of Al on Mg alloys in an ionic liquid for corrosion protection

T09 Ionic liquids surfaces and interfaces

#ILS-P3-01

M. Ueda, Y. Tabei, S. Hariyama, T. Ohtsuka.

Hokkaido University - Sapporo (Japan).

Magnesium alloys recently have a great attention and are expected to be future materials due to good mechanical properties and rightness in various fields of automobile, aerospace, and mobile phone etc. These alloys, however, have poor corrosion resistance which restricts the usage of alloys. For the corrosion protection, several surface treatments have been applied such as chemical conversion, anodization, organic coating, metal coating, etc. We aim in this presentation direct electroplating of Al onto Mg alloys in an ionic liquid. The electroplating is one of the simple processes and functional plating is easily produced. In this study, we report the electroplating of Al on Mg alloys from AlCl_3 -EMIC ionic liquid at the lower temperature of 283 K and 323 K. Observations of surface morphologies of Al deposits and of interfaces between the Al layer and the substrates are also reported. Aluminum chloride (AlCl_3 , 99.999% pure) and 1-ethyl-3-methylimidazolium chloride (EMIC, 99.5% pure) were used as received. All chemicals were handled under argon atmosphere in a glove box. A mixture of 67 mol% AlCl_3 -33 mol% EMIC of 80 ml volume was prepared in the cell. AZ91 and AZ121 magnesium alloy plates with surface area of 3 cm^2 were used as the working electrode. A pure aluminum plate (99.99%) and a pure aluminum wire were used as counter electrode and reference electrode, respectively. Electroplating of Al was done on the Mg alloys electrode under the constant current electrolysis or current pulse electrolysis with current densities of 1.7 mAcm^{-2} and charge density of 7 Ccm^{-2} in the ionic liquid at 323 K and 283 K. The composition analysis and surface observation of electrodeposits were used by EDS and SEM.

In the AlCl_3 -EMIC ionic liquid, the electrodeposition of Al takes place at the potential lower than 0.0 V v.s. Al/Al(III). Al deposits exhibited silver-gray on AZ91 and AZ121 alloys at 323 K. The appearance of Al deposit on AZ91 and AZ121 alloys were relatively smooth however, the needle-like deposits were observed in edge part of the alloy specimens.

The current pulse electroplating on the Mg alloys at 283K was carried out with applied current density of 1.7 mAcm^{-2} , the frequency of 0.67 Hz, and the duty ratio of

67 %. The Al layer on AZ91 and AZ121 were silver-white and some parts of the surface were mirror-like. In the cross-sectional SEM images of Al layers deposited, Al layers on AZ91 and AZ121 were uniformly formed and their average thickness were about 5 μm . Al electroplating on AZ121 reveal a good adherence and no small crevice was observed at the interface.

Ionic liquids (ILs) are molten salts composed solely of ions with a melting point below 100 °C and a negligible vapour pressure at room temperature. X-ray photoelectron spectroscopy (XPS) has proven to be a versatile tool for surface investigations of these materials under ultrahigh vacuum conditions (UHV).[1] It even allows to monitor reactions occurring in the near-surface region of ILs.[2] We demonstrate to our knowledge the first gas-liquid reaction studies between an IL and a gaseous species by means of in situ XPS in the mbar pressure regime. The anion of the IL $[\text{Me}_2\text{N}^+(\text{CH}_2\text{CH}_2\text{OH})_2][\text{H}_2\text{NCH}_2\text{CH}_2\text{SO}_3^-]$ was functionalised with an amine group ($\text{H}_2\text{N}-$), in analogy to aqueous amine systems for carbon dioxide capture applications. ILs are considered as potential replacements for these aqueous amines due to the extremely low vapour pressure and their typically high thermal stability. Under CO_2 pressures up to 0.9 mbar, in situ XPS reveals reaction schemes involving carbamate and ammonium formation via carbamic acid as an intermediate. Supported by the Cluster of Excellence - Engineering of Advanced Materials.

ILS-1-Or-9

Direct Visualization of Electrochemical Behavior on Ionic-Liquid/Electrode Interfaces by Frequency Modulation Atomic Force Microscopy

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-9

T. Ichii, M. Negami, K. Murase, H. Sugimura.

Kyoto Univ. - Kyoto (Japan).

Ionic liquids (ILs) are expected to be adopted as new electrolytes in electrochemistry because of their interesting properties. High-resolution structural analysis on IL/electrode interfaces will provide helpful information for IL-based electrochemistry and frequency modulation atomic force microscopy (FM-AFM) would be a promising technique for this purpose. Recently, we have developed an FM-AFM with a quartz tuning fork (QTF) sensor for imaging in viscous ILs and atomic-resolution imaging was successfully achieved [1].

In this study, we newly developed a vacuum electrochemical FM-AFM (EC-FM-AFM) with a QTF sensor and investigated electrochemical behavior on IL/electrode interfaces. Figure 1 shows a two-dimensional frequency shift vs. distance map (2D Δf map) obtained on a interface of 1-butyl-1-methylpyrrolidinium tris(tentafluoroethyl)trifluorophosphate ([Py_{1,4}]FAP) and a Au(111) surface. At first, the electrode potential was kept -0.4 V vs. Pt-quasi-ref. (hereafter called "V") and then it was abruptly shifted to -1.6 V during the imaging. A stripe-like structure with a period of 0.9 nm, which indicates the presence of multiple solvation layers on the interface, was clearly imaged. In addition, the solvation structure was shifted by approximately 0.5 nm to the Au(111) surface when the electrode potential was shifted to -1.6 V. A plateau with a width of 0.35 nm, which corresponds well to the size of the [Py_{1,4}] cation, was found near the Au(111) surface on the cross-sectional plots (Fig. 2) at -1.6 V. A likely explanation is that the adsorbed cation layer was formed on the surface. This result indicates that the developed EC-FM-AFM is capable of visualizing electrochemical behavior on IL/electrode interfacial structures.

Effect of dissolved LiCl on the Ionic Liquid – Au(111) Interface: *in situ* STM Study.

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-8

N. Borisenko, S. Zein El Abedin, F. Endres.

Clausthal University of Technology - Clausthal-Zellerfeld (Germany).

During the recent 5 years it has been found that ionic liquids (ILs) show an interesting interfacial chemistry. Atomic force microscopy (AFM) measurements reveal that ILs display ion layering (multilayers) at solid surfaces causing an oscillating charge (anion + cation) density profile.^{1,2} *In situ* scanning tunneling microscopy (STM) studies show the potential dependent long-range restructuring of electrode surfaces as well as the formation of anion/cation adsorption layers.^{2,3} For instance, the kinetically hindered formation of the herringbone reconstruction, Au(111)($22 \times \sqrt{3}$), has been imaged at cathodic potentials for a Au(111) surface in contact with neat 1-butyl-1-methylpyrrolidinium tris(pentafluoroethyl)trifluorophosphate ([Py_{1,4}]FAP).²

In this study *in situ* STM has been employed to elucidate the structure of the charged Au(111)-IL interface in the presence of LiCl. The addition of the Li salt to the ionic liquid has a strong influence on the interfacial structure. For instance, similar to pure [Py_{1,4}]FAP (fig. 1), *in situ* STM measurements reveal that the herringbone superstructure can be obtained in the presence of 0.1 M LiCl during cathodic polarization (fig. 2). However, unlike to the pure IL, the reconstruction of the gold surface is not complete. A likely explanation is that either the Li⁺ or Cl⁻ is preferentially adsorbed to the electrode surface (depending on potential), impeding surface-IL contact. This disrupts the templating effect of the surface on the IL, and the strength of interfacial nanostructure is reduced. These results show that the addition of solutes can strongly alter the ILs-electrode interface.

Molecular Dynamics study of frictional properties of confined ionic liquids

T09 Ionic liquids surfaces and interfaces

#ILS-2-Or-2

F. Federici ¹, K. Kurihara ¹, A. Shluger ².

¹WPI-Advanced Institute for Materials Research, Tohoku University - Sendai (Japan), ²Department of Physics and Astronomy, University College London - London (United kingdom).

Friction is one of the most fundamental processes in nature, and remains a key design concept in machines and devices at all scales. Globally, thousands of billions are spent annually on expenses attributable to friction and wear [1], and efforts to reduce and control their effects form a massive research area. Moreover, friction and wear effects become even more disrupting in micro-electromechanical systems (MEMS), where even small changes in the device structure can hamper its functionality. In order to counter frictional processes, a lubricant in liquid form, is usually placed between the two sliding surfaces, with the idea of preventing the formation of a contact region where asperities can interlock. In recent years, ionic liquids (IL) have shown great potential as candidates for lubrication [2] because of their excellent stability in a wide range of temperatures and environmental compatibility. The initial experimental success of these systems, triggered the theoretical investigation of the nanoscale mechanisms that makes IL such good lubricants., in order to aid researchers in designing lubricants at the molecular level. We focus our efforts on two IL systems, [C4MIM+][BF4-] and [C4MIM+][NTf2-] confined between two silica plates: their viscous properties were previously studied experimentally [3] with the resonance shear measurement apparatus. In our molecular dynamics (MD) simulations, the organic molecules of the ILs, were treated classically using a coarse-grained model [4], while the silica surfaces are represented by hydroxylated cristobalite (110) surfaces consisting of frozen atoms. Our simulations, carried out both with the HOOMD code, delivering excellent performance on graphics processing units (GPU), and the more conventional and well tested DL_POLY. The results show the formation of three molecular layers in the confined region; in the boundary layers interact strongly with the surfaces, the anion molecules arrange themselves next to the hydroxyl groups while the imidazolium ring of the cation is filling the gaps between H rows. These molecules exhibit very long residence time and effectively behave like a solid. On the other hand, molecules in

the middle layer are more mobile, their time-average density plot does not reveal any dominant structure in the layer plane and they diffuse with the slow dynamics typical of ILs.

Characterization of Ionic Liquid interfaces with Metastable Induced Electron Spectroscopy (MIES) and Photoelectron Spectroscopy (UPS/XPS)

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-1

S. Krischok ¹, A. Ulbrich ¹, M. Marschewski ², O. Höfft ³, W. Maus-Friedrichs ², V. Kempter ², F. Endres ³.

¹Institut für Physik und Institut für Mikro- und Nanotechnologien, Technische Universität Ilmenau - Ilmenau (Germany), ²Institut für Physik und Physikalische Technologien, Technische Universität Clausthal - Clausthal-Zellerfeld (Germany), ³Institut für Elektrochemie, Technische Universität Clausthal - Clausthal-Zellerfeld (Germany).

Ionic liquids (IL) are highly interesting solvents for electrochemical processes; mainly due to the combination of their high electrical conductivity, their electrochemical stability and their ability to dissolve a wide range of compounds [1].

It has been shown recently that electrochemical reactions are influenced by solvation layers of ILs on electrodes [2]. Therefore, a detailed knowledge about the structure at the phase boundary between solid interfaces and ionic liquids is important to understand electrochemical processes at electrodes. Furthermore, the molecular composition of the ionic liquid vacuum interface is also of great interest.

Due to the low vapour pressure ionic liquids interfaces can be investigated with electron spectroscopic methods like metastable induced electron spectroscopy (MIES), ultraviolet photoelectron spectroscopy (UPS, HeI/II) and X-Ray photoelectron spectroscopy (XPS) [3]. In this study we use the different surface sensitivity of these methods to investigate liquid solid and liquid vacuum interfaces of ionic liquids with the imidazolium cation in detail.

For the analysis of the solid liquid interface we have prepared monolayers of 1-octyl-3-methyl-imidazolium bis(trifluoromethylsulfonyl)amide ([OMIm]Tf₂N) on Au(111) by vapour deposition at room temperature and at 140K. The obtained data are

compared with results for the thick IL films. At room temperature we find a reorientation of the [OMIm] cation during the growth of the first two layers. In contrast, at 140K an ordered growth of [OMIm]Tf₂N on Au(111) beyond the first monolayer is observed. Heating up the film produced at 140K to room temperature, results in the formation of a disordered film and the data are comparable to those obtained for thick IL layers prepared at room temperature.

The electron spectra of thick [OMIm]Tf₂N films indicate a preferred orientation at the outermost surface. The measurements reveal that the alkyl chain sticks out of the surface. This seems to be a general behavior for [XMIm]Tf₂N (X=Ethyl, Butyl, Hexyl and Octyl) films [4], whereby with increasing alkyl chain length this effect is more pronounced. However, unlike [XMIm]Cl, where no chlorine induced feature is detected in the MIES spectra and the anion seems to be completely buried under the alkyl chain [5], the MIES spectra of [XMIm]Tf₂N show still some features of the [Tf₂N] anion proving that the surface density of states shows still contributions of both, the cation and the anion.

Ion size effect on the structure of quaternary ammonium-based ionic liquids at gold electrode interface studied by SEIRAS

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-7

K. Motobayashi ¹, K. Minami ², N. Nishi ², T. Sakka ², M. Osawa ¹.

¹Hokkaido University - Sapporo (Japan), ²Kyoto University - Kyoto (Japan).

Ionic liquids (ILs) are promising electrolyte materials for electrochemical reactions or electrochemical devices due to their fascinating properties such as high thermal stability, wide electrochemical window, and high ionic conductivity. Although IL/electrode interfaces must play important roles in such applications, the structures and dynamics of ILs at interfaces are still under debate. The structures of electrode interface of ILs including aromatic cations such as imidazolium or pyridinium ions have been studied by surface-selective spectroscopy techniques. However, the structure of electrode interface of ILs including quaternary ammonium cations have not been studied yet. Here we report in-situ surface enhanced infrared absorption spectroscopy (SEIRAS) studies on the structures of quaternary ammonium based ILs at Au electrode interfaces under electrochemical potential control. We found unique size effect on the interface structure of these ILs.

ILs used in this study (Fig. (a), (b)) are synthesized by the method described in the previous literature¹. SEIRAS experiments have been performed on an Au thin film electrode deposited on a Si prism. The electrode potential was controlled by a potentiostat and three electrode system (Au film as WE, Pt mesh and wire as CE and RE) introduced in the vacuum glass cell ($< 10^{-6}$ Torr).

SEIRA spectra of [TOMA][C₁C₁N] show four CH stretch modes: symmetric/asymmetric stretch of methyl groups and those of methylene groups (Fig. (c)). Increasing electrode potential leads to smaller band intensities of vibrations of methyl group and larger intensities of methylene groups. Following structure model was proposed from this result. At negative electrode potential, positively charged N

atom of TOMA cations are attracted by the electrode, resulting in methyl groups near the electrode and butyl chains including methylene groups far from the electrode. At positive potential, the electrode is surrounded by C_1C_1N anions and neutral butyl chains of TOMA cations fill the gap in the anion layer without breaking charge compensation.

Alternation of anions showed that the structure of cations at the interface is strongly affected by anions. SEIRA spectra suggested that bulky anions prevent butyl chain from filling the gap in the anion layer. Also shown is that less bulky cations cannot reach to the C_1C_1N layer to fill its gaps. Thus the effect of ion size on IL/electrode interface structure was directly observed.

Lateral Electrochemistry Without Electrolyte in a Patterned One-Atom-Thick Surface Layer

T09 Ionic liquids surfaces and interfaces

#ILS-2-Or-1

J. Sagiv, R. Maoz, J. Berson, D. Burshtain.

Weizmann Institute of Science - Rehovot (Israel).

We present a generic supramolecular platform that allows deliberate assembly of surface-immobilized one-atom-thick ion fields and ion channels with layout precisely definable over the full range of length scales from nanometer to centimeter. Such single layer ionic entities enable effective spatial confinement of ionic traffic to planned surface paths, thus paving the way to electrochemical surface fabrication without any added electrolyte. This conceptually new electrochemical strategy is based on the use of highly ordered self-assembled organosilane monolayers patterned by a nondestructive electrochemical process (*constructive lithography*) [1-4] carried out with the assistance of a conductive AFM tip (serial patterning) [1,3,4] or stamp (parallel patterning) [2-4] that effects local conversion of the inert, electrically insulating outer surface of the monolayer to a highly efficient solid ionic conductor. Monolayer-supported circuits combining electronic (metal nanowires and contact electrodes) and ion conducting components exhibiting extraordinary lateral ionic conductivities could be successfully fabricated using this novel approach.

Adsorption, Desorption and Reaction of [C₈C₁Im][BF₄] Ionic Liquid Multilayers on Cu(111)

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-2

K. Syres, R. Jones.

The University of Nottingham - Nottingham (United Kingdom).

Ionic liquids (ILs) are composed of ions held together by a strong Coulomb potential. Their ultra-low vapour pressures allow them to be studied using UHV surface science techniques. In the present study, multilayers of [C₈C₁Im][BF₄] were deposited on a Cu(111) surface by evaporation in UHV and the adsorption and desorption behavior studied.

X-ray photoelectron spectroscopy (XPS) shows that [C₈C₁Im][BF₄] adsorbs without decomposition. The F 1s signal was monitored as the IL was deposited at both room temperature and 120 K (which is below the glass transition temperature of the IL). Despite identical dosing conditions the signal grew much faster when deposited at 120 K. When the F 1s signal was clearly observable on the 120 K surface it was barely visible on the corresponding room temperature surface. This suggests that at 120 K the IL sticks where it lands forming multilayers in a layer by layer process. At room temperature the IL is deposited as islands hence reducing the measured F 1s intensity. With further dosing the F 1s signal does increase as the Cu surface between the islands also becomes covered with IL. XPS shows that multilayers deposited at 120 K melt and convert to the island structure when heated to room temperature.

Further heating causes the IL multilayers to desorb from the surface leaving a monolayer of ≈ 10 Å thickness at ≈ 430 K. At higher temperatures the monolayer reacts with the surface. By ≈ 470 K the B 1s signal has completely disappeared, the F 1s signal has nearly disappeared but the C 1s and N 1s signals are still visible and in the same ratio as when deposited. This is consistent with the emission of BF₃ from the surface leaving products containing C, N and some F on the surface.

ILS-1-Or-4

Adsorption, Desorption and Evaporation of [C₈C₁Im][BF₄] on Au(111)

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-4

M. Buckley, R. Jones.

The University of Nottingham - Nottingham (United Kingdom).

Ionic liquids (ILs) possess properties such as low vapour pressure, electrical conductivity, large liquid ranges and chemical tunability which have excited enormous interest over the past decade. Here we investigate the fundamental bonding energetics of ILs on Au(111), and the mode of evaporation of the IL by studying 1-octyl-3-methylimidazolium tetrafluoroborate, [C₈C₁Im][BF₄] and comparing it with previous work¹ for 1-ethyl-3-methylimidazolium bis[(trifluoromethyl)sulfonyl]imide, [C₂C₁Im][Tf₂N].

Using temperature programmed desorption, [C₈C₁Im][BF₄] desorbed with first order kinetics (monolayer desorption) followed by zero order desorption (multilayer desorption). The clean surface Au(111) LEED pattern was obscured by monolayer coverage, confirming that the IL wets the surface. The multilayer zero order desorption peak gave an activation energy of 133 kJ mol⁻¹ and a pre exponential of 10¹⁶ s⁻¹, the latter corresponding to an entropy of activation of ≈50 J K⁻¹ mol⁻¹ that is consistent with an evaporation mechanism involving direct emission of an ion pair from the liquid surface into the gas phase. The activation energy for monolayer desorption (133 kJ mol⁻¹) is the same as for multilayer desorption, in marked contrast to [C₂C₁Im][Tf₂N] on Au(111) where the monolayer value was higher. This is consistent with the small [BF₄]⁻ sitting on the vacuum side of the imidazolium ring for monolayer and sub-monolayer coverages. This forms dipoles perpendicular to the surface which repel and reduce the chemisorption energy, Fig.1. By contrast, the much larger [Tf₂N]⁻ ion adsorbs coplanar with [C₂C₁Im]⁺ at low coverages, forming dipoles parallel to the surface which are arranged laterally in an attractive geometry, hence increasing the adsorption energy.

1. S. G. Hessey and R. G. Jones, *Chemical Science*, 2013, **submitted**.

Figure 1. Left, anion and cation of $[\text{C}_2\text{C}_1\text{Im}][\text{Tf}_2\text{N}]$ adsorbed coplanar with dipole parallel to surface such that adjacent dipoles can be attractive. ILS-1-Or-6

Activated Absorption of Water, Methanol and Acetone on the Ionic Liquid [C₂C₁Im][EtSO₄]

T09 Ionic liquids surfaces and interfaces

#ILS-1-Or-6

R. Jones, S. Hessey.

School of Chemistry, University of Nottingham - Nottingham (United kingdom).

Ionic Liquids (ILs) are being increasingly used as storage media for gases and supports for catalyst, and have potential as gas capture agents. The kinetics of gas absorption by ILs are dependent upon the interaction of the IL surface with the gas. Here the surface kinetics of three gases on an IL surface are probed using sticking probability measurements (S) and temperature programmed desorption (TPD). The ionic liquid used was 1-ethyl-3-methylimidazolium ethylsulfate, [C₂C₁Im][EtSO₄] Fig.1, and the three gases were water, methanol and acetone. TPD showed that all three vapours physisorb onto the IL surface with adsorption energies, E_{ads} Fig.1, which increase in the sequence acetone ($33 \pm 1 \text{ kJ mol}^{-1}$) < methanol ($36 \pm 1 \text{ kJ mol}^{-1}$) < water ($42 \pm 1 \text{ kJ mol}^{-1}$). Sticking probability measurements showed that absorption into the bulk of the liquid is an activated process, ΔE Fig.1, and increases in the sequence acetone ($8.3 \pm 1 \text{ kJ mol}^{-1}$) < methanol ($9.4 \pm 1 \text{ kJ mol}^{-1}$) < water ($10.7 \pm 1 \text{ kJ mol}^{-1}$). Previous kinetic studies of water absorption into [C₂C₁Im][Tf₂N] and [C₈C₁Im][BF₄] IL surfaces¹ and XPS and TPD studies of water trapped within the surfaces of [C₈C₁Im][BF₄]² and [C₂C₁Im][Tf₂N]³, indicate that ionic liquids are highly structured, comprising a low energy layer at the vacuum interface covering an ionic underlayer where adsorbates are strongly absorbed. Using these ideas, we discuss the experimentally observed trends for adsorption onto the low energy outer surface of the ionic liquid, and the barrier height for penetration of the adsorbates into the ionic underlayer.

Electrohydrodynamic simulation of ionic liquid electrosprays

T09 Ionic liquids surfaces and interfaces

#ILS-P3-02

M. Jugroot, M. Forget, C. Malardier-Jugroot.

Royal Military College of Canada - Kingston (Canada).

A precise understanding of electrosprays is highly interesting especially for highly conductive fluids such as ionic liquids used in micro-technology (such as spacecraft propulsion) systems increases. A multi-component CFD-based model coupling fluid dynamics, charged species dynamics and electric field is applied to flows in capillaries and needles. The simulations will describe the charged fluid interface with emphasis on cone-jet transition under the effect of a electric field. The time evolution solutions of the interface will highlight the close interaction among space charge, coulombic forces and the surface tension in the small scale flows. Colloid thrusters in electrospray/droplet mode and ion mode will be fully discussed and compared.

¹Instituto de Tecnologia Química e Biológica, Universidade Nova de Lisboa - Oeiras (Portugal), ²Centro de Química Estrutural, Instituto Superior Técnico - Lisboa (Portugal).

Any substance that is composed exclusively of anions and cations (a salt) must possess some kind of short-range organization in order to fulfill local electro-neutrality conditions. In the case of Ionic Liquids (ILs) such imposed short-range ordering does not lead, however, to long-range structures (crystalline forms) at room temperature. This unexpected fact is the defining characteristic of this amazing and complex class of compounds. The difficulty of forming stable crystalline structures in ionic liquids is associated in most cases with the size, asymmetry, charge dispersion, charge segregation and flexibility of the molecular ions that compose the ionic liquids. The presence of low charge density residues such as alkyl-side chains is often a controlling issue.

Taking all these facts into consideration it is not surprising that ionic liquids are presently regarded as meso-structured, nano-segregated fluids: if the ionic liquid has to order its polar parts into local structures that obey electro-neutrality conditions, then its non-polar parts must be segregated elsewhere. It is this interplay between the two types of regions/interactions (polar versus non-polar, long-range versus short-range) that eventually leads to the formation of nano-scale domains and the recognition of ionic liquids as polar networks permeated by non-polar regions.^{1,2} In this contribution we will show several examples of such interplay and illustrate the enormous variety of structural effects that can emerge when the nature of the ionic liquids or of their mixtures with molecular compounds is changed. We will explore the meso-structures that can be found in ionic liquids ranging from the original “red-and-green” representations, the interactions of ionic liquids with molecular species or solid substrates (ILs as charge templates), or the influence of the ubiquitous alkyl side chains (per-fluorinated, functionalized, symmetrical) in the morphology of the resulting structures.

To treat vision-threatening complications of diabetic retinopathy, it is important to develop effective and safe therapeutics to suppress retinal neovascularization. In this study, we investigated whether titanium dioxide (TiO₂) nanoparticles maintain antiangiogenic effect on retinal neovascularization even at the concentration without definite toxicity. TiO₂ nanoparticles do not induce cellular toxicity on 3 different cell lines representing vascular, neuronal, and perineural glial cells even at 100 times the presumptive therapeutic concentration (105 nanoparticles per cell, 130.47 ng/ml). Furthermore, they do not result in histologic abnormalities and significant change in gene expression at the presumptive toxic concentration (10 times the presumptive therapeutic concentration, 106 nanoparticles per cell, 1.30 µg/ml). Interestingly, TiO₂ nanoparticles inhibit tube formation and migration of endothelial cells at the presumptive therapeutic concentration. In addition, they suppress ischemia-induced retinal neovascularization in mice model of oxygen-induced retinopathy at the same concentration. In particular, the antiangiogenic effect of TiO₂ nanoparticles comes from the suppression of vascular endothelial growth factor receptor-2/mitogen-activated protein kinase pathway, not from toxic effects of them. Taken together, our results demonstrate that TiO₂ nanoparticles can exert antiangiogenic effect at the concentration without genetic, cellular, and histologic toxicity on retinal

neovascularization, suggesting possible application in the treatment of diabetic retinopathy.

Recombination Processes of Photo-carriers in Cu(In,Ga)Se₂ Solar Cells Studied by Photo-assisted SPMs

T10 Nanoscience and Technology

#NST-5-Or-1

T. Takahashi ¹, Y. Hamamoto ¹, H. Yong ¹, T. Minemoto ².

¹Univeristy of Tokyo - Tokyo (Japan), ²Ritsumeikan Univeristy - Tokyo (Japan).

A thin film solar cell based on Cu(In,Ga)Se₂ [CIGS] material has attracted growing interests in recent years because of some advantages of CIGS such as band gap tunability and high photon-absorption coefficient. However, material properties of CIGS have not been fully understood yet. In this study, the recombination processes of photo-carriers in the CIGS solar cells were investigated through photovoltaic measurements by photo-assisted Kelvin probe microscopy (P-KFM) [1] and through photothermal spectroscopy by atomic force microscopy (AFM) [2].

In the P-KFM method, the temporally-averaged photovoltage was measured as a function of the modulation frequency of the incident light on some CIGS solar cells with different Ga contents. Then a time constant τ for photovoltage decay, which is considered to represent a time constant required for the carrier movement across the potential barriers at the hetero-interfaces in the cell structure, and a ratio r of fast carrier recombination process in the whole recombination process were evaluated. As a result, we have found that the solar cell with high Ga content (50 %) [Sample A] exhibits large r and long τ compared with the cell with low Ga content (23 %) [Sample B]. Since large r means that the fast carrier recombination in the CIGS layer is enhanced, we can consider that the solar cell performance in Sample A should be degraded compared with Sample B, which is very consistent with a fact that the conversion efficiencies in Samples A and B are 9.1 and 14.7 %, respectively. In order to investigate the dependence of r on the Ga content in more detail, the similar measurements were performed on other samples and we have found that the value of r gradually increases as an increase of Ga content. These results are attributable to a deduction that the electron-hole separation near a grain boundary is more weakened due to lowering of built-in electric field in the sample with higher Ga content [3]. As for the elongation of τ in Sample A, we interpret it as another

deduction that the electron transport from the surface ZnO layer to the CIGS layer is slightly disturbed due to the broadening of the CIGS band gap.

For the photothermal spectroscopy by AFM, on the other hand, the periodical thermal expansion caused by the non-radiative recombination of the photo-carriers excited by the intermittent light was detected through the dual sampling method in AFM [2], being treated as PT signal. Under the incident light with the photon energy above the band gap of CIGS, an enhancement of the PT signal was observed around the grain boundary in the CIGS material, while the PT signal under the below-gap excitation exhibits relatively uniform distribution over the sample surface except a slight drop around the grain boundary. These results suggest that the distribution of free photo-carriers becomes nonuniform due to the built-in electric field around the grain boundary and that the sub-gap states originating from defects and/or deep level impurities may exist in the CIGS material.

This work was partly supported by JSPS and MEXT.

Influence of Organic Modifier Loading on Particle Dispersion of Plasticized Poly(vinyl chloride)/ Natural Montmorillonite Nanocomposites

T10 Nanoscience and Technology

#NST-12-Or-1

O. Dimitry ¹, A. Saad ².

¹Egyptian Petroleum Research Institute - Cairo (Egypt), ²National Research Centre - Cairo (Egypt).

Nanostructured polymers have attracted much attention in material sciences because of their unique properties and their applications in nanomaterials and nanodevices. In this study; natural montmorillonite (MMT), Cloisite Na⁺ was used as nanoclay and two organophilic montmorillonites (OMMTs), Cloisites 20A and 15A (have the same organic modifier with a loading of 90 and 125meq/100g clay, respectively) were used as organoclays. Plasticized poly(vinyl chloride) (PVC)/MMT nanocomposites containing 1,3,5,7 and 10wt% of Cloisite Na⁺ and PVC/OMMT nanocomposites containing 5 and 10wt% of Cloisites 20A and 15A were prepared via melt compounding using a twin screw extruder to study the influence of organic modifier loading on particle dispersion of PVC/ Cloisite Na⁺ nanocomposites.

Thermal stabilities of nanocomposites were characterized by TGA analysis which shows that addition of 5wt% of filler to PVC increases its thermal stability¹ in the sequence: Cloisite Na⁺ < Cloisite 20A < Cloisite 15A .The interaction between PVC and silicate layer was studied by FTIR spectroscopy which confirms strong interactions between nanometric silicate layers and PVC segments.The electrical conductivity σ which describes the ionic mobility of the systems was studied as a function of temperature and shows that σ of PVC is greatly enhanced on increasing the organic modifier loading at filler content of 5wt% , especially at higher temperatures. The obtained values are situated between the two extremities of those of semiconductors (10^{-10} - 10^{-2} $\Omega^{-1}\text{cm}^{-1}$) of which σ of PVC/ 5wt% Cloisite 15A nanocomposite is increased by three orders of magnitude higher than that of pristine

PVC. The activation energy for electrical conductivity was found to be lowest for composite containing 5wt% of Cloisite 15A. The strong interfacial interactions between silicate layers and PVC chains effectively enhance the mechanical properties of PVC nanocomposites on using 5wt% of clay in the sequence: Cloisite Na+ < Cloisite 20A < Cloisite 15A. The dispersed behavior of clay in PVC matrix was evaluated by XRD, TEM and SEM analyses² which reveal intercalated structures in PVC / Cloisite Na+ nanocomposites and exfoliated structures in PVC/OMMT nanocomposites containing 5wt% of organoclay. In conclusion, organophilic treatment improves the thermal stability, electrical conductivity, and mechanical properties of PVC/clay nanocomposite, due to better interactions between PVC matrix and clay in the sequence: Cloisite Na+ < Cloisite 20A < Cloisite 15A.

Two-Dimensional Magnetic Field Dependence of Josephson Current and Finite Voltage Steps in Current-Voltage Characteristics of Various Shape Niobium Tunnel Junctions and Superconducting Quantum Interference Devices

T10 Nanoscience and Technology

#NST/SS-3-Or-5

A. Nakayama, S. Abe, N. Watanabe, Y. Nishi.

Kanagawa University - Yokohama (Japan).

Two-dimensional (2-D) magnetic field dependences of zero voltage step (superconducting current I_c) and finite voltage resonant steps in current-voltage (I - V) characteristics of niobium/niobium tunnel junction are measured. Superconducting Josephson current I_c through square-shape niobium tunnel junctions Nb/AIO_x/Nb can be changed by the external magnetic field [1-4]. In this article, thin film Nb/AIO_x/Nb (300/5/200 nm in thickness) tunnel junctions are fabricated by DC-magnetron sputtering apparatus with load-lock chamber. In the case of square shape junction, obtained I_c - H_x - H_y characteristics of zero voltage current I_c are the product of two Fraunhofer diffraction patterns in H_x and H_y directions parallel to the junction edges [5]. Finite voltage resonant steps I_{step} are also modulated by the external magnetic field. From measured I_c - H_x - H_y characteristics (Fig. 1) of 'H' shape junction, the heights of the sub peaks increases in applying external magnetic field parallel to the two vertical strokes of the 'H' shape. If the horizontal stroke is removed from 'H' shape junction, two junction Superconducting Quantum Interference Device (SQUID) is obtained, and capture area of vertical magnetic flux becomes huge. So from measured I_c - H_x - H_y characteristics of SQUID, two modulation periods (200 A/m for junction and 10 A/m for SQUID) of vertical magnetic field can be measured as shown in Fig. 2.

Arrays of metallic nanoparticles are interesting for many applications such as optical, magnetic, and catalytic purposes. In this paper self-organized nickel nano particles were grown on titanium nitride coated crystalline silicon previously sculpted by ion beam bombardment. This study was developed following a sequential in situ routine. First, crystalline Si (100) is bombarded by Xe⁺ ions at room temperature, generating regular ripples.¹ Afterward, a thin titanium nitride film diffusion barrier is grown by ion beam sputtering (IBS) on the patterned Si substrate conserving the sculpted ripples (500°C, 5 minutes). Immediately, nano-size nickel particles are deposited by IBS at 750°C during 1 minute, forming a well-defined 2-D lattice (left figure). The self-organized Ni 2-D array is explained by a combination of preferential Ni nucleation on the top of sculpted Si groves formed by the ion bombardment and the characteristic surface mean free diffusion length of the metallic particles.² The 2-D lattice constants **a** (171 nm) and **b** (184 nm) are indicated (right figure). Each deposition step is analyzed in situ by XPS and ex situ by XRD and AFM. The process of diffusion and ordered nucleation process is presented and discussed.

Electron transport through π -stacked system and ionic wires using the single molecule measurement

T10 Nanoscience and Technology

#NST-12-Or-2

M. Kiguchi, Y. Takahashi, I. Junichi.

Tokyo Institute of Technology - Tokyo (Japan).

The single molecular junction has attracted attention due to its potential application in ultrasmall electronic devices [1-3]. In this study, we study the electron transport through π -stacked systems and ionic wires based on the experimental technique of the single molecular junction [4]. Electron transfer in non-covalently bound, π -stacked systems is of particular interest, and plays a vital role in biological systems, organic electronics. However, electron transport through the initial building blocks of π -stacked systems has never been directly examined because creating molecular junctions of stacked π -molecules between nanogapped electrodes is nontrivial. Here, we investigated the conductance of the π -stacked aromatics where the π -stack was sequentially increased from 4 to 6 stacked aromatic molecules.

The single π -stacked aromatics molecular junctions were fabricated by STM break junction technique. The atomic configuration of the single π -stacked systems was characterized by the conductance change during the breaking process of the single molecular junction. The analysis showed that top and bottom triangular aromatic panels of the π -stacked molecules were bound to the Au electrodes. In general, the conductance of a short molecular junction is given by $G = A\exp(-BL)$, where L is the molecular length. The B value for single-molecule π -stacked molecules was 0.1 \AA^{-1} , derived from the slope of L vs. $\ln G$ plots, and was smaller than that of insulating alkane chains, and comparable to that of conductive π -conjugated organic molecules. The small B value for single-molecule π -stacked molecules indicates the efficient electron transport through π stacked system.

We extended our research into the electron transport through the ionic wires. Discrete $[m \times n]$ metal ion arrays are readily available as metal ion clusters by stacking cofacial m nuclear metal complexes in n layers within the cages. The number of such assembled metal ions and the whole cluster structure are uniquely determined by the cages, as is the case of the π -stacked system. Using $[m \times n]$ metal ion arrays, we demonstrated that electron transport through metal ionic wires with low attenuation

are comparable to that through metal atomic wires and that the absolute conductance value is much larger than that of conventional organic wires containing metal ions.

Growth of Centimeter-Scale Single Crystal Graphene on Copper Substrate by Chemical Vapor Deposition

T10 Nanoscience and Technology

#NST/SS-5-Or-1

X. Chen, L. Guo, X. Bai, L. Wang.

Lanzhou Institute of Physics - Lanzhou (China).

Among the intrinsic properties of graphene, the near-perfect 2D lattice is one of the major characteristics of this material. The honeycomb lattice of one atomic layer thick with almost no defects, which has never been achieved before by any other thin film deposition technology, played a major role for the very low scattering and super-high mobility of carriers. Due to the super intrinsic properties and its planar nature, graphene is of great potential for the upcoming nanoelectronics era.

Graphene deposited on substrate by CVD usually comes out as polycrystalline with typical crystal size of microns. Graphene exfoliated from graphite is also in the form of micron-scale flakes. In view of technology, however, large-scale single crystal graphene is essential for nanoelectronics, as single crystal silicon for microelectronics. In the present work, we report our research on large-scale single crystal graphene growth using Chemical Vapor Deposition (CVD) technique. The experimental results have shown that under precise control of deposition parameters and substrate processing procedure, extremely low nucleation density can be achieved and large single crystal graphene domains up to 10mm in size can be grown on copper substrate in about 10 hours of deposition time. Raman and LEED measurements have confirmed the monocrystalline and monolayer nature of the deposited graphene. The results also revealed that the vapor of copper might play a key role in suppression of graphene nucleation. Mechanisms of graphene nucleation and growth dynamics are qualitatively discussed.

Template assisted synthesis and characterization of CuSe nanowires

T10 Nanoscience and Technology

#NST-P2-06

H. Kaur, J. Kaur, S. Singh, L. Singh.

Guru Nanak Dev University - Amritsar (India).

In the past few years, research on copper selenide is continuously increasing due to their unique physical and chemical properties and its wide range of applications in the fields such as electronic, optoelectronic and thermo-electronic devices. Copper selenide plays a significant role in the fabrication of solar cells, optical filters, photodetectors, super-ionic conductors and thermoelectric converters.

Copper selenide is that kind of metal-semiconductor material which may possess both stoichiometric (Cu_2Se , Cu_3Se_2 , CuSe_2 , CuSe) and non-stoichiometric compositions (Cu_{2-x}Se) with different crystallographic forms (such as cubic, monoclinic and orthorhombic) and each of these compositions are totally depend on the method of preparation. Due to the formation of different stoichiometric compositions, band gap of copper selenide is not well defined.

In the present work, CuSe nanowires were successfully grown electrochemically into the nominal pore diameter (100 nm) of nuclear track etched membranes (Polycarbonate, Whatmann, UK). Morphological characteristics of the so fabricated nanowires were studied by scanning electron microscopy (SEM). Later samples were characterized using X-ray diffraction (XRD) and UV-Visible spectroscopy. XRD result shows the formation of lattice planes confirming the orthorhombic nature of nanowires. The optical properties of these nanowires shows direct band gap at 2.8eV as and indirect band gap at 3eV.

Formation of metallic glass nanowires

T10 Nanoscience and Technology

#NST-10-Or-4

K. Nakayama, Y. Yokoyama, T. Wada, N. Chen.

Tohoku University - Sendai (Japan).

The gas atomization which is a conventional technique in powder metallurgy is adapted for the formation of metallic glass nanowires. This approach is able to produce a large quantity of the nanowires with the diameters of 50-2000 nm in range, as shown in Fig. 1. Experiments performed with different conditions and alloy compositions confirm that the key mechanism of the nanowire formation is the spinnability which increases exponentially when the melt stream is supercooled from the liquid state. The results follow the spinnability rule where the viscosity below the melting point plays an important role in determining the aspect ratio of the nanostructures [1].

Magnetism of Fe on Pt(111) Revisited by Inelastic Scanning Tunneling Spectroscopy

T10 Nanoscience and Technology

#NST/SS-3-Or-6

J. Wiebe, T. Schlenk, A.A. Khajetoorians, R. Wiesendanger.

Institute of Applied Physics, Hamburg University - Hamburg (Germany).

We revisited the magnetism of single Fe atoms [1] and complexes of Fe atoms with a different number of hydrogen atoms adsorbed on the surface of Pt(111) by means of magnetic field dependent inelastic scanning tunneling spectroscopy [2,3]. We found that the magnetic easy axis is either perpendicular to or within the surface plane, depending on an fcc or hcp adsorption site. Adsorption of hydrogen atoms changes the strength of the magnetic anisotropy and leads to Kondo screening for one of the Fe-hydrogen complexes. For all investigated cases, the magnetic anisotropy energy is almost an order of magnitude lower than recently reported [1].

*These authors contributed equally to this work.

Transport phenomena present in sessile droplets were studied with pre-deposited carbon nanotubes on Si wafers. When a droplet of liquid was allowed to evaporate on such a surface, a distinct ring-shaped imprint could be discerned. Majority of the debris particles became depleted from this region, while most of the CNTs remained. The remaining CNTs appeared to exhibit a radial orientation with respect to the ring geometry. Possible causes for these phenomena include microscopic flows inside the droplet due to the Marangoni effect, a flow arising in response to a surface tension gradient caused by evaporation of the fluid (fig.). Alternatively, the re-positioning may be driven by the contact line motion in response to the broadening of the droplet. We have studied these phenomena by comparing the imprints produced by droplets of different liquids, and analyzing the nature of CNT orientation in more detail.

The Marangoni effect is a well-documented phenomenon known to play a major role in a variety of every-day phenomena, e.g. in the formation of the famous “tears of wine” [1]. While most past work has been focused on the effects of Marangoni flow on the deposition of particles from evaporating colloidal droplets, there exists little information regarding to its influence in repositioning of particles already present on the substrate. Previous work has also been hampered by lack of efficient methods to measure the related flow in situ. The situation has improved with the recent introduction of optical coherence tomography (OCT), by which the flow patterns can

be visualized and measured in three dimensions. In the future, our intent is to apply the OCT technique on CNT-deposited samples to gauge the flows in droplets of different liquids of varying evaporation rate, viscosity and surface tension, so as to help unravel the factors that determine the ring formation and CNT re-orientation.

Correlation-mediated processes for electron-induced switching between Néel states of Fe anti-ferromagnetic chains

T10 Nanoscience and Technology

#NST/SS-3-Or-7

J. Gauyacq ¹, S.M. Yaro ², X. Cartoixa ³, N. Lorente ⁴.

¹ISMO, Institut des Sciences Moléculaires d'Orsay - Orsay (France), ²Escola Tecnica Superior d'Enginyeria, UAB - Barcelona (Spain), ³Escola Tecnica Superior d'Enginyeria, UAB - Barcelona (Spain), ⁴Centre d'Investigacio in Nanociencia y Nanotecnologia, CIN2 - Barcelona (Spain).

A recent experimental study by Loth et al (1) revealed that chains of Fe atoms on a CuN/Cu(100) surface couple anti-ferromagnetically (AFM) to form two Néel states with alternating spin directions on the atoms along the chain. Furthermore, they could show that electrons tunnelling from an STM (Scanning Tunnelling Microscope) tip through one of the Fe atoms can efficiently induce a switch between the two Néel states. A complete view of the electron-induced switching process was missing for this quantal AFM nano-magnet. We developed a theoretical quantal modelling of the transitions between the two Néel states using a model description of the Fe chain incorporating: magnetic anisotropy terms on each Fe atom (local spin $S=2$), anti-ferromagnetic coupling between first neighbours, Zeeman energy term. We added a phenomenological Zeeman term on the first atom of the chain to enforce the Néel magnetic structure. The transitions between the various magnetic states of the chain induced by tunnelling electrons were then computed using the strong coupling approach developed to treat magnetic transitions in adsorbates induced by tunnelling currents (2,3). Calculations were performed for chains with up to 10 atoms. Our study reproduces the experimental findings in a very satisfying way. In addition it allows identifying three different switching processes that dominate the switching in different ranges of the STM voltage: -at low voltage, a direct transition between Néel states induced by a single electron-chain interaction -in the intermediate voltage range (6-10 mV), an indirect process in which the

tunnelling electron excites the chain into an intermediate state (quantized spin wave modes) that later decays to the Néel states -at high voltage (above $\sim 10\text{meV}$), an indirect process involving domain wall formation as intermediate states

It must be stressed that the above three mechanisms for magnetic excitations are quite different from the more usual local spin-flip mechanism at play e.g. in magnon excitation in ferromagnetic chains. Switching between the two Néel states in a chain requires the flip of all the local spins in the chain and the quantal correlations in the chain (mixing between different configurations of local spins in the chain) yields the driving force of the three above mechanisms for Néel switching.

NST-9-Or-2

Size control of colloidal particles via mechanistic knowledge: exemplified for silver nanoparticles

T10 Nanoscience and Technology

#NST-9-Or-2

M. Wuthschick, K. Rademann, J. Polte.

Humboldt Universität - Berlin (Germany).

Metal nanoparticles have attracted much attention due to their specific catalytic, optical and magnetic properties. These properties are dependent on size, composition, crystal structure and morphology.¹ Thus, size control provides one effective key to an accurate adjustment of the colloidal properties. Most of the common synthetic procedures (usually chemical reductions) are relatively simple but do not provide a precise size control. The common approach to size control is testing different sets of parameters via trial and error. The actual particle growth mechanisms and in particular the parameter influences on the growth process remain a black box.²

This contribution presents an approach to size control which is based on a profound mechanistic knowledge. It comprises three steps: (i) the investigation of the principle growth mechanism for one set of parameters, (ii) the investigation of parameter influences on the growth mechanism which leads to the identification of size determining parameters and (iii) the well-directed development of synthetic recipes. This approach is exemplified for common silver nanoparticle synthesis (reduction of AgClO_4 with an excess of NaBH_4).

Recently, we deduced the principle growth mechanism from time-resolved in-situ Small Angle X-Ray Scattering investigations (see Fig. 1).³ It comprises (1) the rapid reduction of the ionic silver to silver atoms which immediately form dimers, trimers etc., (2) the coalescence of these clusters, (3) an intermediate phase of stability and (4) a second coalescence which is the result of the complete conversion of residual BH_4^- to B(OH)_4^- . The final particle mean radius ranges from 4 to 9 nm and is poorly reproducible.

In the next step of the approach, the influences of reaction parameters on the growth mechanisms were elucidated.⁴ It was found that reproducibility can be achieved by a controlled aging of the reducing agent. In addition, the decisive size determining parameters could be identified. As a result, synthetic procedures for silver colloids were developed which allow a size control in a wide range without additional steric stabilization.

The presented approach to size control based on mechanistic knowledge is not limited to a certain kind of system. It can also be applied to different nanoparticles (e.g. oxidic, bimetallic particles), matrices (e.g. organic solvents, glass⁵) and methods (e.g. photochemical reduction, thermal decomposition).

Fe-14Mn-6Si-9Cr-5Ni (mass. %) shape memory alloy specimens were obtained from powder compacts, with equal amounts of as blended and mechanically alloyed particles, by cold pressing under 400 MPa pressure and sintering for 2 × 3.6 ks, with a rate of 10 K /min, up to 1423 K, [1]. In order to increase the compactness degree, sintered specimens were hot rolled at 1373 K and solution treated at 1473 K [2]. Aiming to emphasize the influence of solution treatment holding time and atmosphere on martensite plate morphology, the treatment was performed using three maintaining periods and environments. The nine solution treated specimens, obtained after 0.6, 2.4 and 4.8 ks holding periods, in vacuum, nitrogen and argon atmospheres, respectively, were analysed by optical, scanning electron and atomic force microscopy. The micrographs revealed that an intensification of chemical segregation was noticeable at the surface of specimens solution treated in inert atmospheres while vacuum enabled a marked reduction of segregated zones which became more uniformly distributed. For instance, after solution treatment for 2.4 ks in nitrogen atmosphere a marked segregation of Silicon and Manganese was noticeable, as illustrated in Fig.1. The detail displays a brown segregated area, with

large crystalline grains, rich in Si and Mn, which coalesced during solution treatment. These results confirm previous observations [3] which reported that protective atmospheres are not always effective in preventing the occurrence of certain chemical reactions, at elevated temperatures. These phenomena were less severe in vacuum.

Quantitative Ballistic Electron Magnetic Microscopy: magnetic imaging of buried nanostructure with a sub-nanometric lateral resolution

T10 Nanoscience and Technology

#NST/SS-3-Or-8

M. Hervé, S. Tricot, S. Guézo, G. Delhaye, B. Lépine, P. Schieffer, P. Turban.

Institut de Physique de Rennes - Département Matériaux-Nanosciences - Université Rennes I; CNRS, UMR 6251, Campus de Beaulieu, Bât. 11E, 35042 Rennes cedex - Rennes (France).

Ballistic Electron Emission Microscopy (BEEM) is a scanning probe technique derived from STM, which allows characterization of the electronic properties of buried interfaces with a lateral nanometric resolution [1,2]. In the case of a Schottky contact, hot electrons are injected in the metal layer with an energy defined by the STM tip bias voltage. A small part of the injected electrons crosses ballistically the metal layer and reaches the buried interface. If their energy is high enough to overcome the Schottky barrier height, electrons can enter into the conduction band of semiconductor and be detected as a BEEM current. If the single metallic base layer is replaced by a spin valve, the hot electron current will be modulated by the GMR effect. Thus, we can probe the local magnetoconductance properties of spin valves [3]. We report in this communication the investigation of the local magnetoconductance properties of epitaxial sub-micrometric spin valves Fe/Au/Fe/GaAs with an Fe electrode evaporated through a nanostencil. These sub-micrometric Fe dots can have a circular shape (450nm of diameter) or a rectangular shape (450nm×1700nm). In these structures, the modulation of the collected current by the local magnetic domain structure in the Fe dots allows magnetic imaging of buried nanostructures with strong contrast (500% of relative variation of the BEEM current) and a nanometric lateral resolution. The experimental magnetocontrast observed on these sub-micrometric Fe dots are in excellent agreement with BEEM current maps calculated via micromagnetic simulations [4]. This opens the way to a quantitative

magnetic microscopy technique with a high sensitivity and a nanometric lateral resolution.

Graphene has been attracted a great deal of interest in recent years due to its excellent properties and potential applications [1]. Graphene can be prepared by several methods including the mechanical exfoliation of graphite, chemical vapor deposition, epitaxial growth, and a reduction of graphene oxide (GO). Among these methodologies, the reduction of GO has been regarded as the most convenient route to produce the graphene at a large scale [2]. GO is generally reduced into reduced GO (RGO) using a chemical method with various reducing agents. However, this method has several problems such as the requirement of toxic and explosive chemical reducing agents and high temperature [3].

To overcome these problems, an eco-friendly and simple radiation-induced reduction method of GO is developed in this study. GO prepared by a modified Hummer's method was dispersed in DMF, and then irradiated by γ -rays under various conditions to reduce GO. The analytic results of the resulting radiation-reduced GO (RRGO) revealed that GO in DMF was effectively reduced by γ -ray irradiation-induced deoxygenation, and that its reduction extent was dependant on the absorbed dose. The electrical conductivity of RRGO increased to 12.7 S/cm with increasing the dose, whereas its work function decreased to 4.24 eV. Based on the performance test results of the polymer solar cell devices, the RRGO can be used as a hole transport layer, and the cell device with the RRGO prepared at 50 kGy exhibited the highest performance.

THE EFFECT OF MULTI-WALLED CARBON NANOTUBES ON RADIATION RESISTANCE OF LOW DENSITY POLYETHYLENE

T10 Nanoscience and Technology

#NST-P2-07

C. Jung, D.H. Lee, J.H. Choi, I.T. Hwang, J.H. Choi.

Korea Atomic Energy Research Institute - Jeongup-Si (Korea, republic of).

Polymers have been widely used in the equipment and components of nuclear power plants, which are generally exposed to high energy radiation. Thus, the physical and mechanical properties of the exposed polymers are deteriorated due to the crosslinking and chain scission reactions caused by high energy radiation, and therefore leading to a considerable reduction in the lifetime of the polymers [1]. To extend the lifetime of the polymers used in the equipment and components of nuclear power plants, the fabrication of polymer composites with various nanofillers such as carbon black, multi-walled carbon nanotubes (MWCNTs), nanoclays, and metal nanoparticles has been recently explored to improve the radiation resistance [2,3]. In this study, MWCNT-reinforced low density polyethylene (LDPE) nanocomposites were fabricated through a melt blending to improve the radiation resistance of LDPE. LDPE nanocomposites prepared through a melt blending at different compositions were exposed to gamma-rays at absorbed doses ranging from 50 to 500 kGy. The exposed nanocomposites were investigated in terms of the tensile properties, activation energy, oxidation stability, thermal stability, and durability. The experimental results revealed that the prepared MWCNT-reinforced LDPE nanocomposites had a higher radiation resistance than the control LDPE. This strategy based on the incorporation of MWCNT into a polymer matrix for the improvement of the radiation resistance can be applicable to the development of new radiation resistant materials.

NST-P2-08

Investigation of mechanisms of gas-phase atoms adsorption on the boron nitride nanotubes surface

T10 Nanoscience and Technology

#NST-P2-08

I. Zaporotskova, A. Shkodin.

Volgograd State University - Volgograd (Russian federation).

Currently, boron nitride nanotubes [1-2] are the second most sought-after (after carbon nanotubes) for researchers because of their appealing properties, stable conductivity, sufficiently well-tested method of synthesis and their scope for widespread use. However, composites based on BN-tubulenes have been little researched, which can be obtained through different modifications of the surface, including by joining different atoms and molecules, which may lead to changes in their properties.

The possibility of joining gaseous atoms hydrogen, oxygen, fluorine and chlorine to the outer surface of single-walled boron nitride nanotubes (BNNT) was studied, such as "arm-chair" (n, n) and "zig-zag" (n, 0), namely, (6, 6), (8, 8), (10, 10), (8, 0), (10, 0), (12, 0). Calculations were carried out with a molecular cluster using a semi-empirical method MNDO. A segment of BN-nanotube was selected as the cluster model with three, four or six layers of BN-hexagons. The tube system was circumferentially closed, the cluster boundary closed with hydrogen pseudoatoms. The BN bond length in the nanotube was equal to 1.4 Å.

The adsorption process was modeled using step by step approach (in increments of 0.1 Å) of the adsorbed atoms to the target-atom of the surface along the perpendicular to the longitudinal axis of the tube and passing through the target atom where the adsorption takes place. Four alignments of the adatoms on the surface are considered: I) over the boron atom, II) over the center of BN bond length, III) over the nitrogen atom, IV) over the center of the hexagon BN. Calculations allowed profiles of the potential energy surface of these processes to be drawn.

Analysis of the interaction between the oxygen atom and BN-nanotube leads to the conclusion that, in the case of the option II orientation of the atom relative to the surface BNNT oxygen, the following types are adsorbed on the tubes: (6, 6), (10, 10) and (8, 0), (10, 0), (12, 0), respectively, i.e., for all the candidates, except for (8, 8), for which there is the possibility of a metastable state. The highest adsorption energy

$E_a(\text{II}) = -2.24$ eV is obtained by adsorption of the oxygen atom on the surface of (12, 0) BN-nanotube. The adsorption distance in this case is $r_a = 1.3$ Å, and the height of the energy barrier at a distance $r_b = 2$ Å was $E_b = 1$ eV (activation energy).

The interaction of the adatoms H, F, Cl with the outer surface of BN-tubulen was explored. Analysis of the energy curves showed that the adsorption of the fluorine atom occurs in positions I, II, IV; the chlorine atom in position II, and the hydrogen atom in position III for the tube (12, 0).

These studies have proved the possibility of adsorption of gaseous molecules on the surface of boron nitride nanotubes, and that the preferred types of adsorption are due to the peculiarities of the adsorbed atoms.

The study was supported by The Ministry of education and science of Russian Federation, project 14.B37.21.0080.

IONIC CONDUCTIVITY OF BC₃ BORON-CARBON NANOTUBES

T10 Nanoscience and Technology

#NST-P1-06

P. Zaporotskov, I. Zaporotskova, S. Boroznin.

Volgograd State University - Volgograd (Russian federation).

The ionic conductivity and structure in which it can be realized research is very important for the development of modern batteries. Using of new materials will enable from such deficiencies as little time of life, small energy, and possibility of leak from battery.

In this paper we present the results of investigation of ionic conductivity process of (6,0) boron-carbon nanotubes BC_n, n=3 [1]. Two variants of boron and carbon location on the nanotube surface were modeled. The research was performed using the MNDO method within the framework of a molecular cluster model. For investigation of ionic conductivity process the vacancy formation has been modeled. Energetic and electronic characteristics of these processes have been carried out. The vacancy migration process has been modeled (fig. 1). The energy curves of process were constructed and the activation energies were calculated. Then the conductivity coefficient dependence of temperature has been found. The study was supported by The Ministry of education and science of Russian Federation, project 14.B37.21.0080.

SENSOR ACTIVITY OF CARBON NANOTUBES WITH BOUNDARY MODIFICATION

T10 Nanoscience and Technology

#NST-P2-01

N. Polikarpova, I. Zaporotskova, D. Vil'keeva, P. Zaporotskov.

Volgograd State University - Volgograd (Russian federation).

High sensitivity of electronic characteristics of carbon nanotubes to existence on their border of adsorbed molecules or radicals [1, 2] speaks about creation possibility on this basis of the high-sensitivity super tiny sensor. With its help it will be possible to find availability of the slightest impurity in samples.

We studied the carbon nanotube which border was modified by carboxyl functional group -COOH (fig. 1). This system represents a test probe, capable to react to various chemical elements. For the proof of its sensor activity the theoretical researches of possible interaction of the modified single-walled carbon nanotube type (6,0) with atoms of alkaline metals K, Na, Li, Mg were executed. The quantum-chemical MNDO method within a molecular cluster was used. The process of accession of carboxyl group to the open border of nanotube was simulated and studied. Process of scanning by the test probe of any surface containing subject initialization atoms created thus is investigated, and activity of nanotube with the functional group to K, Na, Li, Mg atoms is defined. Process was modeled by step-by-step approach of metal atoms to hydrogen atom of functional group along the straight line parallel to modified border of the (6, 0) nanotube (fig. 1). Power curves of this process were constructed. The analysis of the constructed power curves found the fact of interaction between the modified nanotube and the chosen atoms (K, Na, Li, Mg). It is illustrated by characteristic minima on curves.

The received results proved possibility of use of the modified carbon nanotube as a sensor for certain elements and radicals.

The study was supported by The Ministry of education and science of Russian Federation, project 14.B37.21.0080.

STRUCTURE AND SOME PROPERTIES OF BORON NANOTUBES

T10 Nanoscience and Technology

#NST-P2-09

D. Polikarpov, I. Zaporotskova, E. Boroznina, S. Boroznin.

Volgograd State University - Volgograd (Russian federation).

In 2004 scientists synthesized pure single-walled boron nanotubes [1] which can be considered as a new class of topological structure of boron with the unique physical and chemical properties, opening the widest prospects of its use in nano - and microelectronics. However there is no unequivocal opinion on exact structure of nanotubular boron, practically it is not known about its electronic and energy structure, physical and chemical properties. In this work results of research of influence of structural modifications of boron nanotubes on electronic structure and conductive characteristics, and also results of calculations of superficial properties single-walled boron nanotubes are presented. The nanotubes with small diameter received by rolling of hexagonal, triangular boron sheets and α -sheet of boron (Fig. 1) are studied. Nanotubes of the arm-chair types (n, n) and zig-zag $(n, 0)$ for each configuration (hexagonal, triangular and α -boron nanotubes) are considered. Features of electronic and energy structure and conductive characteristics of boron nanotubes of various types and configurations are discussed. Calculations are executed within the framework of the ionic-built covalent-cyclic cluster model and the appropriately modified MNDO quantum chemical scheme [2]. The study was supported by The Ministry of education and science of Russian Federation, project 14.B37.21.0080.

NST-P1-13

Orientation of PCBM in an intermixing overlayer of C₆₀ and PCBM on Au(111) surface

T10 Nanoscience and Technology

#NST-P1-13

H. Suzuki, K. Todaka, H. Sakaue, T. Takahagi.

Hiroshima University - Higashi-Hiroshima (Japan).

Phenyl-C₆₁-Butyric Acid Methyl Ester (PCBM) is one of the promising acceptor materials for organic photovoltaic devices [1]. It is similar structure to C₆₀ but it has additional substituent: phenyl-butyric acid methyl ester group. This difference increases solubility of fullerene in a solution and modifies HOMO and LUMO levels. Such differences should change the intermolecular interaction of fullerene derivative, which would result in its different behaviors on a surface from that of C₆₀. In this study, we observed behaviors of PCBM and C₆₀ on the same Au(111) surface with UHV-STM. The molecules were deposited on Au (111) surface at room temperature using home-build Ta crucibles. The molecules were observed with variable temperature STM with liquid N₂ cryostat at 134 K.

In PCBM overlayer on Au (111) surface at 134K, double row of bright spots decorating the step edges, bright spots at elbows of reconstruction surface, and superstructure with partially hexagonal lattice and irregularities are observed. Characteristic double row of PCBM has been reported to be due to the hydrogen bonding between tail groups (phenyl-butyric acid methyl ester groups) of PCBM [2]. The tail groups also disturb forming a closed packing of PCBM, resulting in irregular regions in the superstructure. These behaviors of PCBM are different from those of C₆₀. C₆₀ forms a regular hexagonal lattice superstructure, spreading from the step edges. No C₆₀ adsorbs at elbows.

In the case of PCBM and C₆₀ on the same Au (111) surface (Fig. 1), some island showing hexagonal lattice are observed as well as the step edge decoration with a double row of bright spots and bright spots at elbows. Though the island must consist of PCBM and C₆₀, the structure of the island is more regular than that of PCBM and similar to that of C₆₀. There are some brighter spots (C in Fig. 1(b)) in the

superstructures, which are not observed in both of the superstructures of PCBM and those of C₆₀. Such brighter ones are higher than both of PCBM adsorbing at elbows and C₆₀ around them and do not disturb the hexagonal lattice. Considering the facts that symmetric C₆₀ and asymmetric PCBM form the regular hexagonal lattice and the brighter spot is 0.2 nm higher than C₆₀, the brighter one corresponds to the phenylbutyric acid group facing upward of PCBM. It suggests that the structure of C₆₀ has strong mutual attractive interaction with the structure of PCBM.

Two-dimensional (2D) polymers are expected to have a great impact on many fundamental and applied aspects of science. Some recent demonstrations of covalent polymerization performed directly at surfaces have opened promising perspectives. The polymer formation is usually obtained by deposition of the molecular precursors on the surface followed by thermal activation of the polymerization reaction. The growth process of a covalent network is highly non linear: the formation of a supramolecular phase may compete with the polymerization reaction, and the optimum parameters required at the very early stage of the polymer growth (when individual monomers react with each others) vary generally substantially from those necessary when intermediate oligomers are already formed. In addition, the irreversible character of a covalent bond precludes the formation of the thermodynamically most stable structure through defect self-healing. As a consequence, a large number of defects are usually observed, or the polymer domains are limited in size. The defects can arise from incomplete reaction between the reactants due to steric hindering in 2D-confinement, or from the relative flexibility of the covalent bond that allows easy formation of various geometries with limited stress.

Boronic acids can undergo a self-condensation (dehydration) reaction to create rigid boroxine rings and a planar polymer sheet. By using 1,4-benzenediboronic acid (BDDBA) evaporated onto a well-defined metal surface extended nanoporous 2D networks could grow. I will present recent scanning tunneling microscopy (STM) results of our group,[1-5] reflecting various efforts to control the growth process of these two-dimensional covalent organic frameworks (influence of the deposition parameters, local activation of the reaction, coupling with an Ullmann reaction, etc.).

Aluminium on the Si(100)2×1 – growth, morphology and different modifications of aluminium dimers studied by STM

T10 Nanoscience and Technology

#NST-P1-14

M. Kucera, F. Rozboril, P. Sobotík, I. Ošťádal.

Charles University in Prague - Prague (Czech republic).

At low coverages, group III metals (Al, In, Ga) grow on Si(100) 2x1 surface in a form of single-atom wide chains consisting of dimers. We thoroughly studied growth and morphology of Al chains for coverages from 0.02 ML to 0.09 ML and substrate temperatures from 110 K to 420 K. For all the investigated coverages and temperatures we found significant discrepancies in behaviour and appearance between Al and other group III metals. Indium and gallium atoms assemble into long straight unbroken chains. Additionally there is no difference in appearance of individual dimers. The aluminium atoms, however, form short (several dimers long) chains, which tend to branch and sometimes seems to be broken. Moreover individual Al dimers differ in appearance. We identified three types of the aluminium dimers – “dark”, “faint” and “bright”. They vary in brightness and assemble into distinctive types of chains. Experiments at 115 K showed strong anisotropy of surface migration of single aluminium atoms. The atoms preferably hop in direction parallel to Si dimer rows. We used a statistical analysis of recorded motion of single Al atoms (method used for In in [1]) to estimate heights of diffusion barriers.

Growth of Al on Si(100) studied by a kinetic Monte Carlo method

T10 Nanoscience and Technology

#NST-P1-15

F. Rozbořil, M. Kučera, I. Ošťádal.

Charles University in Prague - Prague (Czech republic).

Group III and IV metals deposited on clean Si(100) surface with sub-monolayer coverage form one atom wide chains. These structures have potential applications in various fields of nanotechnology. The process that leads to formation of these structures is called a surface polymerization reaction and its driving force is surface diffusion – thermal motion of adatoms [1]. If the growth occurs far from thermal equilibrium, the kinetics of surface processes plays a significant role.

The growth is affected by temperature, deposition rate and several intrinsic parameters, such as binding energies and diffusion barriers. Kinetic Monte Carlo simulations can be used to study the influence of these parameters on the morphology of metal chains on Si(100). By comparing the simulated structures to relaxed layers observed by scanning tunneling microscope, surface processes in early stages of growth can be studied.

Gallium and indium have already been investigated using this method [2-3]. Theoretical values of diffusion barriers have been calculated for In, Ga and Al [4] and experimentally confirmed for indium [5], but there are no experimental publications about aluminium structures. Our experiments show that Al on Si(100) exhibits a number of interesting properties. We observed that the scaled island size distribution function is monomodal, while the other metals show monotonically decreasing distributions. Aluminium chains grown at room temperature are shorter and create so called "kinks", which are two connected chains separated by one lattice constant on the surface (Fig. 1).

We created a growth model that takes these morphological features into consideration and found the values of the input parameters (especially the activation energies for diffusion) that represent the best agreement with our experimental data.

Volgograd State University - Volgograd (Russian federation).

Carbon nanotubes can be used to create a unique tip for atomic force microscope. The most interesting possibilities are opened up for use in AFM of chemically modified nanotubes with functional groups at the end of the tip. In this case it is possible to study the chemical composition of the surface. Now carbon nanotubes with the carboxyl -COOH group on open bottom ends were obtained [1]. Theoretically the mechanism of attachment of this group to the boundary carbon atom of the tube was studied [2]. However, at present, much attention is paid to non-carbon boron and boron nitride nanotubes, which has more stable conductive characteristics. That would suggest that the creation of a boundary-modified sensor systems, based on them is possibly and effectively.

We have made calculations of interaction -COOH group with semi-infinite boron nitride tubulenes (8, 8), (10, 10), (10, 0), (12, 0) in the framework of the molecular cluster model, using the semi-empirical scheme MNDO. The process of connecting the -COOH group to the boron atom on the open nanotube boundary was modeled by step approach of carboxyl group along the perpendicular arranged to the tube boundary, and oriented on boron atom. As a result, the curves of the interaction "nanotube - COOH" were built, and their analysis revealed the presence of the energy minimum corresponding to the result of the formation of the chemical bond between the tube and the functional group for each test case. The energy minimum is located at a distance of 1.5Å from the boundary of the tube. Similarly, the analysis of possibility connection of -COOH group to the nitrogen atom on the open boundary of BN-tubule was made. As in the previous case, on the curves of the interaction is clearly visible minimum of energy at a distance of 1.3Å from the tubule – point of formation of chemical bonding to the nitrogen atom and the carboxyl group. Then the simulation of formation of a boundary modification of hexagonal and

triangular boron nanotubes by the carboxyl group was performed. Constructed energy curves were illustrated the possibility of the process creating nanotubular sensor system based on a single-walled boron nanotube, which would be chemically sensitive to the atoms and molecules.

Thus, the use of chemically modified nanotubes in atomic force microscopy is a way to create probes with distinct chemical characteristics.

The study was supported by The Ministry of education and science of Russian Federation, project 14.B37.21.0080.

Optoelectronic switching and negative differential resistance of molecular self-assembled monolayer junctions

T10 Nanoscience and Technology

#NST-2-Or-6a

D. Ba, X. Gong, J.C. Li.

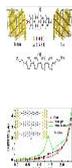

Vacuum and fluid engineering research center, Northeastern University - Shenyang (China).

Addressable Au/dipyrimidinyl-diphenyl/Au molecular crossbar junctions are fabricated using elastic polymer stamp-printing method. Figure 1 shows the schematic junction and molecular structures. Current-voltage measurements are carried out from 95 up to 295 K in vacuum under both dark and light conditions. Reversible diode, optoelectronic switching and negative differential resistance (NDR) phenomena are observed. The rectification efficiency and the current ratio dramatically decrease with temperature increase or under light irradiation. Data analysis shows that the direct tunneling and the Fowler-Nordheim tunneling act as the main transport mechanism at the low and high bias regions, respectively. The barrier heights is dependent largely on the light irradiation, bias polarity and substrate temperature. The temperature dependence of the charge transport and the NDR phenomena are further investigated using the non-equilibrium Green's function method combined with density functional theory. The NDR mechanism is analyzed in terms of the molecular projected self-consistent Hamiltonian states and transmission spectra. The distinct chemical natures of the top-printed physisorbed Au/molecule interface and the bottom S-Au contact (see Figure 2) may account for the as-observed performances.

Keywords: Metal-molecule-metal junction; Diode rectification; Optoelectronic switching; Charge transport; Negative differential resistance

The adsorption of the amphiphilic Ru^{II} complex Z907 onto the surface of ZnO nanospheres and nanorods causes the gelation of organic solvents, such as THF or acetone. The gels are thermally stable at very low concentration (nanoparticle volume fraction $\phi = 0.009$), but mechanically fragile, the behavior being dependent on solvent nature, nanoparticle concentration, and Z907-to-ZnO molar:wt. ratio. Rheological experiments confirmed the solid component built up a network to give a viscoelastic gel-phase material with a rather low value of the storage modulus G' around 100 Pa, but all characteristics of a rubbery material (Fig. 1). The brittleness of the manifests itself in a linear-viscoelastic limit around $\gamma_0=0.1\%$.

However, TEM and SEM experiments did not give evidence that nanoparticle long-range ordering occurred under the experimental conditions investigated. Moreover, time-dependent SAXS measurements pointed to a decrease of the nanoparticles aggregates size upon gelation. All together, the data obtained might be rationalized in terms of aggregate-to-aggregate transition in solution, the primitive large aggregates giving rise to smaller ones upon reaction with Z907. The resulting smaller hybrid aggregates could be the active species that act as self-assembling components in the gelation process.

Given the interesting electronic and photonic properties of zinc oxide nanoparticles, such hybrid organic-inorganic gels could open new directions in materials sciences, low-cost electronics, and photovoltaics.

A general hydrothermal approach to TiO₂, TiO₂@metal-ions, TiO₂@graphene, TiO₂@C, and TiO₂@CNTs hybrid nanostructures

T10 Nanoscience and Technology

#NST-10-Or-6

G. Cheng, F. Stadler.

Chonbuk National University - Jeonju (Korea, republic of).

TiO₂ has attracted much attention recently due its excellent physicochemical properties and potential applications in environmental remediation as well as energy conversion and storage. The optimization of the structure and composition of TiO₂ for the fabrication of high-performance dye-sensitized solar cells (DSSC), photocatalysts, supercapacitors, and Li-ion batteries still remains a great challenge. Doping TiO₂ with an- or cations, modifying TiO₂ with carbon materials, fabricating TiO₂ with favorable nanostructures have been considered as promising ways to improve the properties Hence, developing an effective approach to TiO₂-based nanocrystals, -hybrids, and -composites is important. Here, we present a general two-step solution-phase reaction to produce TiO₂ with tunable phases, compositions, and structures for exploring the above mentioned properties. Based on the formation mechanism of TiO₂ nanocrystals, we developed this method to form metal ion-doped TiO₂ nanoparticles as well as nanoporous, hybrid TiO₂ (<10 nm) materials on reduced graphene oxide (RGO) sheets, carbon-deposited TiO₂ nanoparticles and nanoporous, and TiO₂ nanodots grown on functionalized carbon nanotubes. TiO₂@graphene hybrid photoanode material exhibited power conversion efficiency $\eta=7.68\%$ in DSSC, significantly better than pure TiO₂ ($\eta=4.78\%$). In addition, the TiO₂ nanostructures doped with carbon and metal ions indicate potential applications in environmental purification.

Fig.1 Illustration of the formation of TiO₂-based nanocrystals and nanohybrids.

Large Magnetoresistance of Self-Assembled Magnetite Type Nanocrystal Films toward Spin Transistor

T10 Nanoscience and Technology

#NST-P1-07

S. Kohiki¹, T. Kinoshita¹, K. Okada², M. Mitome³, A. Kohno⁴, H. Deguchi¹.

¹Kyushu Institute of Technology - Kitakyushu (Japan), ²Osaka University - Osaka (Japan), ³National Institute for Materials Science - Tsukuba (Japan), ⁴Fukuoka University - Fukuoka (Japan).

Spin diffusion is the real issue for spin transistor. Our idea for the source (S)-drain (D) current switching is employing negative magnetoresistance (MR) of oleic acid coated (OA-) magnetite type $M_{0.5}Fe_{2.5}O_4$ (M:Mn,Fe) nanocrystals (NCs) in the spin-glass (SG) state. When two-dimension hexagonal networks of collinear spins form antiferromagnetic and ferromagnetic spin configuration respectively without and with magnetic field (H), electron tunneling between the NCs is enhanced by $H \neq 0$, and tunneling resistivity varies from high to low. In the multiple junctions system, MR is defined as $MR = (R_H - R_0) / R_0$, where R_H and R_0 are the resistances in $H \neq 0$ and $H = 0$, respectively. $MR = 50\%$ corresponds to full spin-polarization $P = 100\%$ [1]. Carriers of Fe_3O_4 with $P = 100\%$ below 840K is suitable for devices workable above room temperature.

$Mn_{0.5}Fe_{2.5}O_4$, an analogue of Fe_3O_4 , is an n -type ferromagnetic oxide. In OA- $Mn_{0.5}Fe_{2.5}O_4$ NC film, the NCs self-assembled in hexagonal arrangement (the upper- and lower-left insets of Fig.1), and exhibited SG transition at 150K. At 200K, $MR = -38\%$ was achieved in $H = 0.5T$ (Fig.1). Spin transport of $P \approx 80\%$ was accomplished between the electrodes separated by 1mm (the upper-right inset of Fig.1). Below 250K, self-assembled OA- Fe_3O_4 NC film exhibited bifurcation of field cooled (FC) and zero-field cooled (ZFC) magnetizations (the lower-left inset of Fig.2). At 300K, $MR = -46\%$ (Fig.2) was achieved in $H = 0.2T$. Long-range spin transport of $P \approx 95\%$ was also accomplished for self-assembled OA- Fe_3O_4 NCs.

In our OA- Fe_3O_4 NCs three terminals device (the upper inset of Fig.2), the S-D current is switched by H , and spin tunneling current is depressed by the gate voltage

(V_G) since the spin polarization is altered by the spin-orbit coupling. Under $H=0.2T$, MR decreased by application of $V_G=4V$ to a half of that at $V_G=0V$.

ABSTRACT

Currently, semiconducting nanowires are attracting much attention as promising components for future nanoelectronic devices such as: chemical sensors or biological, battery electrode and photovoltaic cells. Several approaches have been successfully developed for the fabrication of the nanowires. These include vapor-liquid-solid (VLS) growth [1], metal catalyzed growth assisted by laser ablation, reactive ion etching combined with lithography technique [2, 3] and metal assisted chemical etching (MACE) technique [4].

The metal-assisted chemical etching (MACE) is a technique novel for fabricating silicon nanowires which no needs of an external bias application. It is a simple, fast, and effective method. In this work, we have studied the effect of the etching

concentration AgNO_3 and NH_4HF_2 on the process of formation of silicon nanowires as function of level doping. The etching is performed in a new chemical solution mixture of NH_4HF_2 and AgNO_3 which has been recently developed.

The morphology of the silicon nanowire layers is investigated by scanning electron microscopy (SEM) and the wettability was investigated measuring the contact angle . It was found that the morphology strongly depends on etching parameters and their wettability change from highly hydrophilic to hydrophobic.

Keywords: nanostructure, metal-assisted chemical etching, silicon nanowires, scanning electron microscopy (SEM), contact angle.

Bi-Pb-Sr-Ca-Cu-O oxide superconductors are very attractive material as a highly sensitive magnetic sensor. We tried the technique of adding shock-compacted BPSCCO superconducting crystal grains into the starting materials ($\text{Bi}_{1.85}\text{-Pb}_{0.35}\text{-Sr}_{1.90}\text{-Ca}_{2.05}\text{-Cu}_{3.05}\text{-O}_x$ calcined powder) as seed crystals in order to obtain larger crystal grain, more dominant Bi-2223 phase and higher T_C . The specimens that contain 5%, 10%, 15%, 20% and 25% of seed crystals were prepared. These specimens were tightly encased in copper containers. The sample chamber of shock compaction gun system was vacuumed to 1.10 Torr, and shock compaction experiments were carried out under the shock pressure of 5-10 GPa.

From scanning electron microscope (SEM) images of the specimens after shock compaction, BPSCCO crystal grains of 1-3 μm were found. Larger crystal grains of 10-30 μm were found from the specimens annealed at 840-860 $^\circ\text{C}$ for 48-72 h after shock compaction. The higher content rate of seed crystals, the larger crystal grains were found in average. Figure shows the exceptionally large crystal grains of 95.6 μm found from the specimen content rate of seed crystals 15% - annealed 48 h.

From x-ray diffraction (XRD) analysis, Bi-2223 phase of (0 0 12) and (0 0 24) peaks were found from the specimen seed crystal content rate of 20% before annealing, and then Bi-2223 phase of (0 0 10), (0 0 12), (0 0 14) and (0 0 24) peaks were found from the annealed specimen. Similarly, Bi-2223 phase of (0 0 12) and (0 0 24) peaks were found from the specimen seed crystal content rate of 25% before annealing,

and then Bi-2223 phase of (0 0 10), (0 0 12), (0 0 14), (0 0 16), (0 0 18) and (0 0 24) peaks were found from the annealed specimen. The more peaks of Bi-2223 phase were found from the specimens after annealing. The higher content rate of seed crystals, the more peaks of Bi-2223 phase were found. However, the higher content rate of seed crystals, the lower crystalline were found.

We fabricated a thick film from shock-compacted BPSCCO superconductor. The superconductor bulk was atomized by jet mill. The size of these particles was about 1.8 μm . Particles were dispersed into methyl ethyl ketone, and dropped on the microscope slide. It became a thick film when it dried. From XRD analysis, it became clear not to lose Bi-2223 phase, even if superconductors are atomized and dispersed into solvent.

Charge transport and mechanical properties of molecular junctions formed by acetophenone deposited on Si (100) surface

T10 Nanoscience and Technology

#NST-12-Or-3

O. Krejčí, Z. Majzik, M. Setvín, P. Hapala, P. Mutombo, P. Jelínek.

Institute of Physics ASCR - Prague (Czech republic).

One of the main challenges of Molecular electronics is to understand and control charge transfer through a reproducible single molecule contact between electrodes. Most investigations of electron transport through molecules have been performed in “blind” junction experiments, where the molecular conformation and contact geometry cannot be probed. Therefore large gaps in our knowledge remains since in molecular electronics the atomic-scale structure of the entire junction including the leads is important for its conductance properties.

Our goal is to study electrical transport through well-defined molecular junction on semiconductor surfaces. Formation of molecular junctions using organic molecules on semiconductor surfaces might lead to interesting phenomena such as negative differential resistance [1].

In this contribution, we investigate formation of molecular junction consisting of a single acetophenone molecule deposited on Si (100) surface in upright position by means of simultaneous AFM/STM measurements and DFT calculations. We used a modified UHV VT STM/AFM Omicron machine allowing simultaneous acquisition of the current and forces with atomic resolution using a tuning fork sensor [2]. At first we performed simultaneous force spectroscopy and current spectroscopy to identify and to determine the position of the molecule. Here in addition we have an idea now how far the tip is located from the molecule and enable us to have precise control of contact formation. All this can be done only with the guide provided by DFT calculations that gives us better insight into interaction mechanism between probe and molecule. Afterwards, we record Kelvin-force spectroscopy, in which the bias voltage is swept and both frequency shift and the current through the junction are monitored as function of tip-sample distance. In addition, we performed DFT-based simulations, which allows us to get more insight into ongoing processes along tip

approach. Our approach combining AFM/STM/KPFM and theoretical simulations provides complex information about the charge states and charge transport through a single acetophenone molecule on Si(100) surface.

In particular, we found strong dependence of transport and mechanical response of single molecule on tip chemical reactivity.

Introduction

Recently, extensive investigations have been focused on field emission (FE) property on conducting materials due to their applications in vacuum micro/nanoelectronic such as field emission displays and microwave sources. Among various nanostructures, one-dimensional system such as carbon nanotubes [1] and molybdenum oxide nanostars [2] because of their stability and high aspect ratio have received much attention. In this investigation, we report the result of FE measurements from sputtered nickel oxide nanorods.

Experimental

NiO nanorods have been synthesized in two steps procedure. First, by using DC sputtering method, Ni thin films were deposited on the Si(100) substrate under different growth conditions. The optimized condition for nanorod formation were: Ar discharge power density of 3.60 W/cm², P ~ 4 × 10⁻² Torr, deposition rate 20 nm/min and growth time 30 min. Second, the films were annealed in air at 600 °C for 180 minutes with heating rate of 16 °C/min to obtain crystalline structure with nanorod formation based on SEM observations. Surface chemical composition of the produced layer was examined by XPS. FE measurements were performed under UHV (P ~ 10⁻⁸ Torr). Different cathode-anode separation distances (d) were examined to achieve optimum field emission current density (J).

Results and Discussion

Figure 1 shows the XPS spectra of the de-convoluted Ni (2p_{3/2}) core level. It was found four different chemical states of Ni: Ni, NiO, Ni(OH)₂ and, Ni₂O₃. Figure 2

shows typical plots of the measured J , versus the applied electric field (E), at different d values. The inset is Fowler–Nordhiem (FN) linear plot for $d=300\ \mu\text{m}$. Based on our FE measurements, we have found that the turn-on electric field of $\sim 3.8\ \text{V}/\mu\text{m}$ at $d=300\ \mu\text{m}$ and the field enhancement factor of $\beta\sim 5913$.

Colloidal semiconductor nanosheets as photo-transistors

T10 Nanoscience and Technology

#NST-10-Or-1

C. Klinke.

University of Hamburg - Hamburg (Germany).

Controlled assembly leading to anisotropic nanostructures poses a conceptual challenge in materials research. Oriented attachment of nanocrystal, a self-assembly of particles into larger single crystalline objects, is one of the most promising approaches in nanotechnology to synthesize anisotropic materials. One-dimensional assemblies of oriented attachment have been reported, and in most cases the anisotropy during self-assembly is caused by crystal planes with preferred reactivity and dipole moments in the crystallites. Systems with cubic crystal symmetry, however, like PbS and PbSe, where beautiful one-dimensional oriented attachment occurs, are somewhat more difficult to explain. In a new approach we synthesized truly two-dimensional nanocrystals by oriented attachment with lateral dimensions on the micrometer scale. We show that the formation of ordered and densely packed ligand surface layers of oleic acid on {100} PbS surfaces can drive the normally isotropic crystal growth into a two-dimensional oriented attachment of nanocrystals. Hereby the presence of chlorine containing co-solvents during the initial nucleation and growth process of the nanocrystals plays a prominent role. In the talk the synthesis and the formation mechanism will be discussed and detailed characterizations will be introduced. The obtained two-dimensional structures can be readily integrated into a three-terminal device structure. An analysis of the performance as photo-transistor will be presented.

Structure and orientation of crystals at metal/graphene interfaces : The effect of van der Waals interactions

T10 Nanoscience and Technology

#NST/SS-P1-02

M. Yeom.

KISTI - Daejeon (Korea, republic of).

Many theoretical and experimental studies have been made on the interfacial interaction of graphene and metal surfaces because metal-graphene interfaces are of critical importance in graphene synthesis, graphene-based device applications, and metal-graphene-metal materials. Molecular dynamics (MD) in conjunction with the semi-experiential many-body potential of the modified embedded-atom method (MEAM) is used to overcome the system size and time limitations of ab initio calculation. The effect of van der Waals interactions on the structure and orientation of metals at metal/grapheme interfaces has been investigated by using Constant temperature and pressure molecular dynamics (NPT) simulations. Face-centered cubic, hexagonal close packed, and body-centered cubic structures were used as the reference structures for Ni, Mg, and Si, respectively.

The initial slab configurations have been consisted of 48 layers which is a 5.5×6.5 nm plane. The total number of atoms for each system is about 120,000 atoms. The simulation box was replicated periodically in z dimension. The Nosé-Hoover thermostat and barostat with a time constant of 0.1 ps and 1.0 ps, respectively, were used. The modified embedded-atom-method (EAM) potentials were used to compute pairwise interactions of metals and graphene. In order to investigate the effect of van der Waals interactions on the structure and orientation of metals at metal/grapheme interfaces, we also used corrected pairwise interactions of metals and graphene by the addition of interatomic pair potentials to describe van der Waals (vdW) interactions. Van der Waals (vdW) interaction parameters are obtained from density functional theory (DFT) calculations by using Vienna ab initio simulation package (VASP) with gradient-corrected Perdew-Burke-Ernzerhof (PBE). The NPT dynamics for slabs were run for 5 ns for equilibration with a 1 fs time step. The initial configurations of nanopillars and a graphene inserted nanopillars were then obtained from these equilibrated slab systems. All simulations were performed at 298 K.

Structure of metals at interface, stacking sequence, and the orientation of graphene has been analyzed.

SS/NST-P1-01

Modeling secondary electron emission in scanning He ion microscope; comparison with scanning Ga ion and electron microscopes

T10 Nanoscience and Technology

#SS/NST-P1-01

K. Ohya, T. Yamanaka.

Institute of Technology and Science, The University of Tokushima - Tokushima (Japan).

Scanning ion microscope (SIM) using gallium (Ga) focused ion beams has been employed as an observation tool in micro-fabrication processes, in a similar way to scanning electron microscope (SEM). Recently, a helium (He) SIM equipped with new high brightness ion source is of current interest for its higher capabilities to produce a sub-nm beam for observation. Although the image formation mechanisms of the SIMs are similar to those in SEM, there are some differences in image properties. We have performed Monte Carlo simulations of secondary electron (SE) emission in He- and Ga-SIMs to compare with those obtained using SEM. The approach has revealed the theoretical spatial resolution and the origin of the image differences [1]. Recent modeling work, including charging of insulating materials and image contrast for nanostructured materials [2], is presented.

When singly charged ions of tens of keV bombard a material surface, kinetic emission mechanism dominates the SE emission, which is similar to SE emission induced by electrons. Irrespective of whether a material is conducting or insulating, the kinetic emission is modeled by a three-stage process. The first stage involves generation of internal SEs by the ions and recoiled material atoms. The second is transport of the SEs to the surface. In the third, the SEs escape over the surface barrier. Trajectories of all the particles are simulated using a Monte Carlo technique [3]. For insulating materials, the model is combined with charge accumulation, electric field formation, and analysis of equation of motion for SEs in the vacuum [2]. The SE emission is simulated also for electron impact.

For He ions, the SE yield increases with increasing the atomic number of metals, in a similar way to that for electrons. However, it shows an opposite dependence for Ga ions, which gives an evidence of the material contrast observed on Ga-SIM, which is

different from He-SIM and SEM. The incident angle dependence of the SE yield for He ions approximately obeys the inverse cosine law even at high angles of 85° and more, whereas for electrons, the dependence is much weaker for high atomic number. This indicates that the topographic contrast on He-SIM is clearer than those of SEM. The spatial image resolution in SIM using zero-diameter He beams is prospected to be smaller or better (<0.1 nm) than for Ga ions and electrons. The SE energy distributions for He ion impact show no high-energy component. This results in higher voltage contrast, down to a nm-sized area, than electron impact. Since the insulating material is positively charged from arrivals of ions and emissions of SEs, some of emitted SEs are drawn back to the surface and are unable to produce a net emission. The net SE yield decreases as a result of successive positive charging, and finally vanishes. However, thin insulating layers (<250 nm) on a conducting substrate is much less charged for He ions, due to the wide depth and lateral distributions, than for Ga ions and electrons where the distributions are much localized. This is different from the charging of thick materials.

Pollution of the environment is one of the most threatening problems afflicting people. Besides the pollutants such as heavy metals, halogenated organics and pesticides, a large variety of microorganisms including disease causing pathogens as for example bacteria (*Salmonella enterica*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*), protozoa (*Giardia lamblia*), fungi (*Candida* spp.) and viruses (hepatitis A virus) pose a great threat [1]. In order to address this point, we synthesize magnetic bimetallic Fe-Ag nanoparticles which exhibit significant antibacterial and antifungal activities against a variety of microorganisms. Moreover, the bimetallic nanoparticles reveal a prolonged action and high efficiency of phosphorus removal. The preparation of these multifunctional hybrids is fast, simple, feasible in a large scale with a controllable content and size of Ag nanoparticles. We also find out that the air-stability and the efficiency of phosphorus removal are related to the formation of Fe₃O₄/γ-FeOOH double shell at the interface between iron and silver. As an important environmental aspect, silver nanoparticles are not released from the composite even upon sonication and heating. Taking into account the possibility of easy magnetic separation of Fe-Ag nanoparticles, they represent highly promising material for advanced technologies of water treatment including waste and drinking water.

How to study changes of proteins structure and stability upon protein-nanoparticle interaction

T10 Nanoscience and Technology

#SE/PST/TF/BI-3-Or-7

L. Calzolari, S. Laera, G. Ceccone, F. Rossi.

European Commission - Ispra (Italy).

The behavior and toxicological properties of nanoparticles (NP) in biological medium depends heavily on their interactions with proteins. In return, the structure, stability and biological properties of the proteins that interact with the nanoparticles are strongly affected by this interaction. Unfortunately, the mechanisms of interaction and their structural consequences are very difficult to analyse. Here we show how biophysical techniques used in structural biology can be adapted to study the changes in structure and stability of proteins upon interaction with nanoparticles. By using synchrotron radiation circular dichroism spectroscopy it is possible to detect changes in the secondary structure and stability of proteins upon interaction with nanoparticles [1]. In some cases it is also possible to identify the protein-nanoparticle interaction domain by using high resolution Nuclear Magnetic Resonance spectroscopy [2].

NST/SS-5-Or-2

Ultrafast charge transfer at graphene surfaces with widely varying coupling to their substrates

T10 Nanoscience and Technology

#NST/SS-5-Or-2

D. Menzel ¹, P. Lacovig ², K. Kostov ³, R. Larciprete ⁴, S. Lizzit ².

¹Physik-Dept., TU Muenchen - Garching (Germany), ²Elettra, Sincrotrone Trieste - Trieste (Italy), ³Inst. General and Inorganic Chemistry, Bulgarian Academy of Sciences - Sofia (Bulgaria), ⁴CNR Institute for Complex Systems - Roma (Italy).

Ultrafast charge transfer (CT) is decisive for electronic dynamics important for processes involved in photochemistry and electrochemistry at surfaces, and in related devices. A convenient method for investigation of CT at surfaces in the low femtosecond range is the so-called core hole clock method [1,2]. It uses the creation of a localized resonant core excitation of an adsorbate atom, coupled with analysis of the core hole decay spectra; this allows to derive the CT times. With adsorbed Ar as probe, the range between about 1 and 30 fs is accessible, using the $2p_{3/2}$ to 4s excitation [2].

Graphene layers on metallic or insulating substrates show a wide variety of substrate coupling [3] which should have consequences for electron transfer dynamics. So far no such data are available. We have therefore used the core hole clock method with adsorbed argon to measure the transfer rates of a localized electron - the 4s electron on core-excited Ar with an energy of 1 to 2 eV above E_F - to the surface of graphene monolayers (Gr ML) on a wide range of substrates with varied coupling. We have investigated the full range from very strong and locally varying coupling for corrugated Gr ML on Ru(0001) (with "valleys" and "hills"), via still corrugated Gr/Ir(111) and even weaker coupled Gr/Pt(111), to essentially decoupled Gr ML on SiC and on intercalated SiO_2 [4] or O on Ru(0001). Indeed strong variations paralleling the coupling are found. Expressed as charge transfer times (CCT), we find values between ~ 3 fs (Gr ML strongly coupled to substrate on Gr "valleys"/Ru(0001)) and ~ 16 fs (quasi-free Gr on SiC, and on SiO_2 , or O/ Ru(0001)). Between the "hills" and "valleys" of the corrugated Gr/Ru layer a CCT ratio of 1.7 is found. The very fast

CT on Gr/Ru is explained as due to hybridized Ru orbitals "reaching through" the Gr layer which change with the relative Gr/Ru alignment and distance, so that three-dimensional final states of CT result. The intermediate CT times for the Gr hills on Ru, for Gr/Ir, and on Gr/Pt show that these regions are far from the "decoupled" condition. On the Gr layers decoupled from their substrates the intrinsic coupling to the two-dimensional Gr empty π^* states determines the CT time. Their comparatively large CCTs are partly due to low empty DOS but may also be connected with dynamical Coulomb blockade [5], due to relatively localized empty states in the relevant energy range (around 1.5 to 2 eV above the Dirac point). The results contribute new information on the influence of substrate coupling on CT which could have importance for the use of Gr as contacts in photo- and electrochemical applications. They also have bearing on the understanding of the (still controversial) states of Gr/Ru.

NST-P2-10

High-purity magnetite nanoparticles prepared by co-precipitation via solvent extraction from an iron ore

T10 Nanoscience and Technology

#NST-P2-10

D. Kil, Y.J. Suh, H.D. Jang.

Korea Institute of Geoscience and Mineral Resources - Daejeon (Korea, republic of).

Magnetite nanoparticles are suitable as a heavy metal adsorbent in wastewater treatment due to their high heavy metal adsorption capacity and can be easily recovered after use due to excellent magnetic properties[1]. Also, they can be used as a solute in a purification or desalination plant using osmosis due to water retention properties[2]. In the industrial fields such as wastewater treatment or desalination plants, the amount of water to be treated is huge, and in turn the demand for magnetite nanoparticles is expected to be significant. In the preparation of magnetite nanoparticles in the conventional methods, commercially available high-purity iron salts such as FeCl_2 , FeCl_3 , $\text{Fe}(\text{CH}_3\text{COO})_2$, and $\text{Fe}(\text{CO})_5$ have been used as starting materials[3]. However, the high-purity iron salts are expensive, which would be problematic in the industrial applications. Therefore, it is necessary to develop a means to reduce the cost of magnetite nanoparticles. Here, we produced high-purity magnetite nanoparticles directly from a low-grade iron ore by a simplified process excluding intermediate steps such as the preparation of an iron salt as a precursor.

After removing the impurities from the leachate of a low-grade magnetite ore by solvent extraction, we prepared magnetite nanoparticles of 10.8 nm in an average size by co-precipitation. Among the major metal components, the weight ratio of Fe increased from 76.9% in the raw iron ore to 99.5% in the magnetite nanoparticles, which is the same level as 99.2% in the nanoparticles prepared from commercially available iron salts. Especially, the contents of Si and Mg that inhibit the formation of magnetite nanoparticles were reduced from 7.26 wt% and 11.49 wt% to 0.18 wt% and 0.02 wt%, respectively. When the Si component is present in an amount of 4.7 wt% or higher in the reactant solution, well-defined magnetite nanoparticles are not

formed. The extractant and stripping agent used were an organic mixture of tri-butyl-phosphate (TBP) and deionized water, respectively. According to X-ray diffraction patterns, the crystal structure of the nanoparticles was identified as magnetite (ICDD 19-0629). The magnetization measurement with a SQUID showed the saturated magnetization of 65.6 emu/g, slightly higher than that of the nanoparticles synthesized with pure reagents, 60.0 emu/g.

In the present study, we have synthesized magnetite nanoparticles with a purity of 99.5% directly from a low-grade iron ore as a starting material by a rather simple hydrometallurgical process. The main impurities of Si and Mg were effectively removed by solvent extraction process. It is possible to reduce the processing cost and the amount of energy used, thus supplying a high-efficiency magnetite nanoparticle adsorbent in large quantities at low cost. This may significantly contribute to the prevention of environmental pollution.

Release of urea from nanofibers of wheat gluten obtained by electrospinning: kinetic studies

T10 Nanoscience and Technology

#NST-P2-11

F. Rodríguez-Félix, B. Ramírez-Wong, P. Torres-Chávez, M. Castillo-Ortega, D. Rodríguez-Félix, L. Armenta-Villegas, D. Castro-Enríquez, R. Dórame-Miranda.

Universidad de Sonora - Hermosillo (Mexico).

Urea is an inexpensive solid nitrogen fertilizer used for agricultural production [1]. However, its use involves the loss of the fertilizer by leaching and volatilization, this due to the techniques of fertilization and irrigation water management [2]. This loss of fertilizer causes poor harvests and great economic loss to farmers, due to the high cost of fertilizers and the low price of the product obtained. Also, creates a potential problem of contamination of groundwater aquifers, therefore, to solve this problem requires seek more efficient techniques of nitrogen fertilization. Recently we reported the preparation and characterization of a prolonged-release material of nitrogen fertilizer (urea, 46-00-00) [3], in order to prevent rapid loss of nitrogen to subsoil and thereby save on this input and simultaneously reduce pollution of the subsoil. This material was obtained from wheat gluten by the method of electrospinning. The wheat gluten was used because it is a material biodegradable, available and inexpensive [4]. The study of release of urea in water at 25 °C showed its potential application as prolonged release system of urea. However, a more detailed study is needed to predict their behavior of release in soils with different pH at water and temperatures different of application. Therefore, in the present work the effects of pH and temperature on the kinetics release of urea from nanofibers of wheat gluten obtained by electrospinning were studied. The release kinetic tests were conducted using a buffer solution as the release medium under pH conditions of 4, 7 and 10, and temperature of 25 and 40 °C. An overall evaluation of the kinetics and mechanism of urea release from nanofibers of wheat gluten was done according to the exponential model developed by Ritger and Peppas. The rate of urea release was increased with increasing temperature in the release medium, and at pH 4 and 10 the rate of urea release was decreased. The results indicate that a slow release is

assumed to obey a mechanism of anomalous transport (Non-Fickian) and a fast release is assumed to obey a Fickian diffusion mechanism. It was concluded that the type of mechanism of release depends on the temperature and pH of the release medium, which affected the release rates.

Energy-dependent Phase-shift of Electrons Scattered in 2D Subband States

T10 Nanoscience and Technology

#NST-12-Or-5

K. Nagaoka ¹, S. Yaginuma ², T. Nakayama ¹.

¹International Center for Materials Nanoarchitectonics (MANA), National Institute for Materials Science (NIMS) - Tsukuba, Ibaraki (Japan), ²RIKEN - Wako, Saitama (Japan).

As a fundamental step towards a practical use of electron phase-operation via scattering in a solid-state device, we have investigated an atomic-scale scattering phenomenon on a 2D subband state formed in a space charge layer of Si by using STM.

Measurements were performed with Si(111)- β - $\sqrt{3}\times\sqrt{3}$ Bi surface. Particularly, we have noticed a certain point-defect at the surface, around which a standing wave pattern was created by interference of incident and scattered electron wave functions in 2D subband states (Fig. 1). A profile analysis on the dI/dV images provided energy-dependent phase-shift of electrons scattered by the single point-defect potential (Fig. 2).

Consequently, from the dispersion of the scattering phase-shift with respect to the energy, the height and the radius of its induced scattering potential were estimated 0.62 eV and 0.59 nm, respectively, which corresponded to the maximum scattering cross section of 2.2 nm². To obtain these numerical values of the detail scattering parameters is a fundamental process toward phase-shift operation by the electron scattering in a solid. Therefore, this result is informative for developments of electronic devices utilizing the wave nature of electron, such as a quantum logic device

Antimicrobial Activity of Electrospun Poly (butylenes succinate) Fiber Mats Containing PVP-Capped Silver Nanoparticles

T10 Nanoscience and Technology

#BI/ASS/NST-P1-09

P. Wang, L. Tian, J. Ji.

Technical Institute of Physics and Chemistry, Chinese Academy of Sciences - Beijing (China).

Electrospinning is recognized as a very simple and highly versatile method that produces polymer fibers with diameters in the range of nanometer to micrometer under the external electric field imposed on polymer solutions or melts. At the same time, poly (butylenes succinate)(PBS) is one of the most commercially available biodegradable polymers with good biocompatibility, biodegradability and excellent mechanical properties.^[1-2] In this study, PBS fiber mats were successfully produced by emulsion electrospinning, the ideal of which was mixing a small amount of aqueous solution containing surfactant into PBS chloroform solutions followed by emulsifying.^[3] And biodegradable PBS fiber mats containing silver nanoparticles (AgNPs) are successfully prepared via electrospinning using PVP as capping agent as well as reductant for the synthesis of AgNPs and were well characterized by SEM and TEM as showed in figure1. The AgNPs were randomly distributed throughout the PBS fibers and the diameters of AgNPs were several nanometers. Further evaluation of the bactericidal properties of the PBS-AgNPs fiber mat was conducted by checking the number of viable bacteria versus contacting time and the results are displayed in Figure 2. Because AgNPs with small diameter effectively release from the fiber mats in aqueous solutions, the PBS-AgNPs fiber mats exhibited strong bactericidal activity of in a short contacting time with the bacteria. In addition, long-term release performance of Ag from the fiber mats sustained the capacity to inhibit the bacteria growth of the mats over a long period of time.

Photophysical properties of thin titanium dioxide films doped with a new type of merocyanine dye are studied. These thin films produced using sol –gel technique occurred highly luminescent and durable materials [1].

The absorption and luminescence properties of the material depend strongly on dye concentration suggesting the formation of fluorescent J aggregates [2]. Time resolved luminescence spectroscopy confirmed the formation of fluorescent J aggregates. The performed measurements and numerical analysis allowed to determine some structural parameters of the aggregates as well as their quantum yield and fluorescence lifetimes.

This research has been partly supported within the International PhD Project "Physics of future quantum-based information technologies" (MPD/2009-3/4) financed by Foundation for Polish Science (A.Lewkowicz) and grant NCN 2011/03/B/ST5/03094 (P.Bojarski, A. Synak, B. Grobelna).

We report on the possibility of application of plasmonic antennas for biosensing. The wavelength of localized plasmonic resonance of antennas is dependent on the index of refraction of antenna surrounding. When some molecules are placed on the surface of an antenna or in the close vicinity of it, the resonant frequency shifts due to a resultant change of the effective refraction index. When these molecules are tailored to bond only to a specific molecular group, then the antennas can be used to selectively sense the presence of such group.

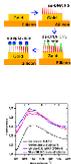

In our experiments the samples containing $50 \times 50 \mu\text{m}^2$ arrays of gold dimer plasmonic antennas on silicon substrates fabricated by electron beam lithography were prepared. The length of antenna rods was in the range from 0.6 to 2.0 μm in order to tune the resonance wavelength of antennas to the middle infrared (MIR). The reflectance spectra of the antenna arrays were taken by FTIR and compared with the results of simulations carried out by the Lumerical FDTD package.

After that the antennas were functionalized. The scheme of functionalization steps is shown in fig. 1. First, a self-assembly monolayer of 24-base single-stranded DNA sequence F5 was bound to the surface of antennas through a thiol group. Then, a complementary single-stranded DNA sequence with biotin molecule was linked to the ss-DNA. Finally, streptavidin which binds strongly to biotin was used. Reflectance spectra were taken by FTIR after each functionalization step. An example of the spectrum is shown in fig. 2.

The spectra taken after each functionalization step show a slight shift of the antenna resonant wavelength (peak maxima) caused by the presence of the DNA monolayer (approx. 3 nm thick) and molecules linked to the DNA.

Fig. 1. Scheme of antenna functionalization steps.

Optical properties of nanostructured bioinspired materials

T10 Nanoscience and Technology

#NST-P3-24

A. Deraoui.

UCL - LIIn (Belgium).

The nature shows us a great many situations where the optics plays a crucial part, this is particularly the case for birds and insects whose color is usually associated with their behavior as a factor of recognition. This variation of coloration depends on the illumination and depending on the direction of observation: it is the phenomenon of iridescence. The material forming for example the elytra of beetles is the chitin and its refractive index is close to that of ordinary glass. The SEM observation shows that the material is in the form of multilayer separated by layers of air. These layers disturb the refractive index of chitin and cause multiple reflections which interfere and explain the phenomenon of iridescence.

The models clearly confirm this interpretation, but they also show that it is possible to produce structured surfaces in the laboratory with properties similar to natural structures. The project aims to develop methods for producing samples based on natural structures where optical properties can be interesting. These samples will be characterized by various methods and techniques in order to understand its properties. The main goal is to analyze the role of roughness. We determined the optical properties changing of these structured surfaces based on the characteristics of surface roughness and we compared them to those of smooth surfaces.

Via Morego, 30 - Genova (Italy).

The development of reliable, sensitive and specific biosensors is a very active research field. Among all the technique, the Surface Enhance Raman Scattering (SERS) is one of most sensitive way to detect protein [1,2]. It has been widely used for ultrasensitive chemical analysis down to single molecule detection. Its field of applications now includes chemical-biochemical analysis, nanostructure characterization and biomedical applications. It is also very useful for the detection of conformational changes and structural differences regarding preferred orientations of molecules with respect to a metal surface. In this work, we present the SERS detection of specific protein in the serum, using a functionalization layer. To investigate the protein detection, the arrays of metallic nanoparticles were made by electron-beam lithography (EBL) to control the Localized Surface Plasmon Resonance (LSPR) position to be closed to the excitation laser wavelength, in order to obtain the best enhancement [3]. The gold nanoparticles were cylinders and rods. To be specific and increase the sensitivity, the surface was functionalized with specific aptamer to catch different targets proteins. In conclusion, we report that we can detect the protein using the LSPR and the SERS. We show that we can characterize the interaction with proteins with the SERS

signal. Moreover, we demonstrate that the functionalization surface assure the specificity of the biosensor and allow to detect the protein at 10^{-8} M. The authors want to acknowledge the Nanoantenna collaborative European project (HEALTH-F5-2009-241818) for financial support.

Improved Hydrophobicity of Tungsten GLAD RF sputtered Nanorods by Poly(tetrafluoroethylene) thin films

T10 Nanoscience and Technology

#NST-P1-04

A. Bayat, M. Ebrahimi, A. Moshfegh.

Sharif University Of Technology - Tehran (Iran, islamic republic of).

Introduction

Hydrophobic and superhydrophobic surface finds many applications in science and technology such as self-cleaning, contamination inhabiting and anti-fogging[1]. Tungsten (W) is well known for its extreme resistance to corrosion. Surface treatment with low surface energy materials such as polytetrafluoroethylene (PTFE) is a key process for hydrophobicity [2]. PTFE can be coated on W surface with a suitable method for water repellency property. Glancing Angle Deposition (GLAD) is a method to grow thin films with desired nanostructures such as nanorods and zigzag columns. In this research, we have used GLAD RF sputtering technique to fabricate PTFE on W over glass substrate for obtaining hydrophobic surface.

Experimental

First, the glass substrates mounted on a rotatable substrate holder in a GLAD sputtering chamber with base pressure $\sim 10^{-7}$ Torr. Discharge power density and the Ar sputter pressure were 3 W/cm^2 and 10^{-3} Torr, respectively. Tungsten layer was formed in one step by varying the substrate angular speed from 5 to 30 RPM. After deposition of W thin films with nanorod structure, a nanometric Teflon layer ($\sim 15 \text{ nm}$) was coated by RF sputtering on top of the deposited W layer.

Results and Discussion

According to SEM observations, tungsten nanorods were formed on the substrate with average diameter of $\sim 50 \text{ nm}$ and length of $\sim 300 \text{ nm}$ (Fig.1). For the PTFE/W/Glass system, the ratio of F/C was obtained about unity based on XPS analysis. Then, hydrophobic property of systems was investigated by water contact angle measurements and maximum contact angle of $\sim 121^\circ$ was obtained at 10 RPM for the PTFE/W/Glass system (Fig. 2). Based on our data analysis, the contact angle varied with substrate angular speed and the results obey Cassie-Baxter model.

Influence of La³⁺-Nd³⁺ ions on the growth of hexaferrite nanoparticles

T10 Nanoscience and Technology

#NST-9-Or-4

P. Barman, A. Thakur, R.R. Singh.

JAYPEE UNIVERSITY OF INFORMATION TECHNOLOGY OF INFORMATION TECHNOLOGY - Solan (India).

The hexagonal ferrite $MFe_{12}O_{19}$ ($M = Sr, Ba, Pb$) is an important materials with magnetoplumbite structure used in various applications such as magnetic recording media, telecommunications equipment and permanent magnets due to appropriate properties including perfect mechanical, chemical and thermal stability [1]. Here, we are presenting some new findings about the substitution of La^{3+} - Nd^{3+} ions in strontium ferrites. The nanocrystalline system $SrNd_xLa_yFe_{12-x-y}O_{19}$: where $x = y = 0$; $y = 0.4$, $x = 0.0$ and 0.2 ; have been prepared using sol-gel method followed by gel to crystallization technique from high purity nitrates. The influence of the Nd^{3+} and La^{3+} substitution, Fe^{3+}/Sr^{2+} molar ratio and the calcination temperature on the crystallization of ferrite phase have been examined using powder x-ray diffraction (XRD) and Fourier transform infrared spectroscopy (ref: figure 1 and 2). The x-ray diffraction and Mid-IR studies confirmed that the synthesized particles exhibit hexagonal structure [2,3]. The diffraction patterns have been used for the evaluation of crystallite size (30-45 nm), lattice parameter c/a (3.92-3.91), x-ray density (5.11-5.37 g/cm^3) and lattice strain (5.41×10^{-3} - 8.11×10^{-3}) of these compounds. Inset of figure 1 representing the micrograph of SEM indicating the formation of nano particles having flake like structure. Infrared spectra of doped ferrite have been analyzed in the frequency range $400-4000\text{ cm}^{-1}$. The Mid-IR analysis show two fundamental absorption peaks at $\nu_1 = 580-600\text{ cm}^{-1}$ and $\nu_2 = 400-436\text{ cm}^{-1}$, that corresponds to octahedral and tetrahedral vibrations respectively [4].

The self-breaking mechanism of Au nanocontacts

T10 Nanoscience and Technology

#NST-P1-08

T. Nakazumi ¹, Y. Wada ², M. Kiguchi ¹.

¹Tokyo Institute of Technology - Tokyo (Japan), ²Keio University - Tokyo (Japan).

Metallic nanocontacts and metal nanogaps have attracted much attention because of their potential applications in ultrasmall electronic devices. The breaking process of the metal nanocontacts is currently a hot topic of great interests. There are several investigations on the breaking process of the metal nanocontacts. The breaking process is affected by many factors, such as the stretching speed, size, and temperature. [1] Whereas most studies on the breaking process were reported for mechanically fabricated metal nanocontacts, self-breaking of the metal nanocontacts has also attracted interest. [2] This is because the self-breaking process can be utilized as a reliable tool to form molecular-sized gap, thereby constituting a useful platform for studying single molecule junction. In the present study, we have investigated the self-breaking process of Au nanocontacts in air at room temperature [3].

Metallic nanocontacts were fabricated using the nano-fabricated mechanically controllable break junction electrodes. Figure (a) shows example of conductance traces during the self-breaking process of the Au contacts. The traces show both 1 G_0 ($=2e^2/h$) and 3 G_0 plateaus or a 2 G_0 plateau. It was suggested that the triple atomic rows preferentially changed into a single row, while the double rows preferentially broke without changing into a single row. This regular self-breaking process was explained by breaking of the thermodynamically stable Au nanocontacts which were formed during the self-breaking of the contacts. Figure (b) shows typical conductance trace of the Au contacts during mechanical stretching of the contact. The conductance decreased in a step wise fashion with each step occurring at integer multiples of G_0 . During mechanical breaking process, the Au nanocontact would break before changing into the thermodynamically stable structure. Hence, the regular decrease of the number of atoms in the minimal cross section of the nanocontacts was not observed for the Au nanocontacts.

Low Voltage Electroluminescence from Thin SiO₂ Layer Including Ge Nanoparticles at Shallow Depth Formed by Negative Ion Implantation

T10 Nanoscience and Technology

#NST-P3-01

H. Tsuji¹, G. Miyagawa¹, N. Arai², Y. Gotoh¹.

¹Kyoto University - Kyoto (Japan), ²Sharp Corporation - Tenri (Japan).

Blue-ultraviolet light emission from Ge nanoparticles (NPs) embedded into SiO₂ thin film is expected for application as light emission source in Si semiconductor device. The emission site of blue-UV light is considered to be Ge-related oxygen defect centers (ODCs). The reported electroluminescence (EL) emission needed a relatively high voltage of 380 V[1]. For an application of this EL emission as light source of communication between Si chips and other general ones, the operational voltage of EL applied to such material must be decreased down to a low voltage around 10 V. We considered that the key issues for lowering operational voltage are (1) optical emission site of ODC should be created at shallow depth about 10 nm and (2) the optimization of oxidation for ODC. Si substrates with 50-nm-thick SiO₂ layer were implanted with Ge negative ions three times at 50, 20 and 10 keV with typical each doses of 9.2×10^{15} , 1.2×10^{15} , and 1.1×10^{14} ions/cm², respectively. Calculated Ge atomic concentration by TRIM-DYN code was shown in Fig.1. Mainly, Ge concentration between 15 to 40 nm was set to 3 at.%. Samples were subsequently annealed twice: (1) in N₂ at 700°C 1h for NP growth, and (2) in air flow at 600-900°C 1h for oxidation. PL properties were measured with a deuterium lamp for excitation. For EL observation, ITO electrode was deposited on SiO₂ surface and Al electrode deposited on the rear side of Si. All samples showed PL peaks at 390 nm and 290 nm after annealing at 800°C. Some samples showed EL emission at applied voltage of 15 – 24 V. The EL photograph is shown in Fig. 2. The EL peak wavelength is 390 nm. Thus we achieved the low voltage EL emission at 15 V, where the ODCs were formed at a very shallow depth by implantation of Ge negative ions and by two-stage-annealing method for growth of Ge NP and their oxidation.

Switching of Plasmon Response Function of Au Nanorods on GeSbTe Phase Changing Material

T10 Nanoscience and Technology

#NST-P3-17

F. Kannari, M. Kusaba, K. Hirose.

**Department of Electronics and Electrical Engineering, Keio University -
Yokohama (Japan).**

For spatiotemporal control over localized plasmon or surface-plasmon polariton (SPP) in noble metal nanostructures excited by ultrafast lasers, the temporal characterization of femtosecond plasmon field is highly required. We have already developed two methods for characterizing ultrafast plasmon both in temporal amplitude and phase: electrical-field cross-correlation imaging using femtosecond laser dark-field microscopy [1]; and spectral cross-correlation interferometer using scanning near-field optical microscopy [2]. Based on the plasmon response function measured by these methods for noble metal nanostructures such as noble metal nanorods or nano bow-ties, we can deterministically control the plasmon field in both temporal amplitude and phase by shaping femtosecond excitation laser pulses. On the other hand, the plasmon resonance of noble metal nanostructures can be modulated by the change of refractive index of the surrounding medium. When applying materials, of which refractive index can be varied optically or electrically, as a substrate of noble metal nanostructure, we can switch the plasmon response function. For example, phase change materials such as GeSbTe (GST) compounds are commonly used for rewritable memory devices due to high contrast between the amorphous and the crystalline phase in refractive index and resistance, fast write and erase speeds as well as non-volatility, and low energy consumption. Nonthermal amorphization of a GST thin film with femtosecond laser pulse excitation was currently demonstrated [3].

We measured change in the plasmon response function of Au nanorods at change of a GST substrate between the amorphous and the crystalline phase. An ultra-broadband femtosecond laser (750~920 nm) was used to excite the Au nanorods on the GST substrate. The dark-field microscope consists of a parabola mirror ($f=1500$ mm), an object lens ($\times 10$, $NA=0.25$) and a CCD camera. One laser beam irradiates multi-Au nanostructures and the scattered light is imaged by the object lens, while

the other laser beam directly reaches to the CCD camera with variable optical delay. We obtained a series of image shots by varying the time delay between the pump and the reference pulses, and analyzed the fringe-resolved cross-correlation images for each of the nanostructures. Based on this measurement, we propose metal-dielectric-metal waveguide-resonator systems as a switchable SPP waveguide.

Gold nanoparticle arrays covalently immobilized on Si

T10 Nanoscience and Technology

#NST-8-Or-2

H. Sugimura, S. Mo, T. Ichii, K. Murase.

Kyoto University - Kyoto (Japan).

Gold nanoparticles (AuNPs) are known to show unique optical properties owing to their localized surface plasmon resonance (LSPR) in the visible range. For practical and advanced applications of AuNP in photonic/electronic devices, AuNPs should be firmly immobilized on a substrate. In order to fulfill the requirement, we have developed a photochemical method by which AuNPs covered with 11-mercaptopdecene (MUD) monolayer are covalently bonded to a hydrogen-terminated Si(111) surface as illustrated in Fig. 1A [1]. Figure 1B shows an FE-SEM image of a 2D array of MUD-AuNPs (diameter = 20 nm) immobilized on a Si(111)-H surface. Hydrogen termination is crucial for this photochemical reaction. Thus, when the surface Si-H groups are replaced with an alkyl monolayer prior to the reaction with MUD-AuNPs, No AuNPs are immobilized on the monolayer-covered region. If we prepare a Si(111)-H surface into a line feature with a width nearly equal to the diameter of the AuNPs, those are aligned into the Si-H nanoline. This strategy is demonstrated in Fig. 2. The Si-H nanoline was fabricated by a scanning probe lithography method [2]. The line width was about 20-30 nm and the remained region was terminated with an alkyl self-assembled monolayer made from 1-hexadecan as a precursor. As shown in an FE-SEM image AuNPs are successfully aligned into the line with forming a 1D AuNP array. In addition, the photochemical reaction between MUD-AuNP and Si(111)-H was confirmed to be assisted LSPR aroused in the AuNPs. Plasmonic enhancement effects in the photochemical process for AuNP assemblies will be presented as well as their optical properties.

Tailoring of the partial band gap in three-dimensional magnetic composites based on magnetoferritin nanoparticles

T10 Nanoscience and Technology

#NST/SS-3-Or-10

S. Mamica, M. Krawczyk.

Faculty of Physics, Adam Mickiewicz University in Poznan - Poznan (Poland).

Biomimetic magnetic nanoparticles (NPs) have been intensively studied because of their unusual physical properties as well as promising applications. The use of protein cages as reaction chambers for the production of NPs has a number of advantages from a high level of homogeneity of the NPs to the possibility of producing highly ordered three-dimensional (3D) structures by self-assembly. E.g. the protein crystallization technique has been successfully used for the production of 3D fcc magnetoferritin (mFT) crystals of highly ordered structure and the external size up to 100 μm . An interesting effect observed in structures produced in this way is a substantial reduction of the lattice constant as a result of dehydration: from 18.5 nm to 14 nm [1].

Magnetic periodic composites, so called magnonic crystals (MCs), the magnetic counterpart of photonic crystals with spin waves acting as information carriers, proved to be promising building-blocks for the construction of new logic systems and improvement of parameters and functionalities of rf devices [2]. The realization of MCs with a lattice constant of tens of nanometers, though technologically possible, remains a challenge. The protein crystallization technique seems to open the prospect of realizing 3D MCs with a lattice constant of ten-odd nanometers. This would be an enormous step forward in magnonics, and would allow shifting the magnonic band gap to the subterahertz frequency range.

In this work we propose an MC based on a 3D mFT crystal with a ferromagnetic material used as a matrix. Our approach is based on Maxwell's equations for magnetostatics, solved by the plane wave method (see [3] for details). In our

previous paper [3] we show that the proper choice of the matrix material can lead to the complete magnonic gap opening. In this work we show that even if there is no *complete* magnonic gap the *partial* gap could exist. Such kind of gap in photonic crystals was proved to lead to many peculiar effects including negative refraction and self-collimation [4].

We study the influence of the mFT NPs total magnetic moment and the lattice constant on the partial magnonic gap for two different directions of the spin wave propagation: parallel and perpendicular to the external field. We found that the partial gap width as a function of the lattice constant has a maximum for a lattice constant of approximately 12-13 nm depending on the mFT magnetic moment. The occurrence of this maximum we address to the character of the lattice-constant evolution of the dynamic magnetization profiles for the lowest excitations in the spin-wave spectrum. We also examine the influence of the mFT NPs filling material on the width and central frequency of the partial magnonic gap. On the basis of our results we determine the conditions conducive to the occurrence and tailoring of a partial magnonic band gap.

NST-P3-14

Formation of nanoclusters in the magnetic field and the magnetoresistance of magnetoactive elastomers

T10 Nanoscience and Technology

#NST-P3-14

G. Stepanov, V. Bakhtiarov A.v, A. Semerenko, A. Storozhenko.

State Scientific Research Institute of Chemistry and Technology of Organoelement Compounds (GNIChTEOC) 105118, Moscow, Russia - Moscow (Russian federation).

Magnetoactive elastomers (MAE) feature a specific type of materials, which exhibit reversible changes of their properties under an external influence.

The MAE are composites prepared on the basis of an elastic polymer matrix impregnated with magnetic micro- and nanoparticles. Placed in the magnetic field, they reversibly change such characteristics as elasticity and viscosity, electroconductivity, dielectric permeability and magnetic susceptibility. These materials also exhibit the shape-memory effect.

In our scientific work the preparation of such materials is conducted by means of the utilization of silicone polymer matrices together with iron and magnetite fillers with particle size in the range 10-1000 nm. Systematic studies of our MAE have demonstrated that the variety of properties and their changes under the influence of the magnetic field is conditioned by the formation of clusters of magnetic particles inside the composite placed in the field. The modelling as well as direct microscopic observations of the material showed that these clusters feature chain-like agglomerates elongated along the force lines of the applied field.

The magnetic field-dependencies of the elasticity and viscosity changes observed in the material have S-shaped curves in the property-field coordinates. The maximal rates of these changes correspond to the beginning of the process of intensive cluster formation observable under the microscope.

The process of the formation of elongated clusters explains the significant magnetoresistive effect exhibited by the MAE. In other words, a change of electroconductivity in fields of up to 400 mT may reach a level of 3-4 orders for a composite having inside its polymer matrix electroconductive particles – such as Fe,

Ni, Co – or particles with an electroconductive coating.

The mechanism of the formation of clusters is based on the dipole interaction of magnetic particles in the magnetic field, whose force lines dictate the direction for the clusters to grow along.

Under the influence of the magnetic field, the magnetic composite material undergoes the formation of clusters and chain-like structures inside its polymer matrix, which results in the appearance of a set of new features including the magnetoresistive effect.

Friction is a basic physical phenomenon, which can be found in most general text books of classical mechanics. However, understanding the microscopic origins of friction is no trivial problem. There have been reports about phononic and electronic contributions to friction, which were identified in experiments on the surface of a superconductor at temperatures above and below the superconducting transition temperature [1]. Spin-dependent friction is also theoretically predicted [2], although the experimental observation was not yet achieved. In our study, we used the combination of spin-polarized scanning tunneling microscopy (SP-STM) and single-atom manipulation imaging [3] in order to slide individual magnetic atoms over a magnetic template surface [4]. By monitoring the spin-resolved manipulation traces and comparing them with results of Monte Carlo simulations, we were able to reveal characteristic friction force variations resulting from the occurrence of spin friction on the atomic scale [5]. In the presentation, we will report on details of the experimental results and the numerical analysis.

Nanotechnology provides the tools to fabricate nanoscale electro-mechanical systems in which we can push the limits of processing single electrons [1,2]. We present measurements on single electron shuttling through two coupled nanomechanical pendula. The pendula are realized as nanopillars etched out of the silicon-on-insulator (SOI) substrate as shown in Fig. 1(a), where the top crystalline silicon is 190 nm thin and the insulating SiO₂ is about 350 nm. A 50 nm top gold layer serves as the final electrical conduction path. The equivalent circuit diagram is given in Fig. 1(b): the two pillars are individually displaced by x_1 and x_2 , which lead to tunable resistances and mutual capacitances. The characteristic current-voltage curve is shown in Fig. 2 where the total Coulomb energy is indicated as E_C [3]. The obtained curve is shown as an overall ohmic response modulated by Coulomb blockade steps at room temperature. From the experimental data we find the charging energy of 40 meV. The observation of Coulomb blockade for a coupled shuttle at room temperature is possible since the cotunneling is effectively suppressed in the coupled shuttles. The application of gate voltages leads to the variation of the charging energy for an additional electron. By controlling the mechanical shuttling frequency we are able to validate the different regimes of electron shuttling.

NST-3-Or-7

Novel 2.5 D transrotational solid state order revealed by TEM in Crystallizing Amorphous Films

T10 Nanoscience and Technology

#NST-3-Or-7

V. Kolosov.

Ural Federal University - Ekaterinburg (Russian federation).

Novel microstructure with unexpected, dislocation independent, regular internal bending of the crystal lattice planes [1] are revealed by TEM in thin films after amorphous – crystalline transitions. Such **perfect crystals/grains with regularly curved lattice** (built up by simultaneous translation and small regular rotation of the unit cell) **demonstrate a new “transrotational” [2] type of solid state order**. The maximal lattice orientation gradients can reach $300^\circ/\mu\text{m}$ (axis of lattice bending \parallel film plane), Fig.1. TEM studies include primarily bend-contour method [3] supported by *in situ* studies and HREM.

Thin (10 - 100 nm) microcrystals (sizes 0.1 - 100 μm) vary from whiskers (Fig. 1a), belts (Fig. 1b) or spherulites (fig. 2b, c) to polycrystalline areas with a complex texture. They are formed by aging/heating/e-annealing in amorphous films of different chemical nature (i.e. oxides, chalcogen/ides, some metals and alloys) prepared by thermal/laser/e-beam evaporation.

Opposite to other unusual regular nano (*N*-) aggregations of atoms widely recognized in last 30 years (quasi-crystals, fullerenes, *N*-tubes, other *N*- C-derivatives, etc.) our less known “transrotational” crystals/structures are less limited in dimensions. For most simple cylindrical geometry, Fig. 2a, bent atom layers in fine areas resemble that of hypothetical 2.5D halves (180°) of endless (continuous in film plane) multiwall *N*-tubes (Fig.1d). Transrotational nano-scale self-assembly can give even more complicated *N*-structures (e.g., Fig. 2b, c).

Surface plasmons (SP) are associated with highly confined electromagnetic fields, which make them appealing candidates for future nano-optical devices. Most often, photonic excitation is used to excite SP; however local, electrical excitation would be preferable in the view of technological applications. This would allow the development of electrically driven plasmon nanosources that combine nanoelectronics and nanophotonics and could be key components in new communication nano-devices.

The scanning tunnelling microscope (STM) is an ideal, low energy, local source of electrons that can excite both localized and propagating SP through inelastic electron tunnelling effects [1,2]. In contrast to techniques based on high energy electrons, STM excitation of SP is operable in air, with junction biases lower than 3 V, and its spatial selectivity is guaranteed by the strong confinement of the tip-induced gap plasmon mode. Hence this excitation mode is fully compatible with break junctions geometries, in-plane or stacked electrodes.

Our STM is coupled to an inverted optical microscope and the resulting emitted light is collected through the transparent substrate with an objective lens of high numerical aperture (see Fig. 1). In such a setup, both the light emitted from localized SP and the leakage radiation from propagating SP may be recorded. Furthermore the image that forms in the rear focal plane of the objective lens constitutes a direct print of the angular emission pattern, which can be imaged on a CCD camera for accurate analysis. As energy and in-plane momentum component are conserved through SP leakage radiation, this angular emission pattern gives the wavevector distribution of the propagating SP. Remarkably, access to this information was not possible in most of the previous studies because they were based on optical collection from the tip-

side of the sample, which precludes the detection of propagating SP. We used this setup on thin gold films to demonstrate that both propagating (film eigenmode) SP and confined (tip-induced) gap plasmons could be excited by the STM tip, with relative proportions that depend on the shape and the composition of the STM tip. We also investigated how propagating SP scatter at the edges of gold metal stripes or at gold nanoparticles deposited on a gold thin film.

NST-P3-02

n- and p-type response and NO₂ sensing properties of Langmuir-Blodgett Fe₂O₃ and CoFe₂O₄ nanoparticle arrays

T10 Nanoscience and Technology

#NST-P3-02

S. Luby¹, P. Siffalovic¹, M. Benkovicova¹, J. Ivanco¹, M. Jergel¹, E. Majkova¹, R. Rella², M.G. Manera².

¹Institute of Physics, Slovak Acad. Sci. - Bratislava (Slovakia), ²IMM-CNR, Unit of Lecce - Lecce (Italy).

Fe₂O₃ and CoFe₂O₄ semiconducting oxides were used in gas sensing less frequently than SnO₂ or WO₃, however, their applications increase nowadays. We present nanoparticle (NP) sensors prepared by Langmuir-Blodgett (LB) deposition of colloid γ -Fe₂O₃ or CoFe₂O₄ NPs onto alumina substrates. NPs were synthesized from Fe and Co acetylacetonates with oleic acid and oleylamine as surfactant precursors [1]. The thickness of the LB deposit is 1, 2, 4, 7 or 10 NP monolayers (ML). NP arrays were analysed by GIXRD, SEM, GISAXS and XANES. The average NP diameters are 6.4 nm and 7.6 nm for Fe₂O₃ and CoFe₂O₄, respectively. The insulating surfactant 1 nm thick was removed by UV irradiation in ozone or by heating in dry air flux which resulted in a discontinuous 1ML (66 % coverage of the substrate) and conductivity dominated by percolation. After formation of continuous structures from 2 or more MLs, the baseline current $\approx 1 \mu\text{A}$ at 5 V at the working temperature $T_w = 400 \text{ }^\circ\text{C}$ was obtained. To avoid NP coalescence $T_w \leq 500 \text{ }^\circ\text{C}$ was used. Measurements were done in the mixtures of dry air with oxidizing NO₂ and, for comparison, with reducing CO gases with concentrations 0.5 – 100 ppm. Besides the standard n-type response of sensors from both oxides (decrease of current at the exposure to NO₂) also p-type response was found in some samples. This transition is ascribed to the NP surface reaction with nitrogen, presumably from oleylamine (C₁₈H₃₇N). The inverse response was observed also in reducing CO gas. The devices with 4 or 7 NP MLs showed the best sensitivity. (An equivalent thickness of the deposits after surfactant removal is about 3 and 5 MLs, respectively.) Similar result was obtained with p-type samples, though the response is lower. The sensing

medium is not homogeneous enough for thinner deposit, with thicker one the gas penetration towards the bottom of array is the limiting factor. The response of 38 was found for the most sensitive Fe_2O_3 4ML sample at 0.5 % ppm of NO_2 , hence we could move even one order of magnitude down to ppb area. Such devices are convenient for air quality control and also for the detection of nitrate explosives, approaching the canine detection capabilities. Response to CO was much lower. Sensors showed no hysteresis. Their response and recovery times are 3 – 20 min. Results of NO_2 sensing are compared to those of other oxides - MnO_2 , TiO_2 , WO_3 and advantage especially of Fe_2O_3 NP sensors is demonstrated. The resistance of NP arrays was studied between 250 and 500 °C. We obtained the activation energy of conductivity of NP arrays 0.45-0.87 eV for Fe_2O_3 and 0.56–0.84 eV for CoFe_2O_4 . High sensitivity of our sensors to electronegative NO_2 matches well the theory of charge self-exhaustion by surface traps in subcritical NPs (size < 100 nm) [2].

Atomically Controlled Heterostructures of 2D Materials

T10 Nanoscience and Technology

#NST/SS-5-Or-8

P. Sutter¹, R. Cortes¹, J. Lahiri¹, P. Zahl¹, B. Wang², E. Sutter¹.

¹Brookhaven National Laboratory - Upton (United states), ²Vanderbilt University - Nashville (United states).

Heterostructures that integrate different materials to achieve novel properties have been the focus of recent materials research, enabling applications from light-emitting devices to catalysts. The advent of new families of two-dimensional (2D) materials has opened the exciting prospect of exploring novel types of heterostructures designed from atomically thin membranes: Stacks of alternating 2D sheets, reminiscent of conventional quantum wells and superlattices; and in-plane heterostructures, in which a single membrane comprises different, tightly interfaced components. Such engineered materials not only promise new functionality, but also raise fundamental questions on interface formation, intermixing, strain, polarity, etc. in a new context at reduced dimensionality.

The controlled synthesis of 2D heterostructures presents formidable challenges in surface chemistry. We will discuss recent advances toward the synthesis and exploration of the properties of heterostructures of 2D materials on metal substrates. Focusing on graphene [1] and hexagonal boron nitride [2], 2D crystals with similar lattice structure but very different electronic properties, we have identified pathways to the formation of in-plane heterostructures with atomically sharp line boundaries [3]. The controlled synthesis of 'superlattices' with arbitrary layer sequences is extremely difficult by conventional methods (e.g., chemical vapor deposition) due to the low reactivity of 2D materials. We have demonstrated alternative processes that can overcome these limitations and provide stacks of 2D materials with atomic-layer control over thickness and stacking sequence [4]. Our combined results establish a powerful toolset for the scalable fabrication of arbitrary heterostructures of 2D materials for fundamental research and novel applications.

Single molecular spintronics: giant magnetoresistance through a single molecule

T10 Nanoscience and Technology

#NST/SS-4-Or-1

T. Yamada.

Chiba University - Chiba (Japan).

Exploring spin-polarized transport characteristics of single molecules is a promising direction of research with an outlook for potential application in future nano-scale electronic devices the functionality of which will employ not only charge but also the electron's spin.

As the first step towards this goal, we present giant magneto-resistance (GMR) measurements of single hydrogen phthalocyanine (H2Pc) molecules contacted by two ferromagnetic electrodes. Using a spin-polarized scanning tunnelling microscopy (SP-STM) at 4K, single molecules were addressed and their conductance in dependence of the magnetization of the electrodes was measured. Magnetic Co nano-islands on Cu(111) and Co coated W tips were used as ferromagnetic electrodes to make a Co/H2Pc/Co single molecular junction. The different magnetization directions were naturally achieved as the Co nano-islands can either be magnetized into or out of the Cu substrate plane. A GMR of +60% was observed which is significantly larger than the tunnelling magneto resistance of +5% obtained from direct tunnelling measurements between the tip and the nano-islands without the involvement of H2Pc molecules [1].

From the experiments of the Co/H2Pc/Co single molecular junction, the hybridization of LUMO states of H2Pc with Co 3d minority spin states was found to be the key to generate large positive GMR, which indicates different GMR for H2Pc and antiferromagnet Mn as majority spin states dominate around the Fermi energy of Mn. With the spin-polarized STM at 4K we measured magneto-resistance through the Fe/H2Pc/Mn single molecular junction.

H2Pc single molecules were deposited on Mn(001) ultrathin films grown on an Fe(001)-whisker. The bct Mn(001) ultrathin films are known to have layer-wise antiferromagnetic coupling between atomic layers, which was directly observed by SP-STM magnetic images [2]. An Fe-coated W tip was gently approached to the molecule and the conductance in contact was measured. Since the coercive field of

Mn/Fe(001) is much smaller than that of the Fe/W tip, it is possible to switch only the magnetization of the Mn/Fe(001), which was directly confirmed by a reverse of magnetic contrast in STM images. In this way, we succeeded to measure GMR through the same single molecule, and obtained, surprisingly, a negative magneto resistance of -54 % [3], i.e. anti-parallel coupling between Fe and the top most Mn layer has lower resistance, which is comparable to the case of the Co/H2Pc/Co junction. Possible reason of the polarity switch of GMR is that the spin transport through the H2Pc single molecule is dominated by minority and majority spins for Co/H2Pc/Co and Fe/H2Pc/Mn junctions, respectively.

Our experimental results show that the single phthalocyanine molecules can be used for near-future spintronics devices. Hybridization of molecular orbital with spin states of 3d nano metals is the key to obtain large magneto resistance.

Preparation of Poly(butylene succinate) /Montmorillonite Nanocomposite

T10 Nanoscience and Technology

#NST-P2-12

Y. Xu, J. Ji, J. Wang, C. Zhang.

Technical Institute of chemistry and physics,cas - Beijing (China).

Poly(butylene succinate) is a biodegradable polyester which attracts more and more attention because of its excellent mechanical properties and processability. But its Vicat softening point is only 98°C, and its elasticity module is low too, all these things have limited its application greatly^[1]. Poly(butylene succinate)/Montmorillonite nanocomposite was prepared via in-situ polymerization with 1,4-butanediol, succinic acid and OMMT. The kind and content of OMMT, the method of adding OMMT were studied. The best situation of in-situ polymerization was attained. Then a pilot scale experiment was successfully processed in this situation. The composite of the pilot scale is a nanocomposite^[2,3], the OMMT is nicely distributed within PBS matrix, the composites has a significantly increased interlayer distance, as seen in fig1, the mechanical properties and Vicat softening point are greatly increased in comparison to the pure PBS, as seen in table 1. With the organically modification of the OMMT becoming better, the intercalation of PBS matrix into the MMT layers increases, but the biodegradability of the composites decreases.

Evolution of electronic excitation states in Ar clusters from surface to bulk properties

T10 Nanoscience and Technology

#NST-P3-03

D. Miura, T. Someya, T. Tachibana, T. Hirayama.

Rikkyo University - Tokyo (Japan).

In these 20 years, interesting features of the cluster, such as evolution of bulk property in a cluster, confinement of electronic excitation inside the cluster, etc., has been experimentally studied mainly using a spectroscopic method [1]. Here we report our recent results on the electronic excitation processes in rare gas clusters using electron energy loss spectroscopy (EELS) method.

A pulsed cluster beam is generated by adiabatic expansion through a conical nozzle. A mono-energetic electron beam merges with the cluster beam, and electrons scattered to 0 deg. are energy-analyzed and detected by a CEM.

Figure 1 shows the electron energy loss spectra of Ar clusters at incident electron energy of 100 eV. Cluster size is controlled by changing the stagnation pressure from 2 to 4 atm. The size of the cluster has not been measured in this study, but it is estimated from our previous study [2] to be in the order of 100 - 500 atoms/cluster. Vertical lines indicate the energy positions of the surface and bulk excitons in solid Ar. It is shown that when the stagnation pressure rises, i.e., cluster size increases, the relative intensity of the first order bulk excitation peak (I_B / I) increases, showing that the bulk feature evolves for the cluster with the size of 10^2 atoms/cluster.

2D Bicomponent Structures Composed of Melamine and Melem at the Solution/Solid Interfaces

T10 Nanoscience and Technology

#NST-8-Or-3

S. Uemura, M. Aono, M. Kunitake.

Kumamoto University - Kumamoto (Japan).

Investigation of 2D self-assembled porous networks composed of organic molecules has been a key issue in nanoscience and nanotechnology. For construction of the 2D porous networks, building blocks with highly symmetrical features and functional groups for multiple intermolecular interactions with neighbour molecules are required because of thermodynamically instability of such networks with low surface density. Among various building blocks, melamine (Figure 1 left) is often used in supramolecular chemistry, because of its symmetrical shape with three functional groups for hydrogen bonding at the apexes. In this presentation, we report the investigation of 2D self-assembly of melamine and melem (Figure 1 right), which is a similar molecular shape to melamine, at the aqueous solution/Au(111) interfaces by electrochemical (EC) STM.

Previously, the self-assembled structures at the monocomponent solution/Au(111) interfaces have been reported.^[1] A melamine honeycomb network was essentially the same structure to that on Au(111) in UHV.^[2] Each melamine molecule was connected by “side-by-side” hydrogen bonds. In the case of melem, two kinds of self-assembled structures were revealed. One is the honeycomb network connected by side-by-side hydrogen bonds, and the unit cell parameters were larger than those of melamine depending on the melem molecular size. The other is the closely-packed structure, which was constructed by two hydrogen bonding systems (side-by-side and head-to-tail), and was with the higher surface density than the honeycomb network. Each monocomponent structure was also managed by electrochemical potential control. Especially, the “order-order” transition between the honeycomb and the closely-packed structures of melem was revealed reversibly by EC-STM.

On using the bicomponent solution, several bicomponent self-assembled honeycomb networks of melem and melamine were found at the interfaces. These structures were based on side-by-side hydrogen bonds. Depending on the mixture ratio and the solution concentration, the constructed mono- and bicomponent networks were

different. In the similar way to the monocomponent networks, the “order-order-order” transition of the self-assembled structures was also occurred under the potential control. The appearing order of the structures from the negative to positive potential agrees with the order of the surface density of the observed structures.

As a holder of genetic information and due to its unique hybridization properties, deoxyribonucleic acid (DNA) represents a key object in modern science and related technology. Self assemble monolayer of single stranded DNA (ssDNA) on coinage metal such as gold can be employed for detection of DNA binding proteins and biosensor applications. A new two-step procedure is developed for fabrication of mixed monolayer of thiolated ssDNA and oligo(ethylene glycole) sub-stituted alkanethiolates (OEG-AT) OEG-AT, which are protein repelling in nature. This approach was combine with surface-initiated enzymatic polymerization (SIEP) for extension in the Z-direction and based on an irradiation-promoted exchange reaction (IPER). This approach allow us to program complex 3D pattern of DNA on surface by electron-beam lithography (EBL). The orientation and ordering of DNA in the one-component A25SH monolayer and mixed ssDNA/OEG-AT monolayers was investigated by near-edge X-ray absorption fine structure (NEXAFS) spectroscopy, which proved a significant control of upright orientation of the DNA strands in both systems. SAMs, homogeneous poly (A) brushes, and poly (A) nanostructures were characterized by laboratory and synchrotron-based PE spectroscopy, ellipsometry and atomic force microscopy (AFM). This system can be widely used as versatile functional moiety and nanoscale building block in such important fields as bio-engineering, bio-sensing, bio-nanotechnology, gene therapy, drug delivery, nanomedicine, and molecular biology.

Room temperature Ionic liquids have been recognized as a suitable medium for preparation of colloids by chemical or physical synthesis of nanoparticles [1] with long-term stability. The current problem is how to deposit the nanoparticles on a proper substrate (battery electrode, sensor surface, etc.) and to get rid of the rest of the ionic liquid.

We used the electrophoretic deposition (EPD) to produce a layer of nanoparticles on the surface of chemiresistive gas sensor consisting of interdigitated gold microelectrodes and polyaniline thin film [2]. Colloids containing metallic nanoparticles (Au, Ni, Ag-Cu or Ni-Fe of the size of 12 or 50 nm) were produced by magnetron sputtering of the metals on the surface of imidazolium-based ionic liquids. Although no surfactants were added, the colloid did not show any agglomeration of the nanoparticles (it is believed that the role of surfactant is played by anions attached to the nanoparticle).

The EPD method is based on the application of an electric field between two electrodes immersed in a suspension of charged nanoparticles, which causes their movement toward the oppositely charged electrode [3]. We successfully deposited the nanoparticles from BMIM bis(trifluoromethylsulfonyl)imide ionic liquid onto the surface of thin-film Au electrode. DC voltage of 5 V was applied between the plane electrode and the stainless steel tip used as a counter electrode. The first deposits of nanoparticles were observed after 5 min with anodic polarization of the electrodes. On the other side, no deposits were obtained under the cathodic polarization, neither symmetrical AC voltage. This supports the assumption that the nanoparticles in the ionic liquid are coated by anions. Although the nanoparticles are charged, the EPD is limited by high conductivity of the ionic liquid. Due to the migration of ions, the electrostatic boundary layers are formed at the liquid-electrode interfaces, which cause the shielding of the bias charge of the electrodes. To overcome this problem,

pulsed potential is to be applied.

Nanoparticles adhered on the electrodes and PANI film were studied by the means of SEM, EDS and FTIR. Gas sensing properties of pristine and nanoparticle-decorated thin PANI films exposed to the gaseous ammonia or hydrogen were measured. We found enhanced sensitivity of nanoparticle-decorated PANI film due to the effect of catalytic properties of nanoparticles.

Graphene growth mechanism during of bulk-dissolved carbon on polycrystalline nickel surface is one of great interest for controlled synthesis of graphene. The growth process has been explored by real time observation using low energy electron microscopy (LEEM) [1]. Although LEEM is a useful method for investigation of graphene growth, the field of view is not large enough to track the nucleation stages and the layer expansion.

Recently, our group reported the capability of imaging monolayer graphene on polycrystalline nickel surface by scanning electron microscopy (SEM), which has a wide field of view and a crystalline orientation effect on the extension of graphene [2]. In the present study, we focused on the graphene nucleation by using in-situ SEM observation and electron backscatter diffraction (EBSD) measurement. We repeated the several cycles of dissolution and segregation carbons on polycrystalline Ni surface. We found that the graphene preferentially nucleates on (111)-oriented grains (Fig. 1). The analysis of the geometric structure using atomic force microscopy (AFM) revealed common morphology characteristic to the nucleation sites. The combination of in-situ SEM observation, AFM and EBSD measurements is useful to gain insights into controlling monolayer graphene growth.

The non-contact atomic force microscope (nc-AFM) allows one to probe forces acting between the apex of the AFM probe and the surface of the sample on the atomic scale. Even chemical identification of atoms can be achieved with this tool [1,2]. However, not only the magnitude of the force but even the mechanism by which the force arises may vary, even for a given surface, depending on the AFM-tip termination and the particular atomic or molecular species directly under the tip. The mechanism of the tip-surface interaction may be, for example, of chemical, electrostatic, or van der Waals origin. Understanding this mechanism is vital for correct interpretation of the experiments, especially when pursuing chemical sensitivity. We have, in particular, explored the interaction of an AFM tip with the Si(111)-7x7 surface partially covered with hydrogen or oxygen. In the experiment with adsorbed hydrogen, two profoundly different types of tip termination could be identified, distinguished by their reactivity. In the same experiment, the hydrogen-free and hydrogen-passivated Si adatoms on the partially passivated surface represented typical reactive and non-reactive surface sites, respectively. Thus, four modes of interaction could be studied on this surface, resulting from either a reactive or a non-reactive tip interacting with either a reactive or non-reactive surface site. We performed first-principles (density functional theory, DFT) simulation, the results of which we compare to the experimental force curves, in order to identify realistic tip models and uncover the mechanism by which the tip interacts with the surface. We propose suitable models for both types of tips, the reactive as well as the non-reactive, and discuss the respective roles of chemical reactivity on the one hand and electrostatic interaction between electrically polarized structures on both the tip and the surface on the other hand. On the partially oxidized silicon surface, the oxygen

atoms form stable structures by incorporating into the backbonds of an Si adatom (see, e.g., [3]). A characteristic pattern arises for maxima of the attractive force when different tips are used to probe this surface. The total force can be expressed as a sum of a component for which the ratio between clean Si and oxidized sites is constant (tip-independent) and an other component, which is almost tip-independent as for its absolute value but which is present only on the oxidized sites. We attribute this observation to simultaneous presence of two distinct mechanisms of interaction. Again, we use DFT calculation to understand the origin of this interactions and we will discuss its implications for the chemical resolution method introduced in [1].

For a fundamental understanding of local electrical and chemical processes in electronic materials and composite structures, advanced microscopy tools are indispensable. Chemical and structural properties, as well as free charge carriers can be studied by optical spectroscopy methods. Particularly in the infrared spectral range the identification of characteristic molecular and phononic absorption bands allows for a detailed characterization of materials. Also the Drude contribution of free charges can affect the optical properties in infrared range. However, most established infrared characterization methods lack in spatial resolution due to the diffraction limit of propagating waves.

In scattering-type scanning near-field optical microscopy (s-SNOM) the diffraction limit is circumvented by using a sharp probe as a local scatterer [1]. The evanescent fields at the apex of this tip allow for an optical sample characterization with a wavelength-independent resolution in the order of the tip radius (20 nm). Since the scattering efficiency of the tip-sample system depends on the dielectric function of the involved materials and on their geometric arrangement, regions with different optical properties can be distinguished in s-SNOM.

In this contribution, we demonstrate the capability of s-SNOM to investigate the local density of free electrons in Si-doped InAs nanowires grown by selective-area metalorganic vapor phase epitaxy (SA-MOVPE) [2]. The method of s-SNOM is highly sensitive to variations in the sample permittivity around $\epsilon(\omega) \approx -2$ [3]. The use of tunable

mid-infrared lasers therefore allows addressing the plasma frequency of free charge carriers in highly doped nanowires [4]. We demonstrate that the sensitivity of s-SNOM is sufficient to detect a slight unintended variation in the carrier concentration during the growth process. In Fig. 1, the optical scattering amplitude is shown in color, together with the topography of a nanowire. The modulation in the scattering intensity reveals an inhomogeneity in the density of free charge carriers. Using model calculations, the actual local density of free electrons can be estimated.

Microarray technology have been developed in order to analyze tens of thousands genes in a single experiment. However, it suffers from various limitations, such as the need for fluorescent labels and optical detection methods, insufficient sensitivity, narrow dynamic range, and non-specific or cross-hybridization. The complete process of sample preparation and measurement is complex and lengthy. Recently, nanopore/nanochannel technology has been proposed for biosensing and genome analysis as a low cost, fast processing and high throughput alternative to microarrays, thanks to the great potentiality of this kind of devices for label-free single molecule analysis and sensing [1]. In this context, we developed a low cost polymeric nanochannel device by using a Focused Ion Beam (FIB) to fabricate a nanometric channel on a pre-patterned silicon master and replicating the structures in a polymeric material by means of soft lithography. The layout of the device is shown in figure 1a: two microchannels are connected by a single nanochannel and two electrodes (yellow) allow applying the voltage and collecting the ionic current. The sensing principle is based on transient interruptions in the ionic current induced by the passage of DNA inside the channel. We show results on single DNA molecule detection [2], demonstrating that, thanks to the elastomeric properties of the used material (PDMS) it is possible to reversibly tune the dimension of the nanochannel by applying a mechanical pressure on the top of the device (figure 1b). This results in the possibility to change in a controlled way the actual detection capabilities of the device [3]. Figure 1c shows a plot of the DNA translocation time across the nanochannel in function of the applied compression of the polymeric device. By increasing the compression, the translocation time increases, demonstrating the possibility to slow down the DNA passage. This simple and low cost method can be coupled with different sensing techniques, is applicable in many research fields (DNA

detection and manipulation) and is promising for further development in sequencing technology. Finally we also show the effects of chemical functionalization of the nanochannel polymer surface, thus opening up a range of possible applications in the fields of bioanalytics and molecular diagnosis.

Friction : Bridging the Nano-to-Microscale with Microfabricated Plates

T10 Nanoscience and Technology

#NST-3-Or-1

S. O'shea, X. Tang, Y. Loke, P. Lu.

IMRE - Singapore (Singapore).

We show results for the sliding of microfabricated (MEMS) structures called “sleds”. The sleds consist of microfabricated Silicon plates with three sharp tips which rest on a surface to form a 3-point contact (Fig. 1a).

We present a new AFM based approach (Fig. 1b) for measuring the friction of such free standing MEMS structures. An AFM tip is brought into contact with a sled resting on a substrate and then, provided the AFM tip does not slide on the sled, the twisting of the AFM cantilever is used to measure the friction of the underlying sled-substrate interface. The method measures nano-Newton to micro-Newton forces and provides a means to measure friction of macroscopic structures at low load.

Another objective is to make the sleds move under user-controlled friction, similar to electrically actuated superlubricity demonstrated using AFM [1] i.e. to induce mechanical conditions at the point contacts such that sliding occurs. Results showing controllable actuation of the sled motion will be shown. The natural resonance frequencies of a free sled, which are proposed as the driving frequencies for actuation, are modelling and compared to vibrometer data.

Using the MEMS sled approach, we envisage studying macroscopic MEMS devices which are controlled by single asperity, nanoscale phenomena.

Electronic transport in multiwalled carbon nanotubes

T10 Nanoscience and Technology

#NST/SS-5-Or-4

M. Ahlskog¹, D. Mtsuko¹, A. Koshio², M. Yudasaka², S. Iijima².

¹University of Jyväskylä - Jyväskylä (Finland), ²NEC Research Center - Tsukuba (Japan).

We have measured the low temperature transport properties of single multiwalled carbon nanotubes (MWNT) of diameters (D) in the range 2-10 nm, see fig. 1. Almost all previous work on MWNT's has been on tubes with diameters above 10 nm. In nearly all samples in this work, with $D < 10$ nm, the gate dependent conductance (fig. 2) exhibits a gap whose size increases with the inverse tube diameter and increasing electrode separation. This so called transport gap is attributed, based on the experimental findings, on a combination of localization effects and narrow diameter induced gaps in the electronic band structure.

These results have significant similarities to the current research on graphene nanoribbons (GNR). As graphene does not intrinsically possess a bandgap, GNR's are fabricated, where a gap is created via quantum confinement due to the narrow width of the channel/nanoribbon. The size of the gap is then roughly in a similar inverse relation with the width of the constriction as in the case of the diameter dependence of the MWNT's in our work.

The transport gap has not generally been observed in the previous works on MWNT's because of the large diameters of the tubes in these. Our work, of which some early results were published previously [1], complements and bridges previous works on both single walled nanotubes and MWNT's, and also to the field of GNR's.

The Relation between AFM-Tip Water Bridge Dimensions and Pull-off Force Measurements under Ambient Conditions

T10 Nanoscience and Technology

#NST-5-Or-5

M. Bartošík¹, L. Kormoš², L. Flajšman², Z. Lišková², R. Kalousek¹, D. Škoda¹, M. Konečný², T. Šikola¹.

¹CEITEC BUT, Brno University of Technology, Technická 2, 616 69 Brno, Czech Republic - Brno (Czech republic), ²Institute of Physical Engineering, University of Technology Brno, Faculty of Mechanical Engineering, Technická 2, 616 69 Brno - Brno (Czech republic).

The atomic force microscopy (AFM) is often performed in ambient conditions where the water condenses between a hydrophilic tip and a sample and affects the tip-surface forces and consequently the whole measurement. Moreover, there are a few AFM-lithography techniques utilizing the existence of such a water bridge. The most famous are dip-pen nanolithography (DPN) and local anodic oxidation (LAO). Despite of its relative simplicity, both of these methods are capable of providing features down to 10 nm. Such a high resolution results from the restriction of chemical reactions to an area of tens nanometers determined by the dimensions of the water bridge. Because of these reasons, the information about the amount of water trapped under the tip is very useful for interpretation of topography measurements, improving the mentioned AFM-lithography techniques and determination of local hydrophilicity/hydrophobicity of the sample.

Here we report on the influence of relative humidity on the pull-off force between a silicon AFM tip- and a SiO₂ surface under ambient conditions. Furthermore, the influence of the shape, radius and chemical treatment of the tip on this force was studied as well. The pull-off forces are determined from force-distance spectroscopy measurements performed at many sites forming a n-by-n matrix. The humidity was controlled by a home-built computer operated system installed in a glove box. In addition to the experiments on pull-off forces the corresponding numerical simulation

was carried out as well. This simulation was based on the solution of Kelvin's equation for water meniscus at boundary conditions determined by the contact angles (surface-water, tip-water) and provided capillary, tension and van der Waals forces.

In the contribution the experimental and theoretical results will be compared. They will be discussed with respect to those obtained previously [1] and to the calculations of pull-off forces carried out by other groups using both the molecular lattice-gas model in Monte Carlo (MC) simulations and density functional theory (DFT). It has been found that the best agreement between the experiment and simulations has been obtained if the dependence of surface tension on the dimension of the meniscus is assumed. The experimental improvement of reproducibility of pull-off force measurements up to 2% has been achieved and will be discussed as well.

Growth of Nano sized Bismuth Oxy Chloride on Carbon Nano Tubes.

T10 Nanoscience and Technology

#NST-P2-13

P. Jagdale, I. Shazad, A. Tagliaferro.

Department of Applied Science and Technology (DISAT), Politecnico di Torino, 10129, Italy. - Torino (Italy).

We report for the first time the growth of nano sized Bismuth oxy chloride (BiOCl) platelets on Carbon Nanotubes (CNTs), achieved by Metal Organic Chemical Vapour Deposition (MOCVD) (Figure 1). This method allows the deposition of thin metallic layers with precisely controlled thickness. Nano sized bismuth (NBs) crystals were synthesized from solution containing Bismuth chloride (BiCl_3) in Acetone ($\text{CH}_3\text{-CO-CH}_3$). Self assembly of nano bismuth crystals was observed on the CNT surface. Various synthesis parameters were investigated to achieve better depositions, as they significantly affect the formation of nano-crystalline bismuth [1]. Crystalline NBs was characterized by X-ray diffraction (XRD), Field emission scanning electron microscopy (FESEM), Energy-dispersive X-ray spectroscopy (EDS). These analyses confirm the Bismuth nanometer-sized platelets are in the form of tetragonal BiOCl with a mean wall thickness similar to the diameter of CNT i.e 80–90 nm (Figure 2).

In electronic devices, it is expected that the quantum limit will soon be reached with decreasing system size. Therefore, manipulating quantum information appears as a new challenge. Solid state Qubits based on superconducting Josephson junction (JJ) are promising systems which take advantage of microelectronics technology. However, decoherence time of the quantum states is still a limiting factor. This has been generally ascribed to the poor crystallographic quality of the materials used so far (crystallographic defects, impurities). We will show that the Molecular Beam Epitaxy (MBE) technique may be used to grow rhenium films of high quality on sapphire substrates. Indeed, alumina- α and rhenium may be in good crystallographic registry when Re is epitaxied on the (0001)-C plane. The growth temperature is the key parameter, as it controls the epitaxial quality. As already shown by Oh [1], a good crystallographic structure is obtained when growth is performed at a temperature above 800°C. We will present how to improve the homogeneity of the film temperature and how to reduce the thickness dependence of the temperature during the deposition. Also it will be shown that different kinds of surface structures may be observed by Atomic Force Microscopy (AFM) and Scanning Tunneling Microscopy (STM) depending on the temperature and the thickness. For thicknesses ranging from 25 nm to 100 nm and temperatures ranging from 800°C to 1000°C, we observe different growth dynamics, involving nano-grains, single and double spirals (Fig. 1). These growth regimes may be explained as an extension of the Burton, Cabrera and Frank theory (BCF) [2], which was developed long time ago for equilibrium growth. We have also investigated the crystallographic quality of our samples by X-ray diffraction and Electron Back Scattering Diffraction. Our heating optimization has increased the quality of our films that are epitaxied and without any variants. Preliminary results have shown that single crystal Al_2O_3 barriers and Re layers may subsequently be grown in order to build a complete epitaxial tri-layer JJ.

Free several-nanometer-sized nanoparticles are mechanical nanoresonators with frequencies in the terahertz range. They have potential applications in nanoelectromechanical systems provided their quality factor is high enough, *i.e.*, if these vibrations are only lightly-damped by the surrounding medium. In this work, we investigated a powder of ZrO₂ nanoparticles whose diameter is about 5 nm under high pressure up to 20 GPa [1]. The terahertz acoustic vibrations confined within the nanoparticles are observed using low-frequency Raman scattering. The propagation of acoustic waves through the compressed nanopowder (wavelength large compared to the diameter of the nanoparticles) is observed using Brillouin scattering. This study shows that the nanoparticles oscillate almost as if they were free in the highly-compressed nanopowder despite the high applied pressure. This is attributed at least in part to a few monolayers of water molecules adsorbed at the surface of the nanoparticles which act as an isolation layer if the layer thickness is in the right range. To corroborate this, we demonstrate theoretically that lightly-damped acoustic vibrations of nanoparticles are possible in this system. A quasielastic signal is also evidenced from the high-pressure and low-temperature low-frequency Raman spectra. In addition, the two phase transitions of ZrO₂ as pressure is increased result in a modification of the low-frequency spectra which we attribute to the change in the ionicity/covalency of the Zr-O bonds with pressure.

New one-pot synthesis of Au or Ag nanoparticles supported on reactive Fe(II)-bearing inorganic particles

T10 Nanoscience and Technology

#NST-10-Or-9

S. Ayadi, L. Legrand.

LAMBE UMR8587 - Evry (France).

Nanoparticles of noble-metals or nanohybrids incorporating nanoparticles exhibit unique optical, chemical and catalytic properties which make them attractive for a wide range of applications in many domains. Nanoparticles are commonly prepared via reducing a soluble metal precursor (Au^{III} or Ag^{I}) by a soluble reducing agent in presence of a stabilizing species to keep them from aggregation [1-2]. In the present communication, we report a new, simple and fast one-pot synthesis of supported Au or Ag nanoparticles by using a reactive inorganic particle (green rust GR = layered $\text{Fe}^{\text{II}}\text{-Fe}^{\text{III}}$ HydroxyCarbonate (GRc) or HydroxySulfate (GRs)) as both the reducing agent and the support. The mechanism involves the solid-state oxidation of Fe^{II} to Fe^{III} in GR [3] and the reduction-precipitation of soluble metal precursor to metal nanoparticles on the surface (Figure 1). All reactions were proved to be complete and metal load vary between 0 and the maximal theoretical (i.e 25% for Au/exGRs). The resulting nanohybrids were characterized by XRD, FTIR and SEM. The inorganic particles keep the platelet morphology of the GR precursor and they support about 1 to 10 metal nanoparticles with a diameter in the 20-120 nm range (Figure 2). With only one final separation step, the synthesis of our nanohybrids is very attractive. Their manipulation is easy and relatively safe since mineral-types iron compounds are generally fully biocompatible and metal nanoparticles are well attached to the inorganic matrices. The surface of inorganic and/or metal parts can be functionalized to target specific properties. The nanohybrids can be compacted or cast-deposited to build permeable reactive membranes or modified (bio-) electrodes.

Self-assembly of organic molecules and bioinspired nanofabrication based on adhesive effect of climbing plant

T10 Nanoscience and Technology

#NST-8-Or-5

W. Deng.

South China University of Technology - Guangzhou (China).

We synthesized and confirmed a series of fluorenone derivatives and used scanning tunneling microscope (STM) to observe these prepared compounds assembled onto HOPG surfaces to form self-assembly monolayers. We especially investigated that those factors such as molecular structure, van der Waals force, dipole-dipole interaction, hydrogen bond, as well as solvent molecule and concentration how to affect assembled structures [1 – 3]. Understanding the super adhesion mechanism of biological system is of great scientific interests and a prerequisite for bioinspired design of adhesive systems. We presented strategies to fully study the super adhesive effect of climbing plant – *Parthenocissus tricuspidata* by measuring the mass, attached area, microscopic structure and adhesive strength of single adhesive disc. Microscopic experiments showed some new microstructures which have never been reported and revealed that the adhesive disc has super adhesive property which inspires us to fabricate a lot of mimic adhesives that have potential applications in biomedical science, bioelectronics and space science and technology [4]. We found that there are more than 20 kinds of organic compounds in adhesive disc and we used polystyrene (PS) to fabricate biomimetic surface structure of the adhesive disc and measured its adhesive force using AFM [5,6]. This template-assisted method provides a new means to prepare the macropores of other soluble polymers in future.

Insights to the interaction between single-stranded DNA and single-walled carbon nanotubes

T10 Nanoscience and Technology

#NST/SS-5-Or-5

S. Srebnik.

Technion - Israel Institute of Technology - Haifa (Israel).

Single-walled carbon nanotubes (SWNTs) have received vast attention over the years due to their unique electronic, mechanical and optical properties. SWNTs are characterized by chiral indices that largely define their geometric and electronic properties (i.e., metallic or semi-conducting). Recent works has focused on single-stranded (ss) DNA-SWNT complexes as a means for separation of SWNTs according to chirality, where outstandingly it was shown that designed ssDNA sequences could be used to separate particular chiral SWNTs. We present small angle neutron scattering (SANS) measurements of some ssDNA-SWNT complexes and use atomistic and coarse-grained simulations to provide insights to this unique registry between the two macromolecules.

Features of the magnetization reversal mechanisms in the magnetoresistive response of magnetic nanostructures

T10 Nanoscience and Technology

#NST/SS-4-Or-3

P. Perna¹, D. Maccariello¹, C. Rodrigo¹, M. Muñoz², J.L. Prieto³, A. Bollero¹, J.L.F. Cuñado⁴, M. Niño¹, C. Navio¹, N. Mikuszeit¹, J. Camarero¹, R. Miranda¹.

¹IMDEA-NANOSCIENCE - Madrid (Spain), ²Instituto de Física Aplicada, CSIC - Madrid (Spain), ³ISOM, Universidad Politécnica de Madrid - Madrid (Spain), ⁴DFMC, Universidad Autónoma de Madrid - Madrid (Spain).

Magnetoresistive effects and related phenomena in magnetic nanostructures have found widespread applications in magnetic sensing and recording technologies [1]. Even though it is commonly assumed that the magnetoresistance (MR) depends on the magnetic anisotropy, the direct proof that the magnetoresistive responses are directly related to the magnetization reversal processes is still lacking. In fact, experiments just relies in either magnetization (usually parallel component) or MR curves measured independently for a given applied field angle, normally close to the easy axis (e.a.) direction.

Here, we present a systematic angular-dependent studies on magnetization reversal processes and magnetoresistive responses of nanostructured magnetic systems, including ferromagnetic thin film with well-defined magnetic anisotropy, exchange-biased spin valve [2] and hybrid metal-organic heterostructures.

To do that, we have employed a new experimental set-up that allows us to measure simultaneously magneto-resistance and vectorial-resolved Kerr [3] hysteresis loops, i.e., including in-plane parallel and perpendicular magnetization components [4] and MR, at different applied field angles in the whole angular range. We advance towards a microscopic understanding of the MR properties by showing that their angular dependence leaves distinct fingerprints, which are directly related to their magnetization reversal processes [3].

In the case of FM thin films with defined uniaxial magnetic anisotropy, the dependences with the applied magnetic field and current direction with respect to the anisotropy axis were investigated. The data show that the anisotropic

magnetoresistance (AMR) is dictated by different magnetization reversal processes and provide the direct experimental evidence that the magnetoresistance response depends on the square of the cosine of the angle between the sample magnetization and the direction of the applied current. In the case of spin valve, well-defined MR-plateaus are observed around the e.a. direction whereas just reversible MR transitions are found around the hard axis (h.a.) direction. The MR-plateau value decreases as the magnetic field is misaligned with respect to the e.a. and the maximum of MR decreases approaching the h.a.

The results directly show that the different magneto-resistive behaviors originate from the magnetic anisotropy of the structure, which ultimately depends on the relative magnetization orientation of the FM layers. In particular, the M-H curves give the relevant information about the magnetization reversal processes and lead the direct determination of the magnetization direction during the hysteresis loop. The magnitude and shape of MR(H) are controlled by the orientations of the applied field and current with the magnetic anisotropy axis.

NST-P1-16

Nanoscale Si/Ge heterostructures prepared by glancing angle deposition

T10 Nanoscience and Technology

#NST-P1-16

C. Grüner, J. Bauer, B. Rauschenbach.

Leibniz Institute of Surface Modification (IOM), Permoserstr. 15, 04318, Leipzig, Germany - Leipzig (Germany).

Free-standing, separated nanoscale structures such as slanted and vertical columns, spirals and zig-zags are of growing interest for many possible applications. In the so-called glancing angle deposition (GLAD) process, contrary to usual PVD thin film deposition, the particle flux reaches the surface under a highly oblique angle. Under these circumstances, self-shadowing processes at the substrate surface lead to the growth of separated needles, inclined towards the particle source. Combined with suitable substrate rotation, this method offers a full three-dimensional control of the nanostructures shape in a bottom-up process with additional capability of self-alignment (details see [1,2]).

For the use of GLAD structures in technical applications, it is necessary to obtain control over the shape of the individual nanostructures, the distribution of the materials inside heterostructures, and the arrangement of the structures on the substrate. Therefore one needs to understand the growth process and the influence of the different process parameters.

Here the GLAD induced growth of Si/Ge hetero nanostructures for different substrate circumstances will be compared, and the influence of pattern periodicity on shape and diameter evolution of the growing structures will be discussed. A fast and geometrically accurate computer simulation is used to support the investigation (see figure).

The growth of the nanostructures is further studied in dependence of substrate temperature, rotation, and deposition rate using scanning electron microscopy, high-resolution transmission electron microscopy, X-ray diffraction and Raman spectroscopy.

Since glancing angle deposition provides a wide nanoscale control over structure, grain orientation and doping characteristics, the mechanical, optical, electrical and magnetic properties of the sculptured thin films may be engineered for various applications.

Synthesis, Characterization and Anti-bacterial Investigation of Silver-Copper Nanoalloys

T10 Nanoscience and Technology

#NST-9-Or-5

M. Taner Camci, N. Sayar, I. Yulug, S. Suzer.

BILKENT UNIVERSITY - Ankara (Turkey).

Silver and copper nanoalloys have been synthesized and incorporated into ultra-thin layers using the layer-by-layer technique for antibacterial applications. Films with Ag-only and AgCu nanoalloys have been tested against Escherichia coli strains to assess their anti-bacterial behavior. No bacteria colony growth was observed as the evidence for superior anti-microbial characteristics of these films with AgCu nanoalloys.(1) These thin films have been characterized using Optical (UV-visible) and X-ray Photoelectron Spectroscopy (XPS). In order to get further understanding at the molecular level, these films were also analyzed while applying square wave electrical pulses during recording of their XPS data. Our experimental details and results will be presented.

Electric double-layer capacitors having nanostructured electrodes

T10 Nanoscience and Technology

#NST-2-Or-7

K. Fujiwara, M. Omiya.

Keio University - Yokohama (Japan).

Electric double-layer capacitors having ultra capacity are expected to be used instead of secondary batteries. Electric energy storage in electric double-layer capacitors occurs by the formation of electric double-layers on the surfaces of both negative and positive electrodes. In this study, we aimed to increase the capacitance of electric double layer capacitors by increasing the surface area of electrodes and the amount of charge on the surface by fabricating nanostructures on them.

Nanostructures are the structures made on a scale of nanometers and prepared by using Dynamic oblique deposition. Dynamic oblique deposition (DOD), in which the deposition angle and in-plane direction of a substrate are varied during deposition, enables us to fabricate nanostructured thin films. This method exploits the atomic self-shadowing effect during physical vapor deposition that arises from deposition at a highly oblique angle.

We fabricated capacitor electrodes which have 200 nm base layer of Au by sputtering and 200 nm nanostructured layer of Cu by using DOD on a glass substrate (20mm × 20mm × 0.7mm). Capacitors were fabricated by laminating polymer electrolyte thin film between electrodes by thermocompression bonding (Temperature:400K, Pressure:0.15MPa, Time:30min). In the same way, capacitors having electrodes without nanostructured layer were fabricated for comparison.

We analyzed the capacitance per unit volume of these capacitors by measuring the Cole-Cole plot using a LCR meter, and fitting equivalent circuit and their results. The electric double layer capacitance of the capacitor having electrodes without nanostructured layer which is measured in 1.5M NaOH solution is $C_1=2.2\text{F}/\text{cm}^3$ and $C_2=1.4\text{F}/\text{cm}^3$. Furthermore, the electric double layer capacitance of the capacitor having electrodes with nanostructured layer which is measured in 1.5M NaOH Solution is $C_1=24\text{F}/\text{cm}^3$ and $C_2=6.8\text{F}/\text{cm}^3$. From these results, the capacitance increase 10 times by fabricating nanostructures on the surface of capacitor electrodes.

The capacitor having electrodes with nanostructured layer contains 0.7mm thick glass substrates and 0.5mm thick separator. Therefore, the capacitance of whole of

the capacitor is approximately 30.8F ($C_1 + C_2$) in size 1cm×1cm×2.19cm. Then, the capacitance per unit volume is 14F/cm³. This capacitance is 5.8 times that of conventional coin type electric double layer capacitors, which has 2.4 F/cm³.

¹ISSP RAS - Chernogolovka (Russian federation), ²Institut des Nano-Sciences de Paris - Paris (France).

The electron growth (EG) model based on quantum size effect was proposed to explain the nature of metallic film growth. In a frame of EG model the total energy balance of a thin film also takes into account the energy of the electron gas. The electron gas is considered as confined in a two-dimensional quantum well (QW) its width d being of the film thickness. At small d comparable with electron wavelength the total energy of electron gas oscillates as a function of d . The oscillations period is determined by electron momentum at the Fermi level. Due to a difference between crystal lattice translational vectors of the film and oscillation period, minimum in energy of the electron system can be realized at certain film thicknesses only. The EG model was confirmed in experiments on growth of Pb thin films. Individual Pb islands grow following so-called bi-layer growth: the island height increases by "steps" of 2 mono layers (ML). Statistically, the islands with odd number of MLs are predominant while the islands of 7ML thickness are markedly privileged. Further increase of the island thickness resulted in a stratification of the islands with a slabs of 7ML in thick. DFT simulations argue that the observed growth mode is in good agreement with EG.

NST-1-Or-8

Evolution of MWCNT-polymer composite field emitter characteristics

T10 Nanoscience and Technology

#NST-1-Or-8

A. Kolosko, E.O. Popov, S.V. Filippov, M.V. Ershov.

A.F.Ioffe Physical-Technical Institute of the Russian Academy of Sciences - St.-Petersburg (Russian federation).

Today, recording and processing of current-voltage characteristics (IVC) constitute a basic tool in the study of the materials promising as efficient field emitters. The computerized data acquisition systems used for these purposes are very effective [1]. Application of multichannel recording and computer IVC processing has advantages when studying field emitter operation. This allows better understanding of IVC dynamics and their correlation with the other emission phenomena [2].

We succeeded in developing the technique of multichannel record and on-line data on the field emitter evolution processing. It includes multichannel data acquisition system of current, voltage, vacuum level, temperature and computer on-line processing of these data performed by own LabView program. The program obtains the field enhancement factor (β) and the number of emission sites (N) time dependences and built the slope-interception diagram (in SK-coordinates [3]). The field emission experiments were carried out in standard construction with flat metal electrodes. For obtaining IVC the high-voltage power unit with frequency 50 Hz was used. Electronic rectifier made positive impulses with duration 10 ms and consequently one such half-sinusoidal impulse gave one IVC.

In the present paper some data obtained in the study of nanocomposite field emitters NC-MWCNT (nitrocellulose - multiwall carbon nanotubes) are given. We use certificated Graphistrength nanotubes by Arkema (with diameter 15 nm).

We obtained IVC emitter evolution with a discrete change of interelectrode gap from 450 to 900 μm . The maximum current value at impulses (I_{max}) was supported by a constant ~ 1.5 mA. The IVC curves in Fowler-Nordheim coordinates shifted to high voltages and their slope angle increased. The corresponding β and N varied asynchronously: β decreased and N grew up.

A consequent I_{max} step change at different interelectrode gaps gave a family of almost linear dependences in SK-coordinates (Fig.1). If the interelectrode gap exceeded 500 μm , the dependences showed the hysteresis. We explained this effect by contribution of thermal field emission from Joule overheated nanotubes

which supported by continuous growth of current loading on one MWCNT (I_{max}/N).
Work is supported by grant N 12-08-31406 of Russian Foundation for Basic Research.

We report the experimental observation of vortices on the surface of a 50nm-thick layer of Cu in the hybrid structure Cu/Nb with ultra-low temperature Scanning Tunneling Spectroscopy (STS). In the studied samples the non-superconducting Cu-layer acquires superconducting correlations due to the proximity effect with 100nm-thick superconducting Nb. To avoid the oxidation at Cu-surface and allow STS, the samples were ex-situ grown on SiO₂/Si in the inversed order, i.e. Cu was deposited directly on the substrate, Nb was deposited on Cu. The samples were then introduced to the UHV STM chamber and cleaved in-situ. The structural analysis showed that, upon cleavage, the samples break at Cu-SiO₂ interface, thus exposing fresh Cu surface.

The presence of the proximity effect at the surface of Cu was first evidenced by observation of a proximity gap in the tunneling conductance spectra $dI(V)/dV$, in clear relation to the value of the superconducting gap of bulk Nb. The evolution of the proximity spectra with temperature was also studied in the range (0.3-4.2) K (Fig. e). Upon application of an external magnetic field, spatial variations of the tunneling conductance spectra were observed (see Fig. a,b,c). These variations appear in the detailed STS maps as round nm-size spots, in the centers of which the proximity gap vanishes. The density of spots rises continuously with magnetic field; it corresponds

perfectly to the expected density of Abrikosov vortices in Nb. We identify the observed spots as proximity induced vortices in the normal Cu. On the basis of our STS data, we have determined the size and shape of the proximity vortex cores, and evaluated the coherence length in Cu. Independent numerical calculations of the quasiparticle spectra in S-N hybrids within the Usadel equation formalism were performed and found in agreement with experimental findings.

a-c) STS tunneling conductance maps acquired at 0.3K on Cu-surface of Cu/Nb (50/100nm) at different values of the magnetic field: a) $B = 0.005$ mT. b) $B = 0.05$ mT. c) $B = 0.1$ mT. d) Typical topographic STM image of the sample surface; the green line shows the location where the cross-section plotted on the bottom graph was acquired. e) Temperature dependence of the tunneling conductance spectra at zero-field.

E. Vishnyakova ¹, A. Romanchenko ¹, S. Saikova ², M. Likhatski ¹, Y. Mikhlin ¹.

¹Institute of chemistry and chemical technology - Krasnoyarsk (Russian federation), ²Siberian Federal University - Krasnoyarsk (Russian federation).

The properties of silver nanoparticles, which determine many of their applications and dramatically depend on the synthetic protocols, particle size and shape, stabilizing agents, support, and so on, are widely explored at the solid-gas interface but are poorly understood for the nanoparticles contacting aqueous solution. We have studied the electrochemical reactions and antibacterial activity of “bare” silver nanoparticles (5 nm and 15 nm) obtained via wet chemical reduction with sodium borohydride, and Ag NPs with stabilizing adlayers produced with glucose or sodium borohydride in presence of sodium citrate. It was found using X-ray photoelectron spectroscopy (XPS) and cyclic voltammetry that small “bare” Ag NPs immobilized on highly oriented pyrolytic graphite (HOPG) completely oxidized to silver oxides in the positive-going potential sweep in 1 M NaOH, while only surface layers of the larger particles transformed to oxide phases. Ag NPs prepared with L-glucose and sodium borohydride in presence of sodium citrate were surprisingly resistant to oxidation, including the anodic polarization in alkaline solutions and oxidation in air. We found a direct correlation between affinity of Ag NPs to oxidation and the content of oxygen exhibiting O 1s line at 530.8 eV (Fig.1) that is commonly associated with an oxygen species incorporated in silver lattice (O_{β}) [1]. There are evidences that the formation of O_{β} is a necessary stage preceding oxidation of Ag to Ag_2O .

O_{β} is expected to diffuse over a shell of the big Ag NPs but the whole smaller particles, determining their reactivity. Glucose and citrate ions, however, react with O_{β} species or their precursors preventing penetration of O_{β} both into small (~4 nm, according to SAXS and TEM) and large (~9 nm) Ag cores, making them oxidation-

resistive. The effect of oxygen on the antibacterial activity of the Ag NPs is less clear, probably because the organic ligands promote silver dissolution.

Lithium Ion Batteries (LIBs) are now widely used in portable equipments such as cell phones, computers and in recent automotive, including hybrid and electric vehicles, because of their high energy densities and flexible design [1]. However graphite, often used commercial anode, is reaching a limit and cannot meet the increasing energy density requirements due to a limited theoretical capacity (372 mA.h.^{-1}) [2]. Nanometric silicon is a promising anode material for LIBs and offers one of the highest theoretical capacity (up to 4200 mA.h.g^{-1}) and a low discharge potential relative to Li^+/Li (below 0.5V) [3]. Yet large volume change in silicon (300 %) during lithiation and delithiation process induces poor cycle stability and rapid capacity fading. Moreover, electrical percolation must be ensured into the silicon electrode.

By reducing the particle size to nanometric level, the effect of volume change may be controlled which improves the performance of the electrode in terms of both life and rate capability. Furthermore, silicon materials in a matrix of carbon attract great interest because of the good electrical conductivity and stress-buffer nature of the carbon. The laser pyrolysis appears to be an ideal tool using gaseous precursors as silane and ethylene. A two stages reactor has been developed to allow the one-step production of nanosized core-shell particles: the nanometric silicon is synthesized at the first stage and the carbon coating at the second stage. The process allows a control on the morphology and growth of the silicon core and the carbon shell by adjusting parameters such as the precursors flow, the reactor pressure and the laser

power. The first results show an increase in both life and rate capability of LIBs thanks to the carbon shell (no degradation after 350 cycles at $1000 \text{ mA}\cdot\text{h}\cdot\text{g}^{-1}$).

Owing to their high stability, nontoxicity and optical properties, titanium dioxide (TiO₂) nanoparticles attract a great interest since several years for applications such as self-cleaning windows, anti-bacterial coating and waste water purification[1,2]. These photocatalytic applications require photocatalysts with high efficiency. To enhance it, metallic ions such as Au can be added to TiO₂. In fact, gold nanoparticles supported in titania improve photocatalytic electron transfer thanks to their absorption under visible light irradiation. This is attributed to the surface plasmon resonance[3]. Photocatalysis mechanism is the following; under UV-Visible illumination, an electron-hole (e⁻/h⁺) pair is created. These electron-hole pairs can then recombine and are lost or be separated which is the efficient way to induce reactions. Holes in the valence band are strong oxidants and the electrons of the conduction band a strong reducing agents. The organic pollutant are oxidized either directly through the holes h⁺, or indirectly by oxidizing agents (radicals) O₂·⁻ / HO₂· generated by the oxidation of water.

Laser pyrolysis[4] appear as a convenient way to prepare various nanoparticles (NPs). This versatile method is used for efficient production of nanoparticles with precise chemical composition, size, cristallinity,... It is based on the interaction of an infrared high power (IR) laser beam with precursors. For TiO₂ synthesis, titanium tetraisopropoxide (TTIP) is used as precursor. It is decomposed in an incandescent flame observed in the laser-precursor interaction zone where NPs nucleate and grow. Their characteristics are really correlated with experimental parameters; in particular the size of the nanoparticles which depends on the residence time in the laser beam controlled by the gas flow rate of reactants. The cristallinity can be

controlled by the reaction temperature in the reaction zone controlled by the laser power. Their chemical composition also depends on the nature of the different reagent in the precursor mixture. In this context, gold or silver precursors were dissolved in the liquid titanium precursor, and droplets of the mixture were carried to the laser using the pyrosol method. We obtained TiO₂ nanocomposite containing gold or silver (Fig.1). They were tested in decomposition of methylene blue, phenol and formic acid. First results are presented there.

Prediction of dimerization enhancement inside dilute alloy nanoparticles induced by the nano-confinement entropic effect

T10 Nanoscience and Technology

#NST-9-Or-7

L. Rubinovich, M. Polak.

Ben-Gurion University - Beer-Sheva (Israel).

Recently, we predicted a unique nano-confinement effect of entropic origin on the equilibrium state of chemical reactions, NCECE [1]. Thus, when a small number of exothermally reacting molecules is confined to a closed nano-space the extent of the equilibrated reaction can shift significantly towards product formation. The greatly enhanced “equilibrium constant” depends on the number of molecules, and for many reactions also on the nano-space size. Then, we demonstrated qualitatively how the effect is manifested in nucleotide dimerization observed previously within molecular cages, and in the extra deuteration commonly observed for molecules reacting on interstellar dust grain surfaces [2]. In the present work we explore the validity of the NCECE in case of reactions involving alloy nanoparticles (NPs) with separation tendency, especially dilute Pd-Ir cuboctahedra (CO). Due to the Pd strong surface segregation tendency in this alloy, Ir atoms are confined exclusively to the particle core, which thus can serve as a nano-space for their possible dimerization. Employing two models for the system energetics (with and without near-surface bond-energy variations [3]), computations of the exact canonical partition function reveal remarkable nano-confinement induced Ir-Ir dimer stabilization within the NPs, reflected, e.g., by doubling of the $\log K$ vs. $1/T$ slope, as compared to the macroscopic thermodynamic limit (TL, Fig. 1). The presentation will be concluded by a brief discussion of the entropic origin of the NCECE effect and introduction of its first quantitative verification based on new analysis of nanoconfined-DNA dimerization data.

NST-9-Or-8

Prediction of size-dependent intra- and inter-particle separation-like phase transitions in nanoalloys: a basis for nanophase diagrams

T10 Nanoscience and Technology

#NST-9-Or-8

M. Polak, L. Rubinovich.

Ben-Gurion University - Beer-Sheva (Israel).

The temperature dependence of site-specific concentrations in equilibrated Pd-Ir cuboctahedron (CO) and truncated octahedron (TO) nanoparticles (NPs) consisting of up to ~1000 atoms is computed by the recently introduced approach for deriving DFT-based coordination dependence of bond-energy variations (CBEV) [1] combined with the highly efficient statistical-mechanical free-energy concentration expansion method (FCEM) [2]. The results reveal sharp intra-core separation-like nanophase transitions (first reported by us for Pt-Ir [3]) from a core-shell structure at low temperatures to almost solid-solution like “phase” at higher temperatures (Fig.1). The transitions, exhibiting critical temperatures significantly lower than the corresponding alloy bulk ones, depend on the NP size and composition (no sharp intra-core transitions were obtained for 309-atom and smaller NPs). Furthermore, convexities in the low-temperature mixing free-energy curves indicate a tendency for inter-particle separation into two equilibrated systems of NPs having different overall compositions and chemical order, which transform at a critical temperature to a uniform system of solid-solution like NPs. The relationship between the two types of separation transitions as well as the role played by preferential strengthening of surface-subsurface inter-layer elemental bonds are elucidated. As demonstrated in Fig.2, the results enabled us to construct for the nanoalloy original intra-particle as well as inter-particle (partial) phase-diagrams.

¹institut jean lamour - Nancy (France), ²Universidade Federal do Paraná - Curitiba (Brazil), ³Université de Yaoundé - Yaoundé (Cameroon).

Recently, atmospheric pressure plasma assisted nanofabrication has shown outstanding capability of promoting self-organization. Plasma-assisted nanofabrication is one of the rapidly emerging methods used for the production of various nanostructured materials and elements of nanodevices. Moreover, nanostructured materials have attracted growing attention due to their unique properties and potential applications.

The possibility to synthesise directly copper oxide nanomaterials with different morphologies has been studied by local oxidation with atmospheric plasma and with atmospheric afterglow. These approaches consist in exposing copper samples in a single treatment step, leading to the synthesis of nanowires, nanowalls, nanoparticles ... with a high level of reproducibility (figure 1).

In this work, we compare results obtained by an Ar – O₂ micro-plasma jet and by an Ar – O₂ micro-afterglow at atmospheric pressure. Their specificities are discussed in detail. This step is followed by a discussion on the role of charge species, temperature and stress on the growth mechanism of nanostructures at atmospheric pressure. Several techniques have been used to analyse the grown structures including Scanning Electron Microscopy, X-Ray Diffraction, Transmission Electron Microscopy and X-ray Photoelectron Spectroscopy.

Ag clusters obtained by the gas-aggregation technique were deposited on the cleavage face NaCl(001). The average size of the nanoparticles was varied in the range from 0.2 to 10 nm and the temperature was varied from room temperature to 470 K. Owing to the mobility of the clusters on the substrate, they coalesced with formation of larger particles, decorating atomic cleavage steps on NaCl(001) already at room temperature. It was shown that the step decoration is possible only when the average size of the deposited clusters is commensurate with the height of the cleavage steps.

NST/SS-P1-04

role of carbon nanotubes in AC-driven CNT-OLEDs

T10 Nanoscience and Technology

#NST/SS-P1-04

S. Yu ¹, S.Y. Jun ¹, B. Won ².

¹Hankuk Univ. of Foreign Studies - Yongin (Korea, republic of),

²Syungkyunkwan Univ. - Suwon (Korea, republic of).

Organic light emitting devices (OLEDs) have been widely investigated these days. There have been numerous researches such as, by modifying the structures of devices, synthesizing new organic materials, and combining zero-, one-, and/or two-dimensional nanostructures. [1] Carbon nanotubes (CNTs), a key material in carbon based nanomaterials, [2] have been examined in organic devices widely. In spite of the fact that the device performances of CNT-organic composite were improved, there have been few remarks on the current [1]. This was caused by the network formation by CNTs which might easily lead to leakage current. Therefore, controlling the properties of CNTs is an important step to reduce the level of the leakage current.

The devices used in this poster were consisted of four layers--a top metal electrode, a dielectric layer, an emitting layer where CNTs were mixed, and a bottom indium tin oxide (ITO) electrode. Cyanoethyl pullulan (CRS), as a dielectric material, was coated on the ITO-coated glass. poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) was used as an emitting material. CNTs were shortened by the mechanical method. [3] CNTs were mixed with MEH-PPV to be a CNT-polymer composite by varying the CNT concentration (0.03, 0.06, and 0.15wt%). A reference sample (an OLED without CNTs) was fabricated for comparison.

The brightness of the CNT-OLEDs was higher than the reference one. The turn-on of CNT-OLEDs were found to be around 20~30 V, which was obtained by reducing the current roughly 50%, especially for 0.03wt% case. (The data are not shown here.) The enhancement in the brightness of CNT-OLEDs shown in Fig. 1 could be explained by the microcapacitor effects. [4] This effect might increase the total impedance of devices by addition of capacitive reactance originated from numerous CNTs within the emitting layer. Due to AC driving, the capacitive reactance might contribute to the total impedance of the devices. Impedance analysis

was currently under progress and the results will be also presented at the conference.

Cancer treatments imply the destruction of tumor cells. Traditional methods such as chemotherapy or radiotherapy [1] are actually widely used. However, these methods suffer from several drawbacks. These treatments are usually not specific to tumor cells and may also affect healthy cells. Consequently, they can subsequently increase postoperative delays. Therefore, researchers are working on alternative treatments to improve the patient's recovery.

Magnetic hyperthermia is a biomedical process that relies on external magnetic fields [2]. The aim is to increase the temperature of tumor cells in order to stop their development and to destroy them. In this work, we provide our first in-vitro results with silver nanoparticles. The main objective is the validation of the process (fig. 1) to obtain such nanoparticles (fig. 2) and to measure the thermal effects when particles are exposed to a specific magnetic field. Silver nanoparticles are a good candidate because of their toxicity in regard to the synthesis of ATP [3] of tumor cells.

Experimental results are provided to demonstrate that the temperature of the silver nanoparticles reaches 33-35 Celsius degrees, which seems compatible with a biological application. The magnetic field is about 15mT with a frequency of 206kHz.

Exploring what holds paper together: An AFM based nanomechanical investigation of single cellulose fibers and fiber-fiber bonds

T10 Nanoscience and Technology

#NST-3-Or-2

C. Teichert ¹, C. Ganser ¹, F.J. Schmied ¹, W. Fischer ², U. Hirn ², R. Schennach ².

¹University of Leoben - Leoben (Austria), ²Graz University of Technology - Graz (Austria).

Although paper is already known for hundreds of years, the process of bonding two cellulose fibers together is still an open discussion. However, the strength of these bonds is what primarily determines paper strength.

Here, we employ a recently developed method based on conventional atomic force microscopy (AFM) technique to measure the joint strength in z-direction between individual cellulose fibers [1]. Besides this single quantity, the behavior prior to the failure is analyzed in force vs. distance plots. Further, the fracture surface is recorded by conventional AFM scanning and its morphology is correlated to the breaking behavior. This comprehensive combination reveals new insights into the mechanisms of fiber-fiber bonding and their contribution to the fiber-fiber bond. Clear indications for mechanical interlocks or fibril bridges acting as interlocking elements between the individual fibers are recognized. With this technique the influence of fiber treatment is explored. Fiber-fiber bonds – made from differently beaten pulp - are investigated. Also, fiber-fiber bonds – established from regenerated fibers – are tested to obtain data from more defined surface structures and simpler chemical composition.

Dynamically loading of the bond allowed the estimation of elastic energy contributions into the single fiber-fiber bond. Further, statically loading is suitable to study time dependent behavior, such as creep and relaxation in the fiber-fiber bond system as well as the determination of the visco-elastic energy contribution. Since knowledge on the mechanical properties of pulp fibers in the wet state – when a fiber-fiber bond is formed – is an important factor for understanding the bonding mechanisms in paper, we also employed AFM based nanoindentation to measure

the change in transversal hardness and modulus of pulp fibers under controlled relative humidity as well as in the fully wet state. Hardness and modulus are calculated from the force-vs.-distance curves by employing evaluation procedures developed for classical nanoindentation. We could clearly show a reduction in hardness and modulus with increasing humidity. However, both parameters are reduced even more if the fiber is completely wet. Compared to the dried state (about 5% relative humidity), hardness is decreased almost by a factor of 100 in the wet state. These data serve as important input to simulate the area in molecular contact between two pulp fibers during the drying process [2].

Supported by Mondi and the Christian Doppler Research Society, Vienna, Austria.

¹IFUSP, Caixa Postal 66318, CEP 05315-970, São Paulo, SP, Brazil; ²UNILA, Av. Tancredo Neves 6731, CEP 85856-970, Foz do Iguaçu, PR, Brazil; ³CCNH-UFABC, Rua Santa Adélia 166, CEP 09210-170, Santo André, SP, Brazil;

Core shell and alloy bimetallic nanoparticles (NPs) are attracting a great deal of attention, since they provide opportunities to tune the NPs' optical catalytic properties and are potentially useful as taggants for security applications [1]. The AuAg system is of particular interest since the Surface Plasmon Resonance (SPR) band might be tunable between ~520 nm for Au and ~410 nm for Ag [1]. These interesting physicochemical properties appear because of the combination of two kinds of metals and their fine structures, evolving new surface characteristics. With a view to contribute to a better understanding of the surface properties of these complex systems, in this work we explore the atomic, electronic and dynamical properties of Au@Ag and Ag@Au core shell NPs. Cube-octahedral NPs are modeled in the supercell scheme, following the procedure described in Ref. [2]. In the following, NPs with 147, 309, 561 and 923 atoms, corresponding to 1.7, 2.3, 2.9 and 3.5 nm, are indicated their number of atoms for simplicity. The simulations are carried out using the Vienna Ab-initio Simulation Package (VASP) [3], as previously detailed in Refs. [2,4]. Our total energy calculations suggest that the addition of a single shell layer stabilizes the system, i.e. the formation energy for a core NP with a single shell layer is smaller than the formation energy of the monometalic NP. This stabilization is more pronounced for Ag@Au NPs, where the decrease in the formation energy of almost 10% are obtained. When the shell thickness increases, the electronic properties of the system approaches the electronic properties of the monometalic

NP. It is also observed that a single shell layer is capable to decisively modify the DOS, as a mixture of both monometallic NPs DOS is seen. In addition, the influence of long range (van der Waals) interactions in the core shell electronic structure and atomic properties is also discussed.

The authors acknowledgement financial support from CNPq and FAPESP (Brazil).

²Ruđer Bošković Institute, Division of Materials Chemistry - Zagreb (Croatia).

Macro and meso-porous silicon (PSi) samples were prepared by electrochemical anodisation of boron low p-doped ($10 \text{ } \Omega\text{cm} < \rho < 23 \text{ } \Omega\text{cm}$) and highly p⁺⁺-doped ($\rho \leq 0.007 \text{ } \Omega\text{cm}$) silicon wafers in aqueous/ethanoic 20% w/w HF electrolyte under galvanostatic conditions. Anodisation time and current were varied in order to obtain different PSi morphologies. Electrochemical dissolution valence n was calculated from electrical measurements during the anodisation and gravimetric measurements before and after anodisations, indicating whether the sample was prepared in silicon dissolution and PSi-producing regime ($n \approx 2$) or in Si electropolishing regime ($n \approx 4$). Samples were characterized by SEM, photoluminescence (PL) spectroscopy and Raman spectroscopy. Samples prepared on low p-doped substrates were macro-porous (Fig 1), showed visible photoluminescence and no observable phonon confinement in Raman spectrum. Porous silicon prepared on highly-p⁺⁺ doped substrates was mesoporous (Fig 2), showed no observable photoluminescence and intense phonon confinement was observed in Raman spectra. Silicon nanocrystallite dimensions in PSi samples were obtained from photoluminescence [1] and phonon confinement models [2]. Nanocrystallite sizes were correlated with electrochemical dissolution valence n , showing decrease in crystallite dimensions for increasing n in highly doped (p⁺⁺) samples as expected, and increase in crystallite dimensions for increasing n in low-doped (p) samples. This seemingly contradictory behavior is discussed, taking into consideration the competing surface effects and quantum-confinement processes responsible for visible s-band photoluminescence from porous silicon.

H. Hassan ¹, N. Aït Hocine ², P. Médéric ³, M.P. Deffarges ¹.

¹LMR, CERMEL, Université François Rabelais de Tours, 29 rue des Martyres - 37300 Joué-Lès-Tours (France), ²LMR, CERMEL, Ecole Nationale d'Ingénieurs du Val de Loire, Rue de la chocolaterie - 41034 Blois (France), ³LLIMATB, Equipe de Rhéologie, Université de Bretagne Occidentale 6 Avenue Le Gorgeu - 29238 Brest (France).

In this study, organically modified montmorillonite (OMMT) / polyamide-12 (PA12) nanocomposites were prepared by melt compounding technique. The PA12 matrix is a commercial product, referenced as Rilsan® AECHVO, supplied by ARKEMA Company (Serquigny, France). The OMMT used as a reinforcement, is referenced as Cloisite® C30B and supplied by Southern Clay Products (Gonzales, Texas, USA).

The composite materials structure was characterized by XRD, TEM and SEM techniques. These structural techniques have clearly revealed a nanocomposite structure, with an exfoliation degree dependent on processing conditions (blade rotational speed). These observations are consistent with melt state rheological measurements highlighting, moreover, that above the OMMT mass fraction threshold of ~2%, the studied nanocomposites present a three-dimensional percolated network structure.

Thermal properties were analyzed by DSC technique and the results showed that the melting point and the crystallinity rate of nanocomposites are not, or slightly, affected by the presence of C30B nanofillers. Consequently, solid state viscoelastic properties were discussed in terms of clay structure.

Dynamical tests were carried out by using a VA4000 Dynamic Mechanical Thermal Analysis (DMTA) machine and the solid state viscoelastic properties of the

nanocomposites were analyzed as a function of clay mass fraction, strain, frequency and temperature. The storage modulus, E' , of the different nanocomposites, in glassy state and even in rubbery state, increases with increasing clay mass fraction, independently of strain level and frequency value. The glass transition temperature also increases with increasing clay content, whereas the peak of the loss angle tangent ($\tan \delta$) decreases.

Moreover, at room temperature, the reinforcing effect of the structure is showed, i.e. the composite modulus E' increases continuously with increasing frequency. The loss modulus E'' also increases, on the one hand, with adding nanoclay and, on the other hand, with strain increasing. However, this parameter decreases when the frequency grows, whichever clay mass fraction.

Blade rotational speed affects the storage modulus of nanocomposites presenting a three-dimensional percolated network structure: the most exfoliated nanocomposite has the highest storage modulus.

Effect of ageing on solid state properties was also evaluated. Results showed that in the linear behavior region, the aged nanocomposite storage modulus value is less than the unaged one. This degradation seems to be significantly limited with reinforcing clay mass fraction increasing.

This work presents some results of computer simulation and experimental study of light metal- and polymer-few layer graphene compositions induced by radiation defects, in particular by bridge-like radiation defects [1]. A possible physical mechanism of modification of carbon nanostructures which are used as reinforcement elements for composite materials is supposed. Results presented show that radiation modification with production of bridge-like defects can become an effective technological tool by production of composite materials, based on light metals or polymers reinforced by carbon nanostructures.

The superconducting proximity effect was revealed in a Scanning Tunneling Spectroscopy experiment on in-situ elaborated Pb/undoped Si(111) network, consisting of superconducting single crystalline Pb islands interconnected by a non-superconducting atomically thin disordered Pb wetting layer. In the vicinity of each superconducting island the wetting layer acquires specific tunnelling characteristics which reflect the interplay between the proximity-induced superconductivity and the inherent electron correlations of this ultimate diffusive two-dimensional metal. The observed spatial evolution of the tunneling spectra was accounted for theoretically by combining the Usadel equations with the theory of dynamical Coulomb blockade. The relevant length and energy scales were extracted and found in agreement with independent experimental data.

Enhanced Oxidation at the Nanoscale – Effects of Particle Size and Interfaces to Other Materials

T10 Nanoscience and Technology

#NST-9-Or-9

E. Sutter, P. Sutter.

Brookhaven National Laboratory - Upton, New York (United states).

When materials are shrunk to the nanoscale they often show behavior and properties that are not simply scaled down bulk properties but are distinctly different. For example, we demonstrated that nanoscale liquid drops crystallize differently from bulk materials [1], and that nanoparticles show dramatically enhanced solute solubility [2,3]. Here, we study oxidation to probe size-effects and the influence of interfaces on the chemical conversion of metal nanoparticles.

Using *in-situ* transmission electron microscopy we investigated the low-temperature growth kinetics during oxidation of In nanoparticles to In_2O_3 . Semiconducting In_2O_3 has widespread applications as transparent conductor in solar cells, light emitting diodes, and displays, due to its high optical transparency paired with good electrical conductivity, and is a promising photocatalyst for visible light water splitting.

Our experiments on arrays of In nanoparticles directly demonstrate for the first time the implications of size and curvature on the oxidation process by showing an accelerated oxidation of nanoscale particles with high curvature (Figure 1, [4]). To investigate the effects of nanoscale interfaces on oxidation, we considered In particles at the tips of Si nanowires. This experimental geometry allowed us to evaluate, under identical conditions, both the oxidation of In at the solid-gas interface and the oxidation in the vicinity of a well-defined nanoscale contact to the adjacent Si NW. The direct comparison of the two modes of In oxidation showed a more than tenfold increase of the limiting In_2O_3 thickness at the nanoscale epitaxial interface with Si demonstrating that the limiting thickness in room-temperature oxidation can be overcome by incorporating a nanoscale junction to a different material [5]. Our results demonstrate modifications of oxidation processes at the nanoscale, which need to be taken into account in processes that use oxidation, e.g., in the processing of nano-electronic devices or catalytic reactions.

Hybrid strongly luminescent materials have been drawing a lot of attention recently due to their numerous applications in multidisciplinary science like physical chemistry, nanomaterials or nanomedicine [1,2]. A common problem which in quantitative description of the properties of such materials is the determination of local mean concentration of fluorophores in the porous inorganic matrix. Concentration is a decisive factor of many physical and chemical processes occurring in various matrices, optical materials and optoelectronic devices. We propose the method of determination of local dye concentration in nanoporous matrix based on the donor – acceptor energy transfer. The method was tested for Rhodamine 110- Rhodamine 101 system in a silica and methylated silica nanolayers. Evaluation of acceptor (Rhodamine 101) local concentration was carried out by comparing the results of Monte-Carlo simulation of energy transfer from donor (Rhodamine 110) to acceptor (Rhodamine 101) with the experimental data of donor fluorescence decay and other luminescent characteristics in which concentration was treated as a best fit parameter. The obtained values of acceptor local concentration occurred about ten times higher than the mean bulk concentration.

This research has been supported by the grant NCN 2011/03/B/ST5/03094 (P.Bojarski, B.Grobelna) and BW-538-5200-0980-12 (A.Synak).

Theoretical Modeling of SiO₂:Si Nanostructures for Understanding Luminescence Phenomenon in SRO Films

T10 Nanoscience and Technology

#NST-P3-15a

N. Espinosa Torres ¹, J.F.J. Flores Gracia ¹, J.A. Luna López ¹, M. Aceves Mijares ².

¹CIDS-ICUAP - Puebla (Mexico), ²INAOE - Puebla (Mexico).

Different types of luminescence at room temperature have been found in thin layers of Si:SiO_x (SRO) . SRO has generated great interest because their possible applications in optoelectronic devices. Different researchers have reported cathode (CL), electro (EL) and photoluminescence (PL) in these materials off-stoichiometry [1]. A clear understanding of the mechanism of luminescence has not been raised satisfactorily. A large number of investigations have been led in order to study the nano-structures and properties of the agglomerates of the silica. Some of the proposed models [2] include structures based on two, three and four members rings (MR) and consist of nanostructures based on 2MR, 3MR, 4MR, hybrid 2MR/3MR and hybrid 3MR/4MR.

In this work, we have calculated the equilibrium energy in the ground and its excited states of this kind of silica molecules with the Density Functional Theory (DFT) to evaluate the contributions to luminescence phenomenon. The computational method employed is an ab initio total energy pseudo-potential technique within DFT, in the Generalized Gradient Approximation (GGA).

Our results include calculated IR and UV-Vis spectra of molecules carefully selected and confirm that the presence of rings of a few members, such as four (4MR), three (3MR) and two members (2MR) show luminescence at room temperature, and Huchino et al [3] have long-established experimentally that those molecules are frequently present in agglomerates of nanometer size silica than in those in which the geometric characteristics of the bulk materials restrict the relaxation of the network.

NST-P1-17

Towards covalently-bonded organic network formation on a semiconductor surface

T10 Nanoscience and Technology

#NST-P1-17

I. Mcgovern ¹, N. Berner ¹, A. Cafolla ².

¹Trinity College - Dublin (Ireland), ²Dublin City University - Dublin (Ireland).

Covalently-bonded organic network formation in ultra-high vacuum was first demonstrated by Grill et al. via a dehalogenation reaction of bromine-modified porphyrin molecules on the Au(111) surface [1]. The phenomenon was subsequently observed on other coinage metal substrates and using a variety of different organic molecules with bromine or iodine end-groups [2]. This paper reports on recent attempts to reproduce the phenomenon on the technologically more relevant surface of a semiconductor, in this case germanium (100).

The evident objection to this approach is that the latter surface will prove too reactive to the molecules to allow the degree of surface mobility required to form the network; the solution is also evident, namely, to passivate the surface. Initial efforts focused on the simplest passivation, that of atomic hydrogen. However, as discussed elsewhere [3], although this prevents any reaction of the as-deposited molecules with the substrate, this situation is not stable against the moderate annealing necessary for dehalogenation. The current study employs the

more robust passivation of chlorine from a home-made electrochemical source [4].

An Omicron VT STM was employed to image clean, Cl-passivated and molecule-deposited surfaces of Ge(001); in the first instance the molecule was the *free base* 5,10,15,20-tetrakis (4-bromophenyl)porphyrin (TBr4PP).

Upon deposition from a Knudsen-type cell, STM images were noticeably streaky, indicating that the passivation was enabling significant surface mobility. Nevertheless, it was possible to image individual molecules and non-covalent self-assembled islands. Upon annealing at 520 K for 5 min the image changed significantly, with the self-assembled islands of molecules largely transformed into chain-like structures. There is strong evidence for leg-to-leg orientation of adjacent molecules without dark contrast in between, which, in conjunction with a significantly reduced surface mobility, indicates the successful activation of the molecules and subsequent formation of covalent intermolecular bonds. Additionally, the average distance between molecular cores in the dimers, chains and pores observed throughout the STM images has been determined as $d=(1.65 \pm 0.12)$ nm, which is in agreement with the $d=1.71$ nm measured and calculated by Grill et al. for the distance between covalently-bonded TPP molecules. However the ease and quality of network formation found on coinage metal surfaces is not replicated to any great degree and possible sources of frustration are further discussed.

Extended polar objects present an electrostatic instability which induces substantial modifications of the surface charge density. Microscopic surface processes related to polarity compensation have been extensively studied in the last decades, also as a potential tool for tuning surface electronic and structural properties [1]. More recently it has become clear that polarity does also concern nano-objects, but that the relevant electrostatic forces and the response they induce may differ from the known ones [2]. In particular, new compensation mechanisms are at work, such as structural transformations of the entire object, resulting in novel structures, with no bulk counterparts, or uncompensated polar states may exist which drive strongly size- and dimensionality- dependent properties [3]. Since oxide nano-objects, such as ultra-thin films and nano-islands, are generally synthesized on metal substrates, their polarity characteristics are additionally modified by the electrostatic coupling between their structure and the interface charge transfer [4].

In this presentation, we will describe how polarity manifests itself in low dimensional objects, such as two-dimensional ribbons or islands [5] and illustrate the theoretical concepts with the recent results on monolayer MgO islands on Au(111), explored with low-temperature scanning tunneling microscopy and density functional theory [6]. We will show that the observed electronic characteristics of the monolayer MgO islands are fully compatible with their predicted induced-polar character, and that their structure and their out-of-plane dipole moment result from a coupling between the film rumpling and the electron exchange at the MgO/Au interface. We will also

identify the in-plane polarity induced by polar edges, and we will analyze its effect on the relative stability of MgO islands of different orientations and under different experimental conditions.

Charge screening at the surface of a topological insulator: Rb adatoms on Bi₂Se₃(111)

T10 Nanoscience and Technology

#NST-1-Or-3

L. Zhou, P. Löptien, J. Wiebe, A.A. Khajetoorians, R. Wiesendanger.

Institute of Applied Physics, University of Hamburg - Hamburg (Germany).

Adsorption of Rb atoms on Bi₂Se₃(111) leads to the formation of a quantum-confined two-dimensional electron gas (2DEG) in the conduction band at the surface [1]. We investigated the coverage dependent distribution of Rb adatoms with low-temperature scanning tunneling microscopy [2]. By a statistical analysis of the interatomic distances, we quantitatively derived the pair interaction between singly charged Rb adatoms, which fits a screened Coulomb potential. Interestingly, the screening length and the dielectric constant turn out to be very small, which is attributed to the contribution of the 2DEG and the topological surface state.

¹Instituto Politécnico Nacional - Distrito Federal (Mexico), ²Institut de Chimie de Clermont-Ferrand - Aubiere (France).

Rare-earth doped lanthanides orthophosphates (LnPO₄) represent a class of materials with significant technological importance. Recently, new applications of nanoscale phosphors, including biolabeling, optical imaging or luminescent transparent layers have attracted intensive interests. As a result, several synthesis methods leading to LnPO₄ nanocrystals with controlled shape have been developed, based on hydrothermal reactions or high-boiling solvent technique for instance. It is well known that the reduction of particles size or the modification of their shape can dramatically modify their physic-chemical properties.

In this work Eu³⁺ and Tb³⁺ doped GdPO₄ nanocrystals, with different shapes were successfully synthesized by a new hydrothermal method. The particles morphology was modified changing different parameters like the pH and the synthesis temperature or using the glycerol as surfactant. Depending on the synthesis conditions, TEM analyses have revealed the achievements of hexagonal nanoparticles, nanorods or nanowires with narrow size distributions. Their structural, morphological and photoluminescent properties were investigated and compared. Luminescent films were prepared by dispersing these nanomaterials in a polymer matrix. The influence of the GdPO₄ shape on the maximum loading rate and on the mechanical properties of composite films was studied.

Stability and breakage mechanism of molecular junctions based on different anchoring groups

T10 Nanoscience and Technology

#NST-2-Or-9

T. González ¹, E. Leary ¹, A. Díaz ², C. Evangelini ², G. Rubio-Bollinger ², N. Agrait ².

¹IMDEA-Nanoscience - Madrid (Spain), ²Universidad Autónoma de Madrid - Madrid (Spain).

The realization and study of molecular junctions formed by a few (down to one) molecules bonded between two metallic electrodes opens the possibility of directly investigating electrical properties of compounds at the ultimate level of a single molecule. Apart from the determination of their electrical conductance, it is important to understand which factors play a role in the formation and breakage of the molecular junctions, and how stable we can expect them to be.

In this work, we present our studies on the stability and breakage mechanism of molecular junctions formed by thiol-, amine-, and C60-terminated molecules. We use a STM (scanning tunneling microscope) break-junction technique to create and characterized single-molecule junctions. We compare thiols and amines on the alkane family [1] and an oligo(phenyleneethynylene) (OPE) [2,3]. By studying the molecular-junction stretching length for these compounds, we conclude that, during the junction formation, thiols affect atomic rearrangement at the electrodes significantly more than amines [1].

In addition, by performing stretching experiments at different pulling speeds, we find that junctions of OPE-diamine can be very stable and have adsorption lifetimes well above the time interval explored in the experiment [3]. We identify the breaking of the single-molecule junctions of this compound to be due to simply the elastic limit of the gold-amine bond. On the other hand, multiple-molecule junctions typically break when the inter-electrode gap reaches the molecule length. We find evidence that individual molecules attach and detach during the stretching of a multiple-molecule junction, which warrants the long-life of the molecular junctions in spite of individual molecular desorption. This shows that even using a weak binding group such as

amine, long-lasting junctions can be established in an environment that allows equilibrium between adsorbed and desorbed individual molecules.

Thermally-Assisted Electron-Induced Nonlocal Desorption in the STM

T10 Nanoscience and Technology

#NST-5-Or-6

T. Pan ¹, S.A. Holmes ¹, D. Kaya ¹, P.A. Sloan ², R.E. Palmer ¹.

¹University of Birmingham - Birmingham (United kingdom), ²University of Bath - Bath (United kingdom).

Atomic manipulation in the scanning tunnelling microscope (STM), provides, at least in principle, a means to create and control nanoscale architectures. A thorough knowledge of the manipulation mechanisms at play is essential to realizing this potential. Here we have investigated the thermally-assisted nonlocal desorption of chlorobenzene molecules on the Si(111)-7x7 surface [1-3] at different temperatures.

In the previous investigation [1], it has been shown that the nonlocal desorption of chlorobenzene can be realized by the electron injected from the STM tip and this process can be affected by different injection sites. Here, we present the effect of temperature to the nonlocal chlorobenzene desorption process. We found that, as the temperature decreased, the range of the non-local effect was reduced from several hundred ångströms down to several tens of ångströms, while the integrated desorption yield also decreased significantly. The difference in yield between 323 K and 77 K, can be as much as one order of magnitude. From the Arrhenius plot, two activation energy regions (~162 meV for the region above 175 K and ~17 meV for the region below 175 K) can be noticed for the nonlocal desorption process. Thus, this one-electron desorption process is thermally-assisted, similarly to the case of C-Cl bond dissociation of chlorobenzene [2-3]. In the lower temperature region, it may be due to the excitation of the surface phonon, while in the higher temperature region, the excitation of the molecule-substrate vibrational mode may come into play.

In recent years, lanthanide-doped ultrafine and nanocrystalline barium titanate materials have been widely investigated due to their interesting optical properties, which make them candidates in different advanced fields, such as phosphors for TV screens optical amplifiers and electroceramic applications. Recently there is an interest to produce rare earth ions doped perovskite base materials as barium titanate powders owing to its promising luminescent properties produced by soft chemical routes. The incorporation of a glassy component on the ceramic system has improved the luminescent properties in similar matrix as Y₂O₃:Eu³⁺. In this context, the solvothermal route was selected as promising option to prepare BaTiO₃:Eu³⁺ ceramic powders while the sol-gel method was chosen to elaborate the SiO₂ matrix. As well as, sol-gel method allow obtaining high purity and homogeneity in the synthesized materials. In the present work, the precursors employed for the synthesis of BaTiO₃:Eu³⁺ ceramic powders, were barium chloride (BaCl₂, 99.9%, Aldrich), Europium (III) nitrate pent hydrate (Eu(NO₃)₃•5H₂O, 99.9% Aldrich), titanium butoxide (Ti[O(CH₂)₃CH₃]₄, 97%, Fluka). Anhydrous methanol (CH₄O, 99.8%, Sigma Aldrich) was used as solvent and metal potassium (K, 98%, Aldrich) as mineraliser. The alcoxide base precursors used for the elaboration of SiO₂ glassy sol, were tetraethyl orthosilicate (CH₈H₂OO₄Si, 98%, Aldrich), ethanol (CH₃CH₂OH, 99.9% Fermont), hydrochloric acid (HCl, Fermont) and distilled water. In order to improve the luminescent properties of the BaTiO₃:Eu³⁺ ceramic powders, the synthesis of BaTiO₃:Eu³⁺@SiO₂ glass ceramic powders are proposed in different Ba:Si molar ratio. The effect of SiO₂ (glassy sol-gel matrix) incorporation in BaTiO₃:Eu³⁺ (ceramic hydrothermal matrix) were chemically, structurally and morphologically analyzed by means of FT-IR spectroscopy, X-ray Diffraction and

Scanning Electron Microscopy characterization techniques. Two glass BaTiO₃:Eu³⁺@ SiO₂ ceramic systems: Ba:Si=3:97 and 5:95 presented the major 611 nm red emission intensity as demonstrated by photoluminescent studies.

NST-P2-20

Synthesis of CdS-ZnS nanostructures by microwave radiation

T10 Nanoscience and Technology

#NST-P2-20

I. Gómez, T. Serrano, A. Vázquez, A. Zamora.

UANL - San Nicolas De Los Garza N.I. (Mexico).

Mixed systems of CdS-ZnS nanoparticles were obtained by means of colloidal synthesis assisted by microwave radiation. The optical characteristics obtained in the synthesized samples were compared versus CdS and ZnS separately, these nanoparticles were also synthesized in the current work. Mixed systems were prepared at three different molar relations between cation precursors, 1:1, 2:1 y 1:2, respectively. The samples were prepared from thioacetamide as sulfide source and from CdCl₂ or Zn(OAc)₂·2H₂O for Cd or Zn ions. The experiment obtained with the best optical characteristics such as the bigger photoluminescence in the first part of the work has been chosen to be prepared with different concentrations of stabilizer (sodium citrate), 1.0, 1.5 and 2.0 mM. In both parts of our work the concentration of thioacetamide, pH 8 and a time of 60 seconds under microwave radiation were constant. The mixed systems improve their optical characteristics in comparison to the compound separately; this was determined by UV-Vis and photoluminescence analysis. FESEM analysis let us to observe arrangements of nanoparticles from 20 to 70 nm. The effect over photoluminescence is function of the relation of CdS versus ZnS.

Influence of Randomly Distributed Impurities on Electronic Transport in Carbon Nanotubes: Wave-Packet Dynamics Simulation

T10 Nanoscience and Technology

#NST/SS-5-Or-6

Y. Takada, K. Takashima, T. Yamamoto.

Faculty of Engineering, Tokyo University of Science - Tokyo (Japan).

Carbon nanotubes (CNTs) are quasi-one-dimensional materials, which are attracting much attention for both academic science and practical engineering interests [1, 2]. Semiconducting SWNTs are potential candidates for future ultra-fast switching devices due to their high carrier mobility. However, there are still several serious problems that degrade the transport properties of SWNT devices. To reveal underlying physics behind these problems is a first step to achieve practical SWNT devices.

Recent experiments showed that the impurity and/or defect scattering in a SWNT causes Anderson's localization even at room temperature, originating from its low dimensionality and phase coherency of an electron [3]. In Anderson's localization regime, the typical width of localized wave function is given by the localization length ξ , and therefore the localization can occur when the tube length L is much longer than the localization length ξ . Thus, the localization length ξ is an important quantity characterizing the Anderson's localization. However, the relation between the localization length ξ and the strength of impurity potential is not sufficiently clarified yet.

In this study, we numerically investigate the impurity scattering effects on the coherent electronic transport in semiconducting SWNTs with randomly distributed impurities using wave-packet dynamics method [4, 5], focusing particularly on the effects of impurity-potential strength on the localization length ξ . The wave-packet dynamics method is a powerful simulation technique that enables us to simulate transport properties of large systems such as the present disordered system, with low computational cost. Using the wave-packet dynamics method, we estimate the localization length ξ as a function of the strength of impurity potential. Our results show that the system exhibits Anderson's localization due to quasi-one-

dimensionality of nanotubes. Moreover, we reveal the dependence of impurity-potential strength on the localization length ξ , and consequently we show that the localization can occur even at room temperature, which is consistent with the recent experimental results.

Formation of one-dimensional ZnS nanostructures and its transformation into ZnS/ZnO heterostructures

T10 Nanoscience and Technology

#NST-6-Or-1

A. Vázquez, Y. Peña, I. Gómez.

Universidad Autónoma de Nuevo León, UANL, Facultad de Ciencias Químicas, Laboratorio de Materiales I - San Nicolás De Los Garza, Nuevo León (Mexico).

One-dimensional ZnS nanostructures were grown through electrophoretic deposition of ZnS nanoparticles prepared by a microwave assisted synthesis by using sodium citrate as stabilizer. HRTEM images show that this synthetic route produces spherical particles with a mean diameter of 20 nm. The one-dimensional ZnS nanostructures were formed without using template membranes after 24 h of electrophoretic deposition on aluminum plates at direct current low voltage. Dimensions of the nanostructures can be varied according to deposition time and electric field. FE-SEM images at different deposition times show that one-dimensional nanostructures are formed by a mechanism of lyosphere distortion and thinning and subsequent dipole-dipole interactions phenomena where the incoming particles are oriented by the particles previously deposited. In this mechanism the first particle/lyosphere deposited act as a dipole and attract the incoming particles to it, creating a polycrystalline one-dimensional nanostructure after some time of electrophoretic deposition. Once the one-dimensional ZnS nanostructures are formed, they were transformed into ZnS/ZnO heterostructures by controlled thermal oxidation at 400° C. FE-SEM images show that the ZnS/ZnO heterostructures can be produced with different ZnS/ZnO ratios by controlling time of heat treatment.

X. Sun, Y. Kuang, G. Zhang, S. Song.

Beijing University of Chemical Technology - Beijing (China).

High dimensional nanodevice is the ultimate goal for nanoscience and nanotechnology. Bottom up approach, which contains synthesis and assembly of monodisperse nanocomponents, is a general method for the fabrication of high dimensional nanodevices. As an assistance and extension of synthesis optimization, we adopted "density gradient ultracentrifuge separation" (DGUS) method for obtaining more monodisperse or unique colloidal fractions. DGUS method was demonstrated a general method not only for sorting nanoparticles with different size and morphology (Fig. 1 B, C, D) but also applicable for various materials, such as noble metal[1, 2], carbon[3], S-group semiconductor[4], or hydroxide compounds etc. Meanwhile, DGUS separation can be carried out in both aqueous[1] and organic media.[4] Models were set up for typical systems. A series of nano-effects were observed or evidenced on these fractions as property investigations were performed, which provided chance to get deeper view into the structure-property relationship of colloidal nanoparticles. More importantly, nanoseparation demonstrated to us that the formation of nanoparticles with varied size or morphologies in one batch is not a random behavior, in contrast, the size or morphology distribution closely related to synthesis condition, properties of fractions, and composition distribution. The findings provide new inspirations for synthesis optimization.[5]

First-Principles Study on Current-Induced Magnetization Switching in Magnetic Tunnel Junctions

T10 Nanoscience and Technology

#NST/SS-P2-02

M. Araidai ¹, T. Yamamoto ², K. Shiraishi ³.

¹Center for Computational Sciences, University of Tsukuba - 1-1-1 Tennodai, Tsukuba, Ibaraki 305-8571 (Japan), ²Faculty of Engineering, Tokyo University of Science - 6-3-1 Nijuku, Katsushika-Ku, Tokyo 125-8585 (Japan), ³Faculty of Pure and Applied Sciences, University of Tsukuba - 1-1-1 Tennodai, Tsukuba, Ibaraki 305-8571 (Japan).

Investigation of magnetic tunnel junction (MTJ) is a key issue for the development of advanced magnetoresistive random access memories (MRAMs). MTJs consist of two metal ferromagnets, thick spin-fixed and thin spin-free layers, separated by a thin insulator, and they exhibit two resistances, low or high, depending on the relative direction of the magnetizations of the spin-fixed and spin-free layers, parallel (P) or antiparallel (AP) configuration. The simplest way to reverse the magnetization of free layer is switching by external magnetic fields. However, absolute currents required for magnetic-field switching do not scale with reducing the junction size, and it is a major obstacle to promote MRAM devices. At present, current-induced magnetization switching (CIMS) proposed by Slonczewski¹ and Berger² is drawing attention as the most promising candidate for a mechanism of magnetization reversal of free layer, owing to the scalability of CIMS³. Although CIMS has been successfully applied to the operation of MRAM, the microscopic mechanisms have not been sufficiently understood yet.

In this work, we have theoretically investigated CIMS in MTJs. While many theoretical studies have been devoted to clarify the microscopic mechanisms of CIMS by the phenomenological Landau-Lifshitz-Gilbert equation, we utilize the non-equilibrium Green's function technique coupled with the density-functional theory to reveal the mechanisms together with its device characteristics. We employed a Fe/MgO/Fe model as a typical MTJ. The current-voltage characteristics indicate high tunnel magnetoresistance of the MTJ (about 600% at zero bias) and is highly antisymmetric with respect to the bias voltage, originating from the antisymmetric structure and spin polarization. We found from the current density dependence of

magnetization of free layer that the switching from AP to P configuration could be realized by lower electrical power than P-to-AP case. Through the close examinations on local variation of magnetization at each electric current, we can propose a rational mechanism for magnetization switching in the MTJ within a conventional energy-band picture, i.e., a single-electron picture.

B. Martins ¹, M. Salomons ², R.A. Wolkow ¹.

¹University of Alberta, National Institute for Nanotechnology - Edmonton (Canada), ²National Institute for Nanotechnology - Edmonton (Canada).

Step edges are a major issue for the implementation of large scale molecular device architecture on silicon surfaces. Electrical resistance associated with this defect imply losses that can prevent efficient signal propagation along the surface. The effect is particularly relevant on Si(111)-7x7 if we consider that its surface is highly conductive as demonstrated by photo-emission experiments [1]. This assumption is quite controversial as evidenced by the large range of surface conductivity values presented in the literature. Wells et al. [2] showed conductivities ranging from 10^{-4} to 10^{-8} S. This huge gap is probably due to the problem of separating surface, space-charge layer, surface contamination, contact variability and bulk contributions to the current. At low temperatures, these components could be disentangled and that surface conduction was not as high as expected, clearly not metallic [2]. However, this result did not take into account the important role played by the contacts [3], whose size determines the transport properties of the system. In the case of very small contacts (nanocontacts), most of the conduction is ballistic and propagates through surface states. The use of small, stable contacts allows us to probe surface conductance and therefore the step edge resistance.

In order to properly consider the contact problem, we propose a novel approach for transport measurements on semiconductors. Using a home-built, three-probe, RT STM we measured the surface potential using ZV spectroscopy instead of direct contact. This way we avoid problems related to the non-linear nature of the Schottky barrier due to the contacts which can strongly influence the experimental outcome. We measured potential profiles (Figure 1) along a low-doped surface and across a step edge. The line profiles were used for the calculation of both surface conductivity

$\sigma = 1.6 \times 10^5$ and step edge resistance $R = 5.0 \times 10^2$. The high conductivity is in full agreement with previous results obtained by Hasegawa et al. [4] using a single STM. The step edge measurement is the first one made. In a last step, we carried out a measurement set

on a dosed surface to remove Si surface states. The dosed line profile, also featured in Figure 1, shows that the step edge potential drop vanishes in this case. This confirms our assumption that the measured signal was due to conduction through surface states.

Graphene-filled syndiotactic polystyrene nanocomposites: microstructure, crystallization and electrical conductivity

T10 Nanoscience and Technology

#NST/SS-5-Or-10

C. Wang, Y.C. Chiu.

Department of Chemical Engineering, National Cheng Kung University - Tainan (Taiwan, republic of china).

Syndiotactic polystyrene (sPS) is a semicrystalline polymer with high melting temperature and good mechanical strength. In this report, sPS nanocomposites filled with different amount of graphenes are prepared by a coagulation method. Two types of graphenes with different thicknesses (denoted to G1 and G10) are studied. Electron microscopy shows that G1 is a wrinkled flake with a thickness less than 2 nm, and G10 is a smooth sheet with a thickness less than 50 nm. The un-modified graphenes are well dispersed in the sPS matrix. After sonication in o-DCB solution, however, the lateral dimensions of G1 and G10 are significantly reduced, and G1 has more defects than G10 as-revealed by Raman spectroscopy. Measurements of electrical conductivity and crystallization of the nanocomposites are carried out to unveil its potential as a conducting material. As expected, at a given graphene content the electrical conductivity is higher for the G1-filled samples than G10-filled ones. Percolation scaling law is applied and the conductivity threshold is determined to be 0.46 vol% for the former and 3.84 vol% for the latter. TEM studies on the melt-quenched nanocomposites reveal that a more uniform dispersion of G1 is developed in the sPS matrix. Striped sPS lamellae are seen in the G10-filled samples with a graphene content higher than 0.5 wt%. Wide-angle X-ray diffraction elucidates the produced sPS crystallites are in the beta form under such a server cooling condition. In contrast, alpha-form sPS crystallites are produced when the melt-quenched samples are cold-crystallized during dynamic heating. With an increase in graphene loading, the isothermal crystallization rate of sPS is increased. Regardless of the graphene content, the glass transition and equilibrium melting temperature of the sPS matrix are unchanged at ~96 and 290 °C, respectively. It is found that G10 is more effective than G1 as a nucleating agent to induce the crystallization of sPS

matrix despite a higher concentration required to form conductive graphene network in the sPS matrix.

An ideal carbon support should have a high specific surface area, good electric conductivity, suitable pore size, favorable surface functional group, good corrosion resistance, and low cost [1]. A lot of work has been done on developing new carbon materials and modifying the carbon materials by treatment with acid, alkali, oxidant, or polymer to meet these requirements. In this work, new carbon nanomaterials that are single-walled carbon nanohorns (SWCNHs) were examined and compared with commercial carbon support such as activated charcoal and carbon black. As-grown SWCNHs were prepared by arc in water with nitrogen gas injection (AIW-GI) method [2]. Acid functional groups were added on the surface of all carbon materials by sulfonation reaction with sulfuric acid at 200°C for 18 hr. Fourier transform infrared spectroscopic results indicated that a sulfonic acid functional group (SO₃H) was formed on the surface of all carbonaceous catalysts. Additionally from N₂ adsorption analysis for pore size distribution results showed that SO₃-SWCNHs exhibited increasing of BET surface area (418 m²g⁻¹), porosity (96 cm³g⁻¹) and higher uniform pore size distribution. TEM image of SO₃H-SWCNH in Fig.1 shows that the morphology of SWCNHs aggregates have not changed significantly after sulfonation. As an environmentally friendly solid acid catalyst, the catalytic performance of all carbonaceous materials were evaluated by the esterification of palmitic acid for methyl palmitate production. Regarding the yield of methyl palmitate, the SO₃-SWCNHs showed higher catalytic performance than activated carbon and carbon black. SWCNHs give better performance due to their superior structural features and high acid site density which was proven by ion exchange titration results.

Intercalation of metals and silicon at the interface of epitaxially grown graphene and Ru(0001) surfaces

T10 Nanoscience and Technology

#NST/SS-02-Or-10

L. Huang, W. Xu.

Institute of Chemistry, Chinese Academy of Sciences - Beijing (China).

Epitaxial graphene on Ru(0001) provides a high quality adlayer, but has a strong interaction with the substrate. This interaction can be effectively weakened via intercalating a layer of Au, Ag, or Cu between epitaxial graphene and its substrate. In this work, we intercalated seven kinds of metals including noble metals Pt, Pd and Au, magnetic metals Ni and Co, a IIIA group metal In and a rare earth metal Ce, at the interface of epitaxially grown graphene and Ru(0001), to show the universality of metal intercalations in this system. Moreover, we intercalated silicon at the interface of graphene/Ru(0001) and demonstrated that silicon-layer intercalation not only weakens the interaction of graphene with the metal substrate but also retains its properties. More importantly, the silicon intercalation process allows for an atomic control of the distance between the graphene and the metal substrate that can be used as a top gate. Our results show potential for the next generation of graphene-based materials with tailored properties.

Computational Simulation on Electronic Transport in Edge- Disordered Graphene Nanoribbons

T10 Nanoscience and Technology

#NST/SS-P1-06

K. Takashima, Y. Takada, T. Yamamoto.

Faculty of Engineering, Tokyo University of Science - Tokyo (Japan).

Graphene is a potential candidate for channel materials of field effect transistors (FETs) because of their high carrier mobility [1]. However, metallic behavior of graphene is a major hurdle to utilize it to the channel of FETs, because high on-off ratios are not achievable without an energy-band gap. One possible way to overcome the gap-opening problem is to process the graphene in the form of nanoribbon with nanometer width. Graphene nanoribbons has an energy gap and they have been successfully applied to FETs with high on-off ratio [2]. The channel length of cutting-edge GNR-FETs is less than 100nm (the minimum length is ~1nm). Because such channel lengths are shorter than the typical coherent length of GNRs, the GNRs is expected to exhibit remarkable electronic transport properties originating from the wave nature of electrons. A recent experiment reported that the resistance of GNRs increases exponentially with their length even at the room temperature [3]. This non-Ohmic behavior is believed to be due to Anderson's localization caused by the interference between coherent electrons scattered by the disordered edges of GNRs. However, the detail relation between the edge roughness and the coherent length L_ϕ of GNRs has not been clarified yet. In this study, we have theoretically investigated the coherent electronic transport in edge-disordered armchair GNRs (AGNRs). The edge disorder has been treated as randomly-distributed carbon-pair vacancies on the edges of AGNRs. We used two simulation methods: (i) the wave-packet diffusion (WPD) method [4] and (ii) the nonequilibrium Green's function method combined with tight-binding (NEGF+TB) method [5]. In the WPD simulation, we have estimated the localization length L_ϕ of AGNRs from the time-dependent diffusion coefficients. On the other hand, in the NEGF+TB method, we have calculated L_ϕ of AGNRs from the length dependence of the electronic conductance. From both simulations, we clarified (i) a relation between L_ϕ and the amount of edge carbon-pair vacancies, (ii) the chemical-potential

dependence of L_φ , and (iii) the ribbon-width dependence of L_φ . We discuss the details of these simulation results in the presentation.

¹Department of Microelectronics, School of Electronics and Information Engineering, Xi'an Jiaotong University - Xi'an (China), ²School of Science, Xi'an Jiaotong University - Xi'an (China), ³Xi'an Jiaotong Univ. - Xi'an (China).

Research on machinery strength, photoelectric absorption efficiency and heat transmission response of low dimension material such as graphene and carbon nanowall has draw broad concern¹⁻³. In the course of the experiment, we found an interesting phenomenon. Electrical conductivity in graphene would change as it folded, especially when you fold it up to nano-scale, you will get local high resistance. Here we reported a triode structure of graphene cathode with nano-scale sharp folds. Figure 1 insert picture shows the cross section schematic illustration of graphene with very sharp folds. Taking advantage of photoetching technology, we have obtained triangular prism structure lying on substrate, in which side length is less than 8 μ m (as shown in Figure 2 insert optical micrograph). We have transferred graphene sheet on one side edge of triangular prism to prepare nano scale graphene folds, and washed off triangular prism afterward as shown in Figure 2. We have measured the triode field emission properties on the setup as shown in Figure 1 insert picture. We found that the current I_{gc} between gate and cathode is decreasing slightly with the voltage U_{gc} increasing when anode voltage U_{ac} is higher than 1000V (we didn't show the picture). Voltage U_{gc} has controlled current I_{ac} between anode and cathode a little bit, which could be seen in Figure 1 clearly. The nano scale sharp folds on monolayer graphene could be regarded as bilayer, and the top zone of folds would be high resistance. When voltage U_{gc} between cathode and gate is applied, the electric field around top zone of folds will be enhanced greatly. The current I_{ac} with U_{gc} applied would be higher than that of without.

Various nano particles (NPs) are used or expect to be used in many nano-technology applications such as magnetic recording materials, catalytic materials, fluorescent markers, drug delivery systems, or quantum electronics. A lot of methods to produce NPs have been studied. Recently, a biological method using protein cages as the bio-template has become used for the uniform synthesis of metal and semiconductor NPs. We fabricated many kinds of NPs in a bio-template, apoferritin protein from horse spleen (HsAFr)¹. HsAFr, the cellular iron-storage protein, is a spherical hollow shell composed of 24 polypeptide subunits. The inner and outer diameters of the HsAFr shell are about 7 nm and 12 nm respectively. Many kinds of metal oxide NP cores (Fe, Co, Ni, In_xO_y) have been efficiently fabricated in the ferritin with small size dispersion. On the other hand, semiconductor NP is also a powerful tool for nano-electric applications, because they exhibit intriguing characters such as a fluorescent, size-effect and quantum effect. We designed a slow chemical reaction system (SCRY) for synthesis of compound semiconductor NPs in the HsAFr. We succeeded in the NPs such as CdSe, ZnSe, Au₂S, CdS, CuS, in the cavity of HsAFr with the narrow size dispersion¹. Especially, CdS NPs synthesized in the HsAFr showed the photoluminescence from their NPs and the size effect corresponding to the diameter of CdS NPs². In addition, the CdS NPs showed the activity of circular polarized luminescent (CPL)³.

In this contribution, we report a successful synthesis of new semiconductor NPs, Ag₂S NPs, in HsAFr. An optimization of Ag₂S NPs synthesis was performed and the results suggested that the concentration of ammonia water in the reaction solution is important to the synthesis of Ag₂S NPs. The synthesized Ag₂S NPs showed photoluminescence at 1280 nm by an irradiation of visible light. The analysis of

obtained Ag₂S NPs by X-ray powder diffraction (XRD) indicated that the NPs were Ag₂S cubic crystal. This is a first report of NP with near-IR photoluminescence in the ferritin protein. The obtained Ag₂S NP will be used as quantum dots for nano-electric devices, solar cell, DDS or infrared therapy. The possible biomineralization mechanism of the Ag₂S NP is now under investigation.

Tailoring two-dimensional hydrogen-bonded organic nanoarchitectures at the liquid-solid interface: the case of star shaped molecules and salen derivatives

T10 Nanoscience and Technology

#NST-8-Or-6

F. Silly¹, J. Hieulle¹, M. Viciano-Chumillas², T. Mallah².

¹CEA - Saclay (France), ²Université Paris Sud - Orsay (France).

Complex supramolecular two-dimensional (2D) networks are attracting considerable interest as highly ordered functional materials for applications in nanotechnology. The challenge consists in tailoring the ordering of one or more molecular species into specific architectures over an extended length scale with molecular precision. Highly organized supramolecular arrays can be obtained through self-assembly of complementary molecules which can interlock via intermolecular interactions. Molecules forming hydrogen and halogen bonds are especially interesting building blocks for creating sophisticated organic architectures due to high selectivity and directionality of these bindings. Molecular shape, size, structure and nature of molecular substituents as well as their position are key parameters governing the formation of self-assembled nanoarchitectures.

We used scanning tunnelling microscopy to investigate at the atomic scale the formation of hydrogen-bonded organic nanoarchitectures at the liquid-solid interface. We observed in the case of 1,3,5-triphenylbenzene star shaped molecules [1] that changing the nature of peripheral substituent modify the self-assembly of the molecules. Various porous nanoarchitectures having differently-shaped cavities can be engineered. In the case of star-shaped 2,8,14-tripropoxy-5,11,17-triazatrinaphthylene derivatives, the nature of the bay substituents also plays a key role in the molecular self-assembly process. Porous or compact structure can be selectively created [2].

In comparison nickel salen derivatives with benzoic acid have a rectangular shape. By changing the nature of the substituents close to the metal atom we show that we

can tailor the structure of salen self-assembled nanoarchitectures. Compact and porous two-dimensional salen structures can be formed.

Metal oxides represent one of the most important and widely employed categories of solid catalysts, either as active phases or supports. For example, oxygen deficient MoO_x/TiO₂ systems are strongly studied because of their wide applications in catalytic processes.^[1] In that context, a lot of effort has been made to improve the surface-to-volume ratio of the system, for example by the generation of MoO_x-based nanostructures.^[1] It has already been reported that evaporation of Mo on a (110) rutile TiO₂ surface leads to an interfacial reaction between the deposited metal and the substrate which generates MoO_x nanostructures.^[1] Metal-coated particles are a state-of-the-art type of composite materials which present a high specific surface area. Among the potential approach to synthesize this type of composite, magnetron sputtering is a good candidate because it allows minimal impurity, good reproducibility, and flexibility in fabricating a wide variety of materials.^[2]

In this work, different amount (0.5; 1; 1.5 and 2 at. %) of metallic molybdenum was deposited by magnetron sputtering on four types of TiO₂ nanoparticles (particle size < 100 nm) differing by their crystalline constitution. Anatase, rutile and two mixtures anatase-rutile (Degussa P25[®] and Aldrich reference N° 634662) are used. The morphology, the chemical composition and the crystalline properties of the resulting compound were characterized by field transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD) analysis. The catalytic properties of the product were evaluated by monitoring the degradation of methanol.

The results indicate that the nano-particles are successfully coated by molybdenum. Whatever the powder used, the XPS results reveal the oxidation of the deposited Mo likely due to oxygen transfer from the TiO₂ substrate. Finally, the catalytic tests show that the decomposition of methanol is dependent on both the amount of Mo and the crystallographic structure of the powders. The anatase powder containing 1 at. % of Mo presents the best conversion rate of ~70%.

Compared to monometallic systems, the addition of one or several metals induces complex behaviors, not always well understood, which give a larger diversity in the structure and morphology of nanoparticles (NPs) and offer an additional degree of freedom to tune their properties for relevant applications - as in magnetic data or energy storage (fuel cell). Besides the composition effect, finite matter quantity effects lead to original variations of atom arrangement, such as disordered/ordered, segregated, core-shell, chemically-induced strained particles. The main challenge is to understand the origin of rearrangements of atomic species in multicomponent nanoparticles, which lead to such structures. The most complete thermodynamic equilibrium description of a nanoalloy is achieved by determining its phase diagram, as a function of size, composition and temperature. However, the kinetic effects which occur during the growth or the evolution of nanoalloys can yield out-of-equilibrium structures, not predicted by thermodynamic considerations alone. In all cases, because of this complexity, the determination of the atom arrangement at the nanoscale in Co-based particles (CoPt and CoAg) is a very difficult task, requiring the synergic efforts of experiment [1,2] and computer modelling [3].

Methods that probe local and average features as well as nanometer to micrometer-sized data, provide highly complementary information about the structure and morphology of nanostructures and are much powerful when used together. For that, we have developed combined X-ray scattering and electron microscopy strategy allowing the determination of the structure at the atomic scale range (small angles) and the morphology at the particle scale range (wide angles), respectively. Because the high reactivity of Co-based particles, x-ray experiments: Grazing Incidence Small-Angle X-ray Scattering (GISAXS) and Grazing Incidence X-ray wide angles

scattering (GIWAXS), are performed in situ in UHV conditions [1,2] during the nanoalloy growth obtained by vapor deposition or during thermal annealing. The quantitative structural analysis have been facilitated and consolidated using Monte Carlo (MC) simulations [2,3] of Co-Pt nanoalloys within a semi-empirical tight-binding potential, to identify the experimental phase transitions (ordered, disordered fcc, multi-twinned decahedra and icosahedra). In addition, the combination of GISAXS and GIWAXS with the anomalous effect (chemical selectivity) have allowed the extraction of scattering data from the two kind of metal atoms to identify core-shell atom arrangement [4].

NST-2-Or-4

Atomic scale study of the first stage of silicide nanocrystals formation on Si(100) for nanoscale molecular contacts

T10 Nanoscience and Technology

#NST-2-Or-4

M. Yengui, D. Riedel.

ISMO, Université Paris Sud, 91405 Cedex - Orsay (France).

Silicides are widely applied in microelectronics devices and have generated substantial research interests due to their electronic structure and metallic properties. In the context of the design of nanometer scale devices, the control of the fabrication of metallic contacts is of crucial importance, particularly when their sizes reach 10 nanometers or below. As a consequence, molecular electronics can take over usual devices. The study of their electronic properties is now possible with scanning tunneling microscopy (STM) techniques bringing new insights to conventional approaches. Earlier experimental study indicate that adsorption of 0.04ML Co on Si(100) surface at room temperature lead to the formation of subsurface site and defect structures [1]. At higher coverage regime (0.1 - 0.8) ML, the formation of conductive pads is shown to be ruled by various parameters such as the surface temperature or the evaporation rate of Co [2, 3, 4]. Within this framework, we have firstly investigated the premises of the silicidation by studying the properties of cobalt atoms adsorbed on the bare silicon Si(100) surface cooled at 12K via at low temperature (9K) STM. We have shown that at 12K, typical Co-Si site can already be observed. Interestingly, the electronically induced reversible manipulation of cobalt adatoms could be performed at 9K. In a second step, we have studied the electronic properties of various cobalt silicide structures on Si(100) fabricated via exposing the hot (500°C ~ 700°C) Si(100) surface to 1ML of Co followed or not by annealing cycles. The various structures observed in each case are compared and their electronic properties are studied. Finally, we have studied the adsorption of Co-TPP molecules on structured silicides pads to potentially create contacts between them enabling new environments for the study of molecular circuits.

Group VI Transition metal dichalcogenides MX_2 (T=Mo, W, X=S, Se) crystallize in a layered structure and can be easily cleaved in single- or few-layers like graphene which is a strong candidate for the future electronic devices because of high electron mobility. The weak point of graphene transistor is very low on/off ratio because of metallic character. Recently, single-layer MoS_2 transistor was demonstrated to have high mobility comparable to that of graphene nanoribbons and much higher on/off ratios [1]. Since then, physical properties of single- and few-layer MoS_2 have been intensively studied, but those of other WX_2 have not yet been reported except for theoretical calculations. In this study, Raman and luminescence properties of single- and few-layer crystals of WS_2 , WSe_2 , MoS_2 and MoSe_2 are investigated in order not only to explore layered semiconductors more suitable for electronic devices, but also to understand the underlying mechanism of the physical properties.

Typical Raman spectra of A_{1g} and E_{2g}^1 modes for single-, few-layers and bulk in WS_2 are shown in Fig. 1. The A_{1g} modes upshift with increasing number of layers in the four MX_2 . On the other hand, the E_{2g}^1 modes upshift in WS_2 and WSe_2 , in contrast, they downshift in MoS_2 [2] and MoSe_2 . Moreover, the downshift of E_{2g}^1 mode with increasing number of layers is apparently correlated with anomalous Davydov splitting between E_{2g}^1 and E_{1u} modes in the bulk. The upshift of A_{1g} mode is due to the short-range interlayer interaction, while the metal-dependent frequency trend of E_{2g}^1 mode is explained in terms of a stronger dielectric screening of the long range Coulomb interaction between the effective charges, in the same way as in MoS_2 [3]. According to this interpretation, present result indicates that the dielectric screening in MoX_2 is stronger than that in WX_2 .

Luminescence spectrum of few-layer MX_2 exhibits two peaks corresponding to direct and indirect transitions. The peak intensity of the direct transition considerably decreases with increasing number of layers as found in MoS_2 [4]. The peak energy of

the indirect transition shifts to lower energies with increasing number of layers. Variation of the Raman intensity ratio $I(E_{2g}^1)/I(A_{1g})$ with number of layers, especially apparent in WX_2 , may be related to this energy shift through some resonant effect.

Methodologies for fabrication of functional nanostructures with specific patterns are in the limelight. Above all, thermal agglomeration phenomenon could be considered as a useful tool for bottom-up materials processing. Recently, we developed a new fabrication process for self-organized nanostructure of metal films by using of a bilayer agglomeration (BLA) phenomenon [1, 2]. In this study, we report the nanostructural control of epitaxial Ag on MgO substrates via Ti seed layer mediated BLA phenomenon.

Ag/Ti thin films were deposited by RF magnetron sputtering on MgO(100) and (110) substrates. A Ti seed layer (2 nm) and an Ag layer (2 ~ 10 nm) were deposited on the substrates without any heating. Then, the Ag/Ti layer was annealed for 3 ~ 6 hours to promote the agglomeration.

A variety of surface morphologies were obtained by changing the growth conditions, such as annealing temperature, duration of annealing, Ag layer thickness, substrate orientation, etc. Fig. 1 shows the typical AFM image of surfaces of the Ag/Ti films on the MgO(100) substrate after annealing. Self-organized nanodot arrays were formed. The diameter and height of the majority of the nanodots are 120 ~ 160 and 50 ~ 60 nm, respectively. In the case of Ag/Ti on the twofold symmetry MgO(110) substrate,

a relatively large number of rectangular-shaped nanodots (aspect ratio is about 1.4) are confirmed (Fig. 2). XPS and AES results indicated that the fabricated nanodots were mainly covered with Ag. The results of XRD revealed that Ag/Ti films were epitaxially grown on the substrates; the growth orientations of Ag nanodots resulted in a fcc-Ag(100) and (110) structure on the MgO(100) and MgO(110) substrate, respectively. We also observed surface plasmon resonance spectra of the nanostructured Ag/Ti samples.

Sensitivity in SubSurface-AFM: Tip-Sample Interaction in Heterodyne Force Microscopy

T10 Nanoscience and Technology

#NST-5-Or-7

G. Verbiest, T.H. Oosterkamp, M.J. Rost.

University of Leiden - Leiden (Netherlands).

Experiments in Heterodyne Force Microscopy (HFM) show the possibility to image deeply buried nanoparticles below a surface [1]. In HFM both the tip and the sample are excited at slightly different ultrasonic frequencies in the range of a few MHz such that a difference frequency signal is generated at 1 kHz that contains the subsurface information. However, the contrast mechanism and the motion of the cantilever, which detects the subsurface signal, are not yet understood.

We present both an experimental and a numerical study of the cantilever motion in a HFM mode, where both the ultrasonic frequencies and the difference frequency are far from any resonance of the cantilever [2,3]. The results provide information on the sensitivity to subsurface features.

We calculate and measure the amplitude and phase of the difference frequency generated by the motion of the cantilever. The amplitude shows in both the numerical calculations and the experiments a local maximum in the attractive Van-der-Waals regime and an even higher plateau in the repulsive regime.

Contrarily to what was previously suggested [4], we show how the repulsive part of the tip-sample interaction does generate a signal at the difference frequency.

Nanopatterning of carbon nanotubes such as single wall and cup-stack carbon nanotubes on nanostructured aluminum surfaces

T10 Nanoscience and Technology

#NST/SS-P1-08

Y. Watanabe, R. Takeuchi, M. Mutoh, H. Kato, S. Takemura, K. Shimada, T. Hiramatsu.

Kanto Gakuin University - Yokohama (Japan).

Development of nano-patterning techniques for the application of carbon nanotubes (CNTs) is an important issue for the production of next-generation devices with CNT.¹ The purpose of the present study is to develop patterning techniques for single wall carbon nanotube (SWNT) and cup-stack carbon nanotube (CSCNT) using nanostructured Al surface as a template. Furthermore the authors intend to investigate the local electronic properties of CNT patterns formed on the nanostructured Al surface. Nanoscale trenches and crater structures were fabricated on an Al surfaces by combined process of chemical treatments and anodization. SWNTs dissolved in catechin containing solution under the ultrasonic wave to separate the bundles of carbon nanotubes. Then droplets of this solution were dropped on the Al template utilizing micropipette and were extended on the surface. Fabricated CNTs patterns were analyzed by Atomic Force Microscopy/Current Imaging Tunneling Spectroscopy (AFM/CITS), Dynamic Force Microscopy (DFM) and Laser Raman Spectroscopy. Figure 1 shows AFM/CITS images of SWNTs on Al line structure. SWNTs were clearly localized in the Al trench and across the line structures as shown in Figs. 1 (a) and 1 (b), respectively. The difference in I-V characteristic was observed on the CNTs as shown in Fig. 1 (c). Next nano-contact transcription was conducted to transfer the CNTs pattern to the Si substrate. Nano-contact transcription was performed according to the following steps. A silicon substrate was attached on a CNT deposited Al template and was removed to transfer the CNTs pattern to the Si substrate. A highly oriented CNTs line pattern was obtained on a Si wafer by nano-contact method using an Al line structure as a template. The line-width of CNTs was less than 100 nm and the height was 3nm. In

the measurement of I-V characteristics by point contact, quantum conductivity such as oscillation-type and staircase-type were observed. On the other hand, in the case of CSCNT deposited on the nanostructured Al surface, the DFM image shows that the CNTs are significantly bending and networking with other tubes. Isolated single CSCNT image was also obtained. Local IV characteristic were also obtained by point-contact indicating that non-linear conductivity associated with negative resistivity. This work was aided by MEXT-supported Program for the Strategic Research Foundation at Private Universities.

Superconducting gap of beta-HfNCl investigated by scanning tunneling microscopy/spectroscopy and break-junction tunneling

T10 Nanoscience and Technology

#NST/SS-3-Or-2

T. Ekino ¹, A. Sugimoto ¹, A. Gabovich ², Z. Zheng ¹, S. Yamanaka ¹.

¹Hiroshima University - Higashi-Hiroshima (Japan), ²Institute of Physics - Kiev (Ukraine).

It is well known that electron doping of the layered compounds β -MnCl makes them superconducting with the critical temperature $T_c = 14$ K ($M = \text{Zr}$) – 26 K (Hf) [1]. Since T_c is relatively high, a question arises about the relevant superconductivity mechanism.

Our previous experiments using scanning-tunneling microscopy/spectroscopy (STM/STS) and break-junction tunneling spectroscopy (BJTS) clarified unexpectedly large superconducting gap (2Δ) with the ratio $2\Delta/k_B T_c$ up to ~ 10 or more [2, 3]. Such a huge ratio in contrast to the weak-coupling BCS one 3.5 cannot be explained in the framework of the conventional approach. In particular, the density functional theory indicates that the strong-coupling electron-phonon Migdal-Eliashberg theory fails to explain superconductivity of β -MnCl [4]. Therefore, further systematic measurements are necessary to elucidate the nature of superconductivity in β -MnCl.

In this paper, properties of temperature, T , evolution of the local gap Δ in β -HfNCl_x ($x = 0.7$) are examined by STM/STS with atomic resolution as well as BJTS measurements.

STM/STS studies were carried out with a micro single crystal and a PtIr tip under $\sim 10^{-8}$ Pa. At the lowest $T = 4.9$ K, the STM image of the ab plane shows a triangular lattice of Hf atoms with a period of ~ 0.37 nm, which agrees with the X-ray diffraction measurements. The local STS conductance $G(V)$ exhibits broadened gap structures, showing rather homogeneous magnitudes within the area of ~ 100 nm² as compared with the results for isostructural ZrNCl_x.

A remarkable feature of $G(V)$ mappings is that the gap distribution systematically varies with T . At 5 K, the spatially averaged gap value defined by the peak-to-peak distance of $G(V)$ is $\Delta_{\text{ave}} \sim 11 - 13$ meV. The gap distribution widely spreads up to \sim

30 meV, while rather sharp cutoff of the tail occurs at 6 - 8 meV. The upper-boundary of ~ 30 meV in the distribution occupies only a few \sim nm domains. Such features are very similar to the gap distribution of β -ZrNCl_x. They are most probably due to the electronic inhomogeneity rather than the bulk crystallographic one, because we observed such an inhomogeneity simultaneously in the regular atomic lattice arrangement on the surface.

At $T = 20$ K, the distribution profile changes, namely, Δ_{ave} is decreased to ~ 7 meV, showing the spread up to ~ 15 meV along with the gapless tail. It means that the local Cooper pairing in some \sim nm regions is kept almost unchanged upon warming, while superconductivity in other surface areas is reduced much faster than what would be expected from the mean-field thermal behavior. This circumstance may be the origin of the unusual T -dependence of the gap value in this compound previously found by BJTS [2]. Wide gap distributions with large maximum gap features are discussed in more detail for β -MNCl_x ($M = \text{Hf}, \text{Zr}$) and α -TiNCl with different crystal structures [3].

Graphene, a very promising material studied extensively in the last decade, is a two dimensional material composed of carbon atoms formed into a honeycomb lattice. It is a building material for other graphitic forms – fullerenes, carbon nanotubes and, of course, graphite. Graphene has extraordinary properties due to its limited dimensions in one direction, primarily low resistance, high mobility and very high transparency for light. Its conductivity can be continuously changed from n-type to p-type due to an ambipolar electric field effect [1]. These properties and also high sensitivity, fast response in electrical properties, and large surface to volume ratio make graphene a very promising candidate for utilization in different types of sensors [2, 3]. As a rule, graphene oxide films are widely used for these purposes. In our work the humidity sensing properties of pure graphene itself have been studied. Graphene was prepared by two methods – the chemical vapor deposition (CVD) and as a reduced graphene oxide by modified Hummer's method. Both types of graphene were transferred onto a dielectric substrate (280 nm SiO₂/Si). The metal contacts on graphene were prepared by electron beam lithography for the measurement of its electrical properties. The resistivity was measured by the 2-point method and its changes were observed in dependence on relative humidity changes. Relative humidity ranged from 10 to 80 %. It was found that graphene resistivity was growing with relative humidity and the sensing response was very fast.

The semiconductors of the group IV are the basic materials in microelectronics. Because of the indirect nature of their band gap, it was necessary to proceed to researches on the semiconductors of III-V group (GaAs, GaInN ...) and II-VI group (CdTe) to use their capability as light emitters in optoelectronics devices. Contrary to Si, germanium presents an interesting optical property, that its gap direct is only at 0.14 eV above the indirect one, while for Si this interval is about 2 eV. Theoretically, it has been demonstrated that the Ge gap could be a direct one under a tensile strain of 1.4%, opening the way towards the realization of optoelectronic devices compatible with the microelectronic technology [1]. One of the experimental approaches to introduce a tensile strain in the film is to deposit Ge on a substrate that has a larger lattice constant. In this context the Ge epitaxy on In_xGa_{1-x}As/GaAs substrate has been recently studied, with x ranges between 4.8% and 21% [2, 3]. However, for higher indium content, the use of the substrate In_xGa_{1-x}As on GaAs becomes very difficult due to the surface roughness and the threading dislocations. In order to study the growth of Ge on a substrate with relatively high lattice mismatch (In-content more than 21%), we used In_{0.53}Ga_{0.47}As buffer layers deposited on InP substrates. Taking into account that In_{0.53}Ga_{0.47}As and InP have the same lattice constant, the In_{0.53}Ga_{0.47}As buffer layer does not contain dislocations, and its surface

is atomically flat. The lattice mismatch between Ge and $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ is of 3.7%, which presents probably the largest value up to now. We carried out a preliminary study on growth of Ge on GaAs in order to optimize the Ge growth parameters. We have found that the growth mode is layer-by-layer for the temperature range [RT; 550°C], and films of a good crystalline quality could be made on GaAs As-rich (2x4)-reconstructed substrates. After that, we have studied the growth of Ge on the As-rich (2x4)-reconstructed $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ surface as a function of the growth temperature (T_C). The growth on $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$ follows the Stranski-Krastanov mechanism. The RHEED analysis shows that the critical thickness corresponding to the 2D-3D nucleation decreases when T_C is increased: 3 monolayers for the deposition at RT and 300°C, whereas 1 ML at 450°C. Several types of island morphologies have been observed. Analysis by photoluminescence (PL) spectroscopy will be done in order to estimate the confinement effects as a function of the islands size.

Electrochemical impedance spectroscopy as a method to control nanowire array quality in porous template

T10 Nanoscience and Technology

#NST-P1-03

G. Kunakova ¹, J. Katkevics ², A. Viksna ², Z. Alute ¹, J.D. Holmes ³, D. Erts ¹.

¹Institute of Chemical Physics, University of Latvia - Riga (Latvia), ²Department of Analytical Chemistry, University of Latvia - Riga (Latvia), ³University College Cork - Cork (Ireland).

Nanowires are eligible for application in different electrical devices as functional and constructional elements. To obtain high density architectures for integrated elements, it is convenient to employ nanowire arrays. Although various approaches of nanowires array fabrication have been shown, the template methods present the most advantages, e.g. nanowires are well aligned and mutually isolated [1]. To characterize template grown arrays, it is important to determine nanowire filling quality into a porous template. Conductive AFM measurements can be used for conductance mapping of small areas [2]. However this approach is incapable to do analysis in a range of several square centimeters. In this work we have applied the electrochemical impedance spectroscopy (EIS) as none-destructive method to determine nanowires' filling quality in a porous template combined with electrochemical characterization.

EIS characterization was performed on Bi₂S₃ nanowire arrays grown in anodic aluminum oxide membranes (AAO). Samples ranging in density of nanowire filling from 77% to 99% of nanowires in AAO template as well as an empty AAO reference sample were analyzed. To measure such fragile samples, a specific electrochemical cell with small total volume of electrolyte was fabricated. Measurements were done with a potentiostat "Autolab PGSTA 30" and impedance spectra were analyzed using a program Frequency Response Analysis (FRA) to determine the equivalent electrical circuit and separate impedance element values.

EIS data of empty AAO and Bi₂S₃/AAO samples we interpreted with equivalent circuit model $R_e([R_2(R_3Q_2)]C_1)$, where R_e is electrolyte resistance; R_2 is electrolyte resistance with nanowires in nanopores; R_3 and Q_2 – resistance and capacitance in nanopores; C_1 – capacitance of aluminum oxide nanopores walls. Analysis of the values of individual elements such as R_2 , C_1 and impedance modulus for high and low nanowire filling density samples showed a specific correlation between these values and nanowire filling density thus indicating on nanowire array quality in porous template.

FMMM/NST-P3-04

Functionalisation and charatcterisation of the Porous Silicon Nanostructure by the peptide Gly-Cys-Gly-Cys

T10 Nanoscience and Technology

#FMMM/NST-P3-04

C. Yaddaden, S. Sam.

CRTSE - Algiers (Algeria).

Hybrid nanomaterials based on organic layer covalently grafted on porous silicon PSi nanostructure appear as promising systems for innovative applications [1]. In this work, we focused on the functionalization of the PSi nanostructure by the peptide Gly-Cys-Gly-Cys, which forms stable complexes with metal ions. This property is exploited to realize toxic metal recognition in water.

The immobilization was achieved using multi-step reactions: Gly-Cys-Gly-Cys was anchored on a previously prepared carboxyl-terminated PSi surface using EDC/NHS coupling agents. This scheme is compatible with the mild conditions required for preserving the probe activity of the peptide. At each step of the functionalization, the surface was monitored by infrared spectroscopy Fourier transform (FTIR) and X-ray photoelectron spectroscopy (XPS).

Electrochemical behaviour of such prepared electrodes was carried out in the presence of copper ions by means of cyclic voltammetry [2]. The recorded cyclic voltammograms showed a quasi-irreversible process corresponding to the Ni²⁺/Ni⁰ couple.

These results demonstrate the potential role of peptide-modified PSi nanostructures in developing strategies for simple and fast detection of metal ions in solution.

Carbon drawn graphene films on nanostructured aluminum surfaces

T10 Nanoscience and Technology

#NST/SS-P1-10

S. Takemura, T. Hirakawa, K. Doi, H. Kato, T. Hiramatsu.

Kanto Gakuin University - Yokohama (Japan).

In the present study, the authors focused on fabrication of graphene on nanostructured surfaces by carbon drawing method using HOPG. The carbon drawing method is simpler than the taping method. It is expected that carbon drawing method is also applicable to non-flat surfaces. In the present study, the authors performed carbon drawing method to drag it along nanostructured Al surfaces. Two Al samples were made by immersion in acid solutions. As for the first sample, an Al substrate was immersed in 0.1M H₂SO₄ solution at 35°C for 24 hours. An Al plate was immersed in 0.1M H₃PO₄ solution at 4°C for 1 week for the second sample. Then anodization was performed for acquisition of finer nanostructures on the surfaces. Then, carbon drawing was performed on the nanostructured surfaces using HOPG whose surface was renewed by peeling surface layers off with using scotch tape before carbon drawing. Rhombic-shaped craters whose diameters were about 100-200 nm were created on the surface treated with H₂SO₄ [Fig. 1(a)]. After drawing, terrace-like structure was observed whose height was about 20 nm [Fig. 1(b)]. In the Raman spectrum, some characteristic peaks due to carbon such as G, D, and G' bands were observed after drawing. If G/G' is equal to 1.8, the number of graphene layer is 23.¹ In this case, G/G' is about 2.0. This result shows that the number of graphene layer is estimated at over 23. Carbon drawing was performed also on the Al surface treated with H₃PO₄. Rhombic-shaped craters whose diameters were about 600-700 nm were created on the chemically treated Al surface. In this case, a thick film was obtained whose thickness was about 500 nm corresponding to 500 layers. Because the size of craters formed on the Al surface was larger than the former sample, it suggests that graphite layers are more easily peeled off from HOPG. In this case, G/G' is about 2.5 in the Raman spectrum. Both samples have D band, so graphene films in both samples are distorted. Since the intensity of D band in the former sample is less than the latter sample, thin film of former sample is not less distorted than the latter sample. The current image after drawing was obtained by atomic force microscopy/current image tunneling spectroscopy (AFM-CITS)

measurements. Current is not flowing along a cliff formed on the film surface. A characteristic I-V curve was obtained also at the edge of the film, which indicates quantum conduction. This work was aided by MEXT-supported Program for the Strategic Research Foundation at Private Universities.

Solid-liquid interfaces play a fundamental role in many biomolecular and electrochemical applications at the nanoscale. Although spectroscopy and diffraction techniques can provide very accurate information about such interfaces, atomic force microscopy (AFM) has the advantage of probing the investigated system locally, thus allowing a deeper understanding of interfaces. Latest developments in frequency modulated AFM (FM-AFM) have opened up a way to observe interfacial liquid structures as a function of the vertical and lateral coordinates [1]. Recently experiments on the p-nitroaniline (101) crystal surfaces in water have been performed in order to better understand the stability and the mechanisms of nucleation or dissolution at crystal surfaces [2]. p-Nitroaniline is an organic compound containing polar NH₂ and NO₂ groups at opposite ends of a benzene ring, and although being a relative simple compound, it gives rise to enough complexity to serve as an excellent experimental test case.

In the experiments clear structuring of the water at the interface is observed. In order to enhance the insight obtained through the FM-AFM experiments on these p-nitroaniline-water interfaces, we performed both DFT and large-scale molecular dynamics simulations of this system. In these simulations we observed that the (101) crystal surface differs considerably from the same surface based on existing crystallographic data [3, 4], giving rise to a more elaborate description of the water interface structure observed in the experiments. As such the computer simulations proved to be an important addition for better understanding the AFM experiments.

Among the ferroelectrics, the layered-perovskite lanthanum dititanate oxide La₂Ti₂O₇ (LTO) is a very promising lead-free ferroelectric material, due to its super-high Curie temperature (TC ~1500°C) and piezoelectric behavior which allow the development of high-temperature devices such as transducers for motor and spatial industry and applications in extreme environments.

In this study, such compounds were grown in thin film form on SrTiO₃ substrates by a sol-gel route.[1] At the nanoscale, both poling experiments performed by the tip of atomic force microscope and the existence of local piezoresponse loops within the domains confirm the piezoelectric behavior of the films.[2] Islands in the lateral range 300-500 nm have been successfully fabricated by focused Ga⁺ ion beam (FIB) etching on platinum top electrode. The impact of Ga⁺ FIB about functional properties of continuous and nanostructured crystallized piezoelectric thin films of LTO has been investigated on the nanoscale by scanning probe microscopy. Modifications of both surface and electrical behavior for area exposed to ion irradiation are revealed by dynamic force mode and Kelvin force microscopies. Nevertheless, local piezoactivity is still detected confirming the highly resistance of this material to ion-beam.[3] Nanoscale electromechanical response is measured inside these nanostructures by piezoresponse force microscopy. In this case, the local piezosignal

is measured at similar level that the one obtained for the unetched film evidencing no manifest sidewall effect, and this without usual post-annealing treatment for recovering functional properties.[4] Consequently, this study demonstrates that LTO material as well as FIB technique are suitable and promising to pattern such low-dimensional nanostructures, allowing the application of such lead-free piezoelectric thin films in the field of nanoelectromechanical systems.

NST/SS-P1-11

Fabrication and Electrical Transport Measurements of Graphene Devices with End-Contact Geometry

T10 Nanoscience and Technology

#NST/SS-P1-11

Y. Sung, A. Subagyo, K. Sueoka.

**Graduate School of Information Science and Technology, Hokkaido University
- Sapporo (Japan).**

The contact properties between metal electrodes and graphene in graphene devices are crucial to the device performance. Various metals such as Ni, Pd, Au, Pt, Cr, Al and Cu have been applied for fabricating the graphene devices. The device performances have been found to strongly depend on the metal species due to the variation of the contact resistance such as the variation of ON current and carrier mobility in graphene field effect transistors [1-4]. In general, high work function metals such as Pd, Ni and Au provide a low contact resistance and, therefore, are routinely applied for graphene devices. However, the improvement of contact properties is still needed, for example, for high speed electronic application. In this work, we propose a fabrication method for realization graphene devices with end-contact (EC) geometry which has been predicted to form lower contact resistance than the commonly fabricated geometry, i.e. side-contact (SC) [5]. The difference in chemical bonding of end-contact and side-contact geometries is the major key for the improved junction properties. The fabrication of end-contact geometry, however, is much more difficult since metals should be vertically contacted to graphene's edges so that the contact length is limited to the nanometers range. Therefore, the development of a fabrication method of EC geometry is a challenge.

We have fabricated side-contacted devices and end-contacted devices on the same graphene channel for direct comparison. Several devices with channel length between 0.5 and 3 μm are fabricated for both SC and EC devices. The transmission line method is used to estimate the contact resistance. The graphene layers were prepared by mechanical exfoliation using a Scotch tape from HOPG and direct transfer into a highly doped Si substrate covered with 285 nm-thick SiO_2 . The number of the graphene layer was determined by Raman spectroscopy and atomic force microscopy measurements. The graphene channel with 1 μm in width and several tenths μm in length is obtained by electron beam lithography patterning and

O₂ plasma etching. Firstly, the SC devices were fabricated by EB patterning and Au-covered Ni electrode deposition. After patterning the electrode areas of EC devices with the same channel length to the SC, the exposed graphene of the patterned areas was removed by Ar⁺ ion etching. In this step, several nanometers of SiO₂ under the graphene are removed altogether to allow perpendicular contact between graphene edges and metal electrode. Finally, Au-covered Ni electrodes of similar thickness to SC devices were deposited. The transport properties were evaluated using semiconductor parameter analyzer with the Si substrate as a backgate. The transport characteristics of both SC and EC devices showed field-effect modulation, but had different contact resistance. The comparison with devices using other metals such as Pd and Au is what we are interested in.

Unique electronic properties make graphene an appealing candidate for novel non-silicon-based electronics. In particular, graphene synthesized on commercially available cubic-SiC(001)/Si(001) wafers could be adapted for graphene-based electronic technologies and directly patterned using Si-electronic lithographic processes. The first reports on graphene growth on the surface of cubic-SiC(001) thin films deposited on Si wafers have been published recently [1,2]. However, they do not provide detailed information on the atomic structure of the graphene overlayer on the SiC(001) surface, its thickness, quality and continuity on a wafer scale. Here we present results of comprehensive atomically resolved scanning tunneling microscopy (STM) and low energy electron diffraction (LEED) studies of graphene layer synthesized on SiC(001). Uniform graphene layers were fabricated on SiC(001)/Si(001) wafers using Si-atom sublimation followed by SiC surface layer graphitization during high-temperature annealing in ultrahigh vacuum. Si-rich 3x2 and 5x2, Si-terminated stoichiometric c(4x2), C-terminated stoichiometric SiC(001)-c(2x2) reconstructions and graphene monolayer on SiC(001) were successively fabricated with increasing annealing temperatures. The atomic structure of the SiC(001) surface on different stages of graphene synthesis and its dependence on the applied sample treatment procedure have been thoroughly studied in-situ by STM and LEED. The results show that graphene monolayer on SiC(001) is continuous

throughout the millimeter-sized samples and consists of rotated nanometer-sized domains with four different lattice orientations connected through the grain boundaries (Fig. 1a). The domains possess atomic and electronic structure typical of single layer graphene. STM image in Fig. 1b demonstrates atomic-scale rippling and asymmetric distributions of carbon-carbon bond lengths typical of free-standing graphene layer [3]. Controlled plasma modification of mono- and bi-layer graphene

T10 Nanoscience and Technology

#NST/SS-5-Or-9

A. Felten ¹, A. Eckmann ², J.J. Pireaux ¹, C. Casiraghi ³.

¹Research Center in Physics of Matter and Radiation (PMR), University of Namur - Namur (Belgium), ²of Physics and Astronomy, University of Manchester - Manchester (United kingdom), ³School of Chemistry and Photon Science Institute, Manchester University - Manchester (United kingdom).

Graphene has recently been proposed as one of the basic building block for nanoelectronics. The ultimate 2D character of the material confers exceptional electronic properties such as outstanding carrier mobility and unusual quantum effect. Unfortunately, the pursuit for applications is impeded by its metallic behavior making it hard to create graphene based transistors. In order to overcome this problem, various approaches to tune and control the electronic properties of graphene have been considered.

In this work, we investigate the controlled modification of mono- and bi-layer graphene using oxygen (O₂) [1], hydrogen (H₂) and tetrafluoromethane (CF₄) plasma treatments. All plasma treatments have been carried out in the same plasma system in order to allow comparison of the results. Chemical functionalization is confirmed by micro-XPS measurements on exfoliated modified graphene. For example, figure 1a shows the C1s spectrum of oxygen plasma modified bilayer and pristine bilayer. The functionalized bilayer presents a shoulder at high binding energy (286-289 eV) corresponding to carbon-oxygen bonds. Structural changes induced on the graphene flakes are monitored using Raman spectroscopy [2]. Figure 1b shows the Raman spectra of pristine and oxygen modified monolayer graphene. After oxygen plasma exposure, new features corresponding to defect activated bands are appearing in the Raman spectra. The most prominent ones are the so called D and D' bands at ~1340 cm⁻¹ and ~1620 cm⁻¹ respectively. Changes in G, D, D' and 2D Raman peaks frequencies and shapes are studied after different plasma treatment conditions.

We show that hydrogen, oxygen and fluorine atoms are grafted on the graphene surface and that a controllable modification can be achieved by varying different

plasma parameters such as plasma power, exposure time, position of the sample inside the chamber and the type of gas. In addition, defect formation kinetics under rf-plasma is found to vary with the number of graphene layers.

Semiconducting polymers have been widely studied for applications in semiconductor devices such as solar cells, light-emitting diodes and thin film transistors. Usually such studies were performed on amorphous thin molecular films [1]. Here, we explore the possibilities to study single crystals as channels for charge carrier transport in a transistor structure. We used long (up to 50 μm) needle-shaped and well characterized single crystals made of 8-hexyl-thiophene (TH8) molecules, prepared in solution and deposited on a field-effect transistor (FET) structures [2]. The electrical properties of these crystals were measured by conductive atomic force microscope (C-AFM) in air. Moreover, the measured I-V characteristics were fitted with the space charge limited current model and values of charge carrier (hole) mobility have been extracted. As first indicated by Reid et al. [3], we also found that this model overestimates the charge carrier mobility. For C-AFM measurements, the standard Mott-Gurney law cannot be used to fit the measured I-Vs. A semi-empirical model has been proposed which takes into account the ratio of the distance between the macroscopic electrode and the AFM tip to the contact area diameter of the tip. Using the semi-empirical expression of the I-V characteristics proposed in [3], we have extracted values of the mobility of charge carriers. We have studied hole mobility for different crystals and found that current increases with crystal thickness. Knowing the internal structure of the single crystals from selected-area electron diffraction analyses (SAED) [2], we expected an anisotropic charge transport with different mobilities in the direction of π stacking (i.e. along the long axis of the crystal) and along the molecular axis which is oriented in the direction normal to the crystal

surface. The increase of the mobility with crystal thickness is associated to an increased contribution of current in the direction of the molecular axis which suggests a significant conjugation of molecular orbital along this direction.

NST-6-Or-4

Photovoltaic application of titanium oxide nanoparticles synthesized by laser pyrolysis

T10 Nanoscience and Technology

#NST-6-Or-4

J. Wang ¹, J. Bouclé ², Y. Leconte ¹, A. Habert ¹, C. Di Bin ², B. Ratier ², N. Herlin-Boime ¹.

¹IRAMIS/SPAM/LFP, CEA-CNRS URA 2453, CEA de Saclay - 91191 Gif Sur Yvette (France), ²XLIM UMR 7252, Université de Limoges/CNRS - 87060 Limoges (France).

The titanium dioxide (TiO₂) is widely used as pigment, or in paints, toothpastes, as well as for photo-catalysis. Over the past decades, since the dye sensitized solar cells (DSCs) were introduced by M.Grätzel in 1991 ^[1], TiO₂ attracted great interest due to its crucial role as meso-porous electrodes. A very active field of research corresponds to the synthesis of oxide materials absorbing a fraction of the solar spectrum in order to improve the efficiency of solar cells. In this context, this work deals with the development of solid-state DSCs based on titanium dioxide (TiO₂) nanocrystals synthesized by laser pyrolysis. Compared to conventional sol-gel synthesis procedure, the laser pyrolysis^[2, 3] method, based on the interaction of a powerful infrared laser beam with a mixture of gaseous or liquid precursors (titanium tetraisopropoxide in the present study), appears as a versatile and efficient way to produce a large variety of well-controlled titanium oxide based nanopowders as well as “doped” nano-TiO₂ by simple introduction of another reactant in the precursor (i.e. NH₃ for N-TiO₂). By varying the power of laser and the flow of carrier gas, we obtained titanium dioxide nanoparticles with controlled particle sizes about 20 nm and controlled crystalline phase (anatase). Moreover, nanoparticles “doped” with different Nitrogen contents were obtained by changing the flow of NH₃. Figure 1 presented a significant augmentation in the UV-visible optical absorption spectra as a function of the nitrogen content. XPS was also used to characterize the role of nitrogen in the structure. We observed that the performances of cells elaborated from N-doped or non-doped nanoparticles are comparable, but specific features are revealed in their IPCE (Incident Photon-to-current conversion efficiency) spectra. An increase of

quantum efficiency is observed in the absorption range of the metal oxide, but no clear interpretation on the corresponding charge generation mechanisms are given up to now^[4]. By introducing very large flow of NH₃, an original titanium oxide TiO_x (x = 1-2) material with a low band gap energy (≈2 eV) was synthesized and used in solid-state DSCs. At the same time, we also synthesized TiO₂ nanoparticles doped with metallic elements such as gold, the first results of the DSCs with this kind of powder are encouraging.

MicroRNA are short (20–30 nucleotides) noncoding RNAs which are processed from endogenously expressed pri-miRNAs by enzymes in several steps. Mature miRNAs are found in the cytoplasm as single-stranded molecules loaded in protein complexes whose primary function consists of mRNA silencing. However, there are evidences that miRNAs can be excreted by cells and the level of circulating miRNAs changes under specific conditions such as in the presence of tumor. Circulating miRNAs are therefore promising non-invasive tumor biomarkers whose abnormal expression in body fluids suggests pathological conditions. Current methods for extracellular miRNAs purification are challenging, mainly due to low body fluid concentration, variability, quantification limits. Here we present the development and functionalization of a silicon-based surface able to selectively bind circulating miRNAs from complex biological samples. Silicon-based surfaces have been functionalized with positive or neutral or mixed molecules in order to have surfaces with different net charge or with different functional moieties. Complementary nucleic acid sequences has also been exploited for the purification of selected miRNAs. Synthetic miRNAs coupled or not with a fluorophore (miR-21 and miR-16, significantly overexpressed in cancer cells) have been incubated on these surfaces and the absorption/release rate has been determined. Different conditions in terms of pH, charge, buffer solutions, mixture of miRNA/total RNA/DNA/proteins have been tested, as well as the purification from cell culture supernatantes (MCF7 and other tumor lines) or patients sera. Moreover, since most of the circulating miRNA are present in exosomes, a functional surface for the purification of miRNA in exosomes has also been developed. Specific

functionalizations have been set up to capture circulating intact exosomes which will be lysed in a second step to release miRNAs. To verify the efficiency of the new solid-state purification, the obtained miRNAs were both stained with specific dyes (e.g. RiboGreen) and quantified via two-step RT-PCR. The latter method was tested in standard conditions, i.e. commercial kit and thermalcycler, but a dedicated micro-module, consisting of a fluidic chamber where RT-PCR is performed, has also been implemented. In fact, the great potential of the innovative solid-state miRNA purification is the possible inclusion in a lab-on-chip device able to process biological fluids, purifying the included microRNAs and analyze their presence/quantity in order to correlate to tumor diseases with diagnostic purpose.

This work was accomplished in the framework of NEWTON (Advanced nanosystems for a new era in molecular oncology) funded by MIUR (Italian Ministry for Education, University and Research) grants-FIRB 2012-2016-for public/private structures involved in research fields characterized by strategic value.

The magnetic moment of an organic radical molecule, if it survives adsorption on a metallic surface, is generally screened at low temperatures by the metal conduction electrons. The resulting Kondo effect causes a characteristic zero bias anomaly in the electron tunneling conductance, similar to that observed for transition metal adatoms. We report joint ab initio theory/scanning tunneling spectroscopy investigations of the Kondo zero bias anomalies in nitric oxide adsorbed on Au(111). Density functional theory calculations predict that NO maintains a $S=1/2$ and adsorbs N-down at the top site of Au with a tilt angle of approximately 60 degrees, breaking the degeneracy of the singly occupied $2\pi^*$ orbitals. Subsequent numerical many-body renormalization group calculations based entirely on ab initio input predict a Kondo temperature of 20 K in close agreement with experiment. The calculations find that the Kondo resonance occurs not in the strongly hybridized $2\pi^*$ -derived orbital but, surprisingly, in the weakly hybridized one. A second case we consider theoretically is the stable α,γ -bis(diphenylene)- β -phenylallyl (BDPA) radical, which the Linz group is studying on Au(111) [1], and which also displays a Kondo effect [2]. We attempt to understand the observed anomaly and its evolution from monomers to dimers and trimers through ab initio and numerical renormalization group calculations.

NST-P2-04

Influence of the field gradient in force detected spectroscopy

T10 Nanoscience and Technology

#NST-P2-04

S. Won, J. Heo.

Korea Institute of Materials Science - Changwon (Korea, republic of).

We review how a force spectroscopy can be applied to perform magnetic resonance spectroscopy of nanometer scale sample. As a result of mechanical detection of magnetic resonance, the substantial improvement is achieved in both signal sensitivity and spatial resolution. In this technique, one of the most important things to determine the high resolution is the magnetic field gradient apart from the thermal motion of the cantilever. It defines a thin shell on constant field in the sample. We report our experimental results on detecting isolated electron spins in a different field gradient, with an inferred resonance slice thickness. Our results are extracted from the DPPH thin film using force detected ESR microscopy. Such measurements allow reliable prediction of the force signal strength and allow force detected spectroscopy experiments to proceed with confidence. With cylindrical iron magnet, the first harmonic coupling of an amplitude modulated spin polarization is measured as a cantilever frequency shift with theoretical predictions. From these results, we suggest that the experiment can be optimized with selective magnet. A home-built force probe was used to measure the signal and systems are well optimized with our equipment.

Magnetotransport studies of few layer graphene (FLG) were performed on samples obtained by chemical vapour deposition on semi-insulating SiC [1]. Two polarities of the substrate were used. FLG was processed by means of optical lithography into relatively large hall bars (526 μ m x 263 μ m) with Ti/Au metallization used for ohmic contacts. Transport measurements were performed in an Oxford Instruments VTI system in temperatures ranging from room temperature down to 1.5 K and magnetic fields up to 12T, with additional illumination of the samples at low temperatures. The samples exhibited significant differences in the electrical properties for the two polarities. The samples grown on the silicon (0001) polarity showed quantum oscillations of the resistivity tensor. They had electron conductivity with Hall mobility of the order of 1000 cm²/V·s and Hall concentration of about 3·10¹² cm⁻². The samples prepared on carbon-terminated SiC were n-type with significant contribution of holes [2] with Hall concentration of 3·10¹³ cm⁻² and Hall mobility few times lower. No oscillations were registered for that group of samples. We have observed that the samples grown on Si-terminated SiC were very sensitive to external environment (making FLG a potentially sensing material), to thermal cycles and exposure to light. In particular, they showed changes of the order of a few % after each thermal cycle while those grown on C-terminated SiC were stable (samples were kept under He atmosphere at all times). Looking for the possible explanation we performed subsequent experiments with illumination of the samples at low temperatures. The behaviour of the samples grown on Si-polarity SiC was influenced by light whereas

the other samples showed no such sensitivity. This diverse response of FLG to thermal cycles and light is discussed in this report.

High energy electron irradiation to carbon nanomaterials is expected to become a technique to tailor the structure with desirable properties [1]. However, the mechanical properties of electron-irradiated carbon nanomaterials are not well understood. In our previous study, we developed molecular dynamics (MD) simulation including electron collision effects to study the structural changes of carbon nanotubes (CNTs) under electron beam irradiation [2]. In the present work, electron irradiation effects on atomic stress variation of CNTs are studied with the simulation.

Figure 1 shows the atomic stress distributions of (10, 0) SWNT with no defect during compression ((a) $\epsilon = 0.00$, (b) $\epsilon = 0.08$) and stress-strain characteristics of atoms near the center and edge ((c)). During the compression, the stress is uniformly applied to the whole CNT surface and the CNT is elastically deformed to the yielding point. Figure 2 shows the atomic stress distributions of (10, 0) SWNT with 5ns irradiation during compression ((a) $\epsilon = 0.00$, (b) $\epsilon = 0.08$) and stress-strain characteristics of atoms near the center and edge ((c)). As shown in Fig. 2(a), residual stress arises due to the defect produced by the electron irradiation. On the other hand, as shown in Fig. 2(b) and (c), the stress concentrates around the defect as the CNT is gradually compressed.

DNA hybridization assays are widely employed in molecular biology and for forensic tests. Next to the traditional fluorescent-based DNA assays, biosensors taking advantage of the plasmonic properties of metal films and nanostructures have emerged as alternative methods for detecting DNA hybridization with lower cost and high sensitivity. Localized surface plasmon resonance (LSPR) sensors, employing noble metal nanostructures, have lately attracted considerable attention as a new class of plasmonic nanosensors.^{8, 9} The detection principle is based on the fact that the position of the nanoparticles extinction maximum is highly dependent on the local refractive index of the nanoparticles and biomolecular binding/unbinding events can be followed in real-time by monitoring the temporal variation in the LSPR signal. However, sensitivity loss can arise when LSPR sensors are functionalized with long surface ligands, as is the case for the linking of oligonucleotides to LSPR interfaces. In an attempt to enhance the sensitivity of LSPR interfaces for the detection of hybridization events, we developed a new detection strategy. The approach is based on the amplification of the wavelength shift of a multilayered localized surface plasmon resonance (LSPR) sensor interface upon hybridization with gold-nanorods and gold-nanostars labeled DNA (Figure 1) as well as by recording the plasmonic signal of the gold-labeled DNA upon hybridization. The amplification of the wavelength shift, produced by plasmonic coupling between the gold particle label and the gold nanostructures on the LSPR interface, results in a significant decrease of the limit of detection from ≈ 40 nM as observed for unlabeled DNA to 200 pM for the labeled DNA. The shape of the nanostructures seems not to influence strongly the degree of coupling as seen in a similar shift of the LSPR

sensors wavelength upon DNA hybridization. However, the structure of the labels becomes of interest if its plasmonic characteristics themselves are used for the detection of a successful hybridization event. Both approaches will be compared and discussed.

LSPR based detection of DNA hybridization with and without gold labeled DNA.

EVALUATION OF HEAT CAPACITY OF

BENZOXAZINE/CNT

NANOCOMPOSITES WITH

AEROSPACE APPLICATION

T10 Nanoscience and Technology

#NST-12-Or-7

F. Untem, M. Costa, E. Botelho, M. Rezende.

UNESP - Guaratinguetá (Brazil).

The benzoxazine resin is a new class of thermoset phenolic resin, which is presenting, in the last decades, a great application in the aircraft industry due mainly to its excellent mechanical and thermal properties. This resin associates the mechanical properties of epoxy resin with the thermal and flame retardant properties of phenolic resin. Besides, polybenzoxazines do not need catalyst, they do not generate by products during its curing and they can be stored at ambient conditions. Therefore, they are considered polymers of elevated performance and they are excellent candidates to substitute the current thermoset matrices used in the processing of high performance composites, either reinforced with continuous fibers or nanometric structures. In this study, this matrix was reinforced with multiwalled carbon nanotubes (MWCNT) in different concentrations (0.1%, 0.5% and 1.0% w/w), in order to promote better properties in relation to the neat benzoxazine resin. The main goal of this work is to evaluate the influence of different amount of MWCNT on the heat capacity (C_p) of the Benzoxazine/CNT nanocomposites using differential scanning calorimetry (DSC) and the analysis of the interactions between the composite's matrix and reinforcement, using scanning electron microscopy (SEM).

The determination of nanostructured composites' heat capacity was performed using the Perkin Elmer's equipment, model Pyris 1. There were used samples of 10 mg, with a constant flow of nitrogen ($10 \text{ mL}\cdot\text{min}^{-1}$), at a heating rate of $20^\circ\text{C}/\text{min}$, ranging the temperature from 10°C to 100°C . It was necessary to do the tests at the same conditions for the sample, the standard (sapphire) and the empty container (alumina). The softwares DSC Subtraction and DSC C_p , version 5.7, from EXSTAR6000 System were used to determine the C_p .

The environmental scanning electron microscopy (ESEM) was performed on a Zeiss EVO LS-15, with tungsten hairpin thermionic type electron gun. It was operated at chamber pressures from 10 to 50 Pa with pressure limiting apertures (100 μm and 500 μm with beam sleeve) for in-lens pumping, using nitrogen gas atmosphere to neutralize the electrons charge up effects under Zeiss extended pressure mode, allowing working with samples without metallization process. The analyses were performed with the use of scintillation type variable-pressure secondary electrons (VPSE) detector with accelerating voltage of 5 kV to avoid sample degradation.

Based on the results, it can be infer that the concentration of the CNT influences the values of the C_p of the composites Benzoxazine/CNT. At 25°C, the values obtained were 1.241 J/g°C for the concentration of 0.1% w/w and 1.690 J/g°C for 1.0% w/w, while at 80°C, these values got up to 1.555 J/g°C and 2.341 J/g°C, respectively, indicating that the CNT addition improves significantly this property. The results obtained by SEM's tests better explain the behavior of the material, based on the interactions between matrix and reinforcement, indicating an appropriate dispersion on the CNT inside of benzoxazine resin.

The growth of copper nanoparticles in a high power pulsed hollow cathode discharge is studied. The material for nanoparticle growth is sputtered from the hollow cathode by applying high power impulses. This technique is known from high power impulse magnetron sputtering where the ionization degree is increased compared to dc magnetron sputtering [1]. The nanoparticles grow in the gas phase and the growth process can be divided into three main stages: nucleation, coagulation, and growth by accretion of atoms and ions [2]. Since nanoparticles above a certain size are negatively charged in the plasma [3], a high ionization degree of the material will be beneficial in the last step of growth (accretion) because the collection cross section for positively charged ions becomes much larger than for atoms. Using the pulsed technique, it has been shown that the nanoparticle size can be altered in a range between 20 and 40 nm by changing the pulse parameters, i.e., frequency, peak current, and pulse width [4]. In this contribution the effect of the plasma on nanoparticle growth is studied by changing the spatial distribution of the plasma, which was controlled by changing the distance between the hollow cathode and the anode ring. It was found that the nanoparticle size increases when the nanoparticles are exposed to the pulsed plasma a longer time. The mechanisms of an enhanced growth of nanoparticles by an exposure of plasma are discussed.

The controlled on-surface synthesis of intricate π -electron systems may overcome the limits of conventional synthesis, which often faces severe problems if large, fragile or insoluble molecules are to be prepared in solution and subsequently deposited on a solid substrate. Surface-assisted cyclodehydrogenation or dehydrogenative polymerisation of polycyclic heteroaromatic hydrocarbons (PAH) is one of the most important strategies for bottom-up assembly of new nanostructures from their constituent molecular building blocks¹. Although diverse compounds have been formed in recent years using this methodology,^{2,3} limited knowledge on the molecular machinery operating at the nanoscale has so far disallowed to control the reaction outcome.

In this work, we show that the strength of the PAH-substrate interaction rules the reaction pathways (cyclodehydrogenation versus dehydrogenative polymerisation). So, starting from the same precursor and controlling its diffusion by the nature of the supporting surface, temperature-triggered dehydrogenation takes place to provide molecular or polymeric structures of variable dimensionality.

We combined advanced surface techniques (STM and NEXAFS) with theoretical ab-initio calculations to achieve a complete understanding of the self-assembling of molecular precursors on surfaces. Herein, by merging information from these techniques and different single-crystal metal substrates, we report on the diffusion control of competitive intramolecular and intermolecular dehydrogenative processes respectively called cyclodehydrogenation and dehydrogenative polymerisation, which operate in the on-surface synthesis of N-doped fullerene, nanographene,

polyaromatic network or graphene (Fig. 1). By choosing the appropriate N-heteroaromatic precursors and by controlling their diffusion, the on-surface (cyclo)dehydrogenation can either lead to monomolecular triazafullerenes and diazahexabenzocoronenes (N-doped nanographene), or to N-doped polymeric networks.

Silver and gold nanoparticles (NPs) were generated via a mild wet-chemistry process in aqueous chitosan solutions. Gold and silver NPs were created in situ in a chitosan solution through the addition of the corresponding salt and subsequent UV irradiation. Gold and silver NPs were also created by using a sequence of gold and then silver and vice-versa. The amine function existing in the chain monomer operates as the anchoring centre of the metal NP, enabling thus a selective generation of the metal NPs through their nucleation followed by their growth [1,2]. The ensuing hybrid systems were characterized by UV/Vis spectroscopy, X-ray Photoelectron Spectroscopy (XPS), Transmission Electron Microscopy (TEM) and X-ray Diffraction (XRD). The NPs average sizes ranges from 10 to 40 nm for gold and ~20 to ~100 nm for silver. The present approach proved to be efficient in generating bimetallic nanoparticles. The results also suggest that through a sequence of gold followed by silver solutions, gold cores enveloped by silver shells with some discontinuities are created. However, results are unclear when the order of solutions is inverted. The composition of the nanoparticles is explained by the dependence on the standard redox potentials of the system.

Huge efforts are nowadays dedicated to the development of relevant methods to fabricate hollow nanostructures of a wide variety of materials [1]. Among hollow nanostructures, oxide nanotubes are considered as potential building blocks for nanoelectronics. Up-to-now, the majority of synthesis method produces oxide nanotubes that suffer from a short length and poor organization. In this contribution, we report for the first time on highly organized ultra-long metal oxide nanotube arrays (length-up to several centimeters) fabricated by thermal oxidation of metal nanowire arrays [2]. The metal nanowires were grown on nanograted surface by the plasma-assisted inverse-template method that we have developed in a recent work [3]. Based on an extensive structural study, performed by transmission electron microscopy, the fundamental mechanisms occurring during the formation of such oxide nanotubes will be discussed and explained according to the nanoscale Kirkendall effect. We further show that such method can be extended for the

fabrication of periodic zero-dimensional hollow nano-objects. This novel fabrication method of oxide nanotubes in a planar configuration opens-up the way to further nanodevice construction and characterization.

Fingerprinting Material Interfaces with BEEM

T10 Nanoscience and Technology

#NST-7-Or-5

K. Goh, C. Troadec.

Institute of Materials Research and Engineering (IMRE), Agency for Science, Technology and Research (ASTAR), 3 Research Link, Singapore 117602, Singapore - Singapore (Singapore).

We show how a fingerprint of a material interface may be obtained by Ballistic Electron Emission Microscopy (BEEM).¹ When dissimilar materials come together, the interface thus formed typically creates a barrier for charge transport with certain transmission characteristics. BEEM plays a rather unique role here in that it can extract both the barrier and transmission characteristics with very high lateral resolution (being based on the scanning tunneling microscope) and hence provide localized measurements of buried interfaces.^{2,3} This allows the interface of nanoscale or larger devices (e.g. a gate-stack) to be studied with the ability to pin-point with ~nm resolution where the charge barrier or transmission characteristics are different.² This is in contrast to conventional techniques such as current-voltage measurements or X-ray diffraction technique which typically averages over much large areas.

A fingerprint defined by the density distribution of the interface barrier and transmission characteristics can be useful for distinguishing between different interfaces and is sensitive even to the presence of a few monolayers of “contaminants” inserted into the interface.² We will present the fingerprint for the Au/n-Si interface and show how the insertion of a “contaminant” layer (inorganic and organic) at this interface alters the fingerprint. In addition, we shall present recent results to demonstrate the usefulness of these fingerprints in helping us to understand nanoscale modifications in devices in the context of process optimization, tuning device characteristics and device stressing.

Distance Depended Near-field Optical Microscopy

T10 Nanoscience and Technology

#NST-7-Or-6

U. Schmidt, M. Tchaya, D. Steinmetz, T. Dieing.

WITec GmbH - Ulm (Germany).

Since its invention, Scanning Near-field Optical Microscopy (SNOM) is used for optical imaging where a resolution below the diffraction limit is required [1]. In conventional optical microscopy, using visible light, a lateral resolution of about 200 nm can be achieved, leaving nano-objects outside the detection range.

In SNOM the light propagates through a subwave-length size aperture (50 nm - 100 nm) which is realized in our case using a SNOM cantilever. The SNOM cantilever is brought in close vicinity of the sample using standard AFM feedback technology. The light emitted or collected through the aperture of a SNOM cantilever leads to SNOM images with a resolution in the range of the size of the aperture.

Digital Pulsed Force Mode (DPFM), one of the AFM feedback methods used to study mechanical material properties in AFM [2, 3] allows the fast approach and retraction of the cantilever to and from the sample, thus enables the control of tip sample distance. By combining DPFM technology with SNOM, it is possible to obtain SNOM images as a function of tip sample separation.

The aim of this contribution is to explain the principle of this SNOM method, highlighted with example measurements.

Deposition of silver nanoparticles on Graphene nanolayers; an antibacterial nanocomposite

T10 Nanoscience and Technology

#NST-6-Or-15

A. Babapour.

Structural Engineering Institute, College of Civil Engineering and Architecture, Zhejiang University, Hangzhou, 310058, China.

Silver nanoparticle-embedded organic or inorganic matrices show extraordinary physical and chemical properties that are size and shape dependent as well as surrounding medium [1]. Preparing metal nanoparticles into thin films is particularly important for various applications such as optical nanodevices, biocide coating and biological sensing [2]. Graphene-metal nanocomposites potentially provide a new way to develop catalytic, magnetic, optoelectronic and bioactive materials. In this report, we show a facile and fast route to prepare silver nanoparticle decorated graphene oxide sheets and embed them into PVP film.

The UV–Visible spectra of the Ag nanoparticles on GrO in PVP film using different concentrations of AgNO₃ indicates the appearance of characteristic surface plasmon band at 420 nm indicates the formation of Ag nanoparticles in the coating. The peaks position of different silver concentration were almost in same range which means the particles are in same sizes. TEM micrograph of silver nanoparticles deposited on graphene oxide sheets are shown in Figure 1. It shows the wide distribution of particles ranging in the diameter of 5–25 nm (Figure 1a). Figure 1b shows that the smaller particles are hexagonal in shape (marked by black arrows) while the larger nanoparticles are in spherical form. The hexagonal shape could be the result of the deposition of the particles on the graphene sheets. Furthermore, the interface between the sheets and Ag is clearly seen (sheets marked 1 and 2), indicating that Ag nanoparticles are well attached between the surfaces of the two sheets. It also presented that uniform single-entity Ag nanoparticle embedded in the GrO sheets, thus confirming their assembly. The presence of the bigger particles can be due to agglomeration of the smaller particles.

Today the integration of C nanomaterials, having peculiar determined specifications and properties, presents fabrication and control challenges. The present attention on graphene research, as an effort to enable the full exploitation of its excellent properties, evidences the necessity to find alternative procedures to completely integrate it in the standard semiconductor planar technologies, following the route for a future graphene-based nano-electronics. The bottleneck is clearly identified in the use of metal as a catalyst for the crystallization and the need of transfer to insulating substrates and metal etching, while preserving ideal graphene features. Our present approach is inspired on the planar technology point of view and strategies. Merging the carbon nanomaterial preparation and lithography in a single stage processing by means of focused ion beam induced deposition of carbon (FIBID-C), the aim is to introduce our new concept as an example of a robust and flexible nanofabrication methodology [1]. A multibeam system JIB-4500 from JEOL has been used, with a Ga ion beam operating at 30 kV with a beam current of 300 pA. Square and rectangular patterns have been deposited on a standard substrate of 100-500 μm thick SiO_2 (fig.1-a), thermally grown on Si wafer, having thicknesses from 3.5 to 20 nm. The as-deposited processed material characteristics have been studied by TEM (fig.1-b), Raman and XPS [2]. In order to overcome some of the intrinsic issues of FIBID, such as its as-deposited high resistance, we explore how to convert C amorphous film into crystalline materials, namely graphene-like or diamond-like, with thermal treatments. C-film after annealing at 975°C results in no morphological distortions, both in terms of shape and thickness. TEM shows that atomic C arrangement has not suffered significant modification and XPS suggests that the treated film is made by a mixture of C sp^2 and sp^3 bonds, and a small portion of C-O bonds (fig.1-c) [3]. The best results to obtain the transformation of amorphous C-film into graphene-like patterns were achieved using annealing @ 975°C and 10 μm of Ni. TEM confirms the

conversion of as-deposited film into multiple graphene layers. The use of the metal catalyst in the form of foils appears advantageous. In addition to the convenience of allowing the synthesis directly on an insulating substrate, such as SiO_2 , spontaneous detachment of metal and C-film patterns after cooling makes unnecessary a metal etching step.

Polyribosomes are clusters of ribosomes held together by messenger RNA that constitute the cellular machinery dedicated to the synthesis of proteins. Using Atomic Force Microscopy (AFM) we have visualized the structure of polyribosomes that have been purified from MCF7 human cell line. Native polyribosomes have been deposited on flat mica after sucrose gradient separation and visualized in liquid and in air environment. The number of ribosomes per polysome increases with the fraction, as expected, ranging from 2-4 in the lightest fraction to few dozens in the heavier ones. While the general shape of the observed polysomes is compatible with cryo-EM results (Brandt 2010), the AFM scans reveals also filaments connecting ribosomes. Two main kind of such objects are detected: filaments with height compatible to that of single strand nucleic acid (Smith 1997), that we found joining clusters of ribosomes, and shorter filaments that often connect a single riboparticle with a larger ribosomal cluster (Fig. 1).

To identify some of the observed structures, we have treated our samples with immuno-gold staining, in order to tag selected proteins with gold nanoparticles, allowing their direct identification in the AFM scans. When using antibodies against a ribosomal protein (RPL26) and against non-polysomal proteins (Ras, Sos) in control samples, we obtain full bead staining and no signal, respectively, confirming the selectivity of the method. When stained against initiation factors (eIF4E, eIF4B, PABP) well separated spots are identified in the images, allowing some insights on their spatial arrangement in the polyribosome.

Imaging and chemical state mapping of zinc oxide nanoparticles combined with gadolinium

T10 Nanoscience and Technology

#NST-P3-09

A. Skallberg, M. Ahrén, L. Selegård, K. Uvdal.

Division of Molecular Surface Physics and Nanoscience, Department of Physics, Chemistry and Biology, Linköping University - Linköping (Sweden).

Zinc oxide nanoparticles combined with gadolinium ions have been synthesized to be used as possible bifunctional probes with tuned properties for increased MR contrast enhancement and fluorescence. Gadolinium based contrast agents have proven to be valuable in magnetic resonance imaging (MRI) by providing high contrast in soft tissues [1]. Zinc oxide nanoparticles have a high stability and inherent photoluminescence properties with a wide band-gap, which has great interest in imaging applications [2]. These probes are promising as contrast agent for in vivo MR studies and as nanoprobes for cell studies and biochip applications. NanoESCA is a powerful tool derived from an electrostatic electron emission microscope for chemical element analysis. In this report, chemical state mapping with energy-filtered photoemission electron microscope has been used to study the zinc oxide gadolinium nanoparticle system. Micro-patterns are formed on silicon surfaces using direct stamping with polydimethylsiloxane (PDMS), which is a simple and reproducible way of producing high resolution structures for a possible biochip application.

IR plasmonic antennas in the vicinity of absorbing silicon-rich oxinitride

T10 Nanoscience and Technology

#NST-P3-19

L. Brínek, É. Zoltán, R. Kalousek, J. Zlámal, V. Krápek, J. Spousta, P. Dub, T. Šíkola.

Brno University of Technology , CEITEC - Brno (Czech republic).

The presentation deals with plasmonic antennas in the vicinity of silicon-rich oxinitride (SRON) having a substantial energy absorption in the mid-infrared (around $\lambda^{-1} \sim 1100 \text{ cm}^{-1}$). This work was originally motivated by an effort to exploit electromagnetic energy at antenna resonances for the thermal transformation of SRON into a nanocrystalline Si. Such antennas reveal nonlinear scaling between resonant wavelengths and antenna lengths [1]. The absorption enhancement in SRON is proportional to its absorption coefficient and to an increase of electromagnetic field at the antenna resonance. Hence, the trade-off between the frequencies providing the maximum absorption coefficient on one hand and antenna resonance on the other hand should be found. The optimization of the structure for the maximal electromagnetic field absorption in the SRON is performed via full-electromagnetic field calculations (FDTD). There are two resulting arrangements possessing: a) a SRON layer below a plasmonic antenna and b) antennas with the blocks of SRON in their vicinity (e.g. in the antenna gap). Both types of structures were fabricated by electron beam lithography and their reflectances measured by FTIR microscopy will be shown.

This presentation deals with the effects of metal nanoparticles on the photoluminescent properties of SRON (silicon-rich oxinitride) films [1] and Si nanocrystals (NCs) in their close proximity. The work was motivated by an effort to enhance the photoluminescence (PL) efficiency of SRON layers and low emitting Si NCs via plasmonic effects. The luminescence of the SRON in the visible region is attributable to the neutral oxygen vacancies [1]. However, annealing to higher temperatures (1100°C) allows the formation of embedded luminescent Si NCs. These NCs contribute to the PL spectrum in the visible-near infrared region (from 600 nm to 900 nm) depending on the size of the NC.

Gold and silver plasmonic nanostructures were fabricated using various preparation techniques (such as EBL, GIS-FIB) on the annealed SRON thin films. Metal nanonstructures were also prepared on bare Si substrates and subsequently Si NCs dissolved in PMMA were deposited using spin coating method. In order to obtain a higher PL signal, the plasmonic structures were arranged in arrays. The PL enhancement was measured for different size and separation of metallic structures and for different excitation wavelengths.

Furthermore, the experimentally observed PL enhancement (or quenching) is compared with the numerical calculations carried out using boundary element method (BEM) and FDTD simulations.

Self-Assembling of NiTPP/Cu(111): an XPS and STM study

T10 Nanoscience and Technology

#NST-P1-19

S. Fatayer, M.J. Prieto, A. De Siervo.

Instituto de Física 'Gleb Wataghin', Universidade Estadual de Campinas, 13083-859 - Campinas (Brazil).

Systems of low dimensions, for instance periodic nanostructures at surfaces, are of great technological interest and present exciting scientific challenges. The formation of nanostructured systems, ordered with long range periodicity can be obtained by self-assembling methods. In particular, metallorganic systems in the scale of few nanometers may be efficiently synthesized by the SAM (Self-assembling of Monolayers) method [1]. Organometallic molecules of porphyrinic groups are interesting for technological applications because it is feasible through the SAM method to produce devices in order to act as organic light emitting diodes, optoelectronic systems and sensors for different applications [2]. In the present research we have investigated the electronic and morphological properties of NiTPP (Nickel-Tetraphenyl Porphyrin) self-assembled on Cu(111) surface. The NiTPP films were deposited under UHV on a Cu(111) single crystal at room temperature using a homemade Knudsen cell with a quartz crucible. The main results are based on UHV Scanning Tunneling Microscopy (STM) and X-Ray Photoelectron Spectroscopy (XPS). The STM images showed the coexistence of three distinct domains at the surface as a consequence of the fcc packing of the substrate. NiTPP forms a "nearly-square" lattice with their vectors equal to 1.16 nm and 1.22 nm. Their angle was calculated to be approximately 86.6 degrees. The growth of the NiTPP was found to begin at the step edge of the Cu(111) since it was not observed "free-islands" of the molecules through the images. Using XPS analysis, we explored the chemical stability of NiTPP on Cu(111) upon annealing and the possibilities of molecular demetallization due to Cu-Ni alloy formation.

THEORETICAL STUDY OF THE ZnTe QUANTUM DOTS CAPPED WITH ZnSe

T10 Nanoscience and Technology

#NST-P3-25

B. Rerbal, G. Merad.

Laboratoire d'Etude et Prédiction de Matériaux, URMER, Université A. Belkaïd, B.P. 119 - Tlemcen (Algeria).

Self-assembled quantum dots (QDs) are of high interest for optical applications such as low-threshold lasers [1] or single sources for applications in quantum information processing [2,3]. It is well known, as demonstrated by a lot of groups, that the driving force for the islands formation is the strain relaxation between the two materials (Stransky-Krastanov growth mode), but it can be, in some cases, strongly perturbed by surface segregation effect [4]. The competition between the formation of islands and misfit dislocations as strain relaxation mechanisms plays a key role: surface and interface energies, elastic energy and formation energy of misfit dislocations have to be taken into account in the island formation process [5]. This makes the control over the island formation with predictable sizes challenging. A novel method to induce the transition from the 2D strained layer to islands was recently developed [6]. It consists of covering a layer of strained ZnTe on (001) ZnSe with amorphous tellurium at low temperature and of subsequent desorption of this amorphous tellurium at growth temperature [7]. Afterward, the ZnTe islands are capped with ZnSe. The growth of the capping layer was begun at 200°C to avoid interdiffusion and to preserve the islands shape as much as possible [8]. In spite of that, high resolution transmission electron microscopy images showed that the islands were drastically flattened during capping [8]. The tellurium content was found to be much lower than the nominal value: this is caused by the strong segregation of the Te in ZnSe occurring during growth which contributes to both the island flattening and the apparent loss of tellurium [8].

In this work, we attempt to describe these phenomena by calculating the ZnSe/ZnTe interface energy. The calculations are done by performing ab-initio calculations based on the density functional theory (DFT) and using the Vienna ab-initio software package (VASP) [9-12]. We found that the ZnSe/ZnTe interface energy does not change when the Te segregation occurs. Interface charge densities are also calculated.

NST-P3-10

A new methodology to produce Iron Nanoparticles by Laser Ablation in organic media

T10 Nanoscience and Technology

#NST-P3-10

Y. Vitta Brito, V. Piscitelli Spinielo, A. Fernandez Cuervo, J. Castillo.

Universidad Central de Venezuela - Caracas (Venezuela, bolivarian republic of).

In this work, we present a new methodology of production for iron nanoparticles (iron Np) in organic solvents, by laser ablation. Using an inert gas stream the particles are blowing into solvent (LAI_{GS}). The nanoparticles produced by this method were compared with others produced by direct laser ablation in metal plate immersed in solvent (LAI_S). The ablation procedure was performed in 10 minutes steps by triplicate with cooling periods of 5 minutes between ablation. Comparatively particles were obtained under continuous ablation iron plate at different time's ablation, 10, 20 and 30 min. The same procedure was utilized in both cases, LAI_S and LAI_{GS}. Optical properties were measured by UV spectroscopy, size distribution were measured by Dinamic Light Scattering and morphological study was performed by atomic force microscope (AFM) to correlate the size and form of the Np whit showed optical properties.

The influence of laser parameters; ablation time, flow gas and employed method on diameter, size distribution and absorption peak intensity of the Np prepared were studied. The absorption peak intensity, number of particles and size distribution of the iron Np obtained in LAI_S method are dependent of laser irradiance. This is attributed that at high fluences and long pulse laser, occur re-fractionation laser induced. In LAI_{GS}, the consecutive ablation is the mechanism preferred for particles production; this because the subsequent ablation produces new particles in the same volume of plasma, the concentration increases and this occurs gradually as often repeat the cooling process and the re-ablation. Nps of size ranging between 8 -10 nm and bimodal size distribution were obtained by both methods. Larger particles (micrometers) correspond to aggregates. The particles exhibited Resonance Plasmon Surface, SPR; band between 300 and 380 nm, typical of Fe Np.

LAiSG method was used to prepare Np in organic flammable solvents, obtaining good Np dispersions usefully in experiments wee water presence is regretted.

Colloidal gold nanoparticles represent technological building blocks which are easy to fabricate while keeping full control of their shape and dimensions. Their assembly onto surfaces is required for many applications, including nanowire growth and plasmonics, where the plasmonic resonance can be tuned by the size of nanoparticles and designing nanoparticle clusters, thus forming a new class of colloidal metamaterials [1]. In another example, a metallic nanoparticle placed in a close vicinity of a quantum dot may significantly enhance the luminescence yield [2]. In our contribution we will present a simple two step technique for the assembly and placement of gold and silver colloidal nanoparticles (spheres and rods) on a semiconductor substrate [3]. The exposure of the desired location on such a substrate by the charged particle beam of a very low fluence (electrons or ions in a dual-beam microscope) results in desorption of impurities and, especially, modification of surface chemical groups (Fig. 1a). If such a sample is immersed into a colloidal solution, depending on its pH, the positive (colloidal nanoparticles adhere to the exposed areas only) or negative (colloidal nanoparticles are deposited all over the substrate except the exposed areas) deposition is achieved. We will show our latest data on improved patterning resolution (spherical particle arrays with the pitch below 100 nm) on silicon and GaAs, as well as patterning of rod-like nanoparticles.

NST-6-Or-7

Secondary electron emission study of copper oxide nanowires

T10 Nanoscience and Technology

#NST-6-Or-7

L. Aguilera ¹, I. Montero ¹, M.E. Dávila ¹, V. Nistor ², L. González ², L. Galán ², D. Raboso ³.

¹Instituto de Ciencia de Materiales de Madrid (CSIC) - Madrid (Spain),
²Universidad Autónoma de Madrid - Madrid (Spain), ³European Space Agency/ESTEC - Noordwijk (Netherlands).

Nanowires have been shown to provide a promising framework for applying their properties in the design of nanostructures for nanoscience investigations and for potential nanotechnology applications. The smaller length scales are being used in the semiconductor, optoelectronics and magnetics industries, and the intense development of the biotechnology industry where the goals are also at the nanoscale. The sizes of nanowires are usually > 1 nm in the quantum confined direction [1].

Low-energy secondary electron emission materials are required for antimultipactor applications in several important technologies and their study and development is also a matter of great scientific interest. Also, electron cloud buildup is a major limitation for high-energy particle accelerators [2]. For this purpose, in this work copper oxide nanowires were grown on Cu substrates by thermal oxidation and the influence of low-energy carbon ion bombardment on the secondary electron emission yield of nanowires was studied. Thus, CuO nanowires were obtained by heating a copper foil in air. The influence of temperature and time on the growth of copper oxide nanowires was investigated. Either a linear or a stepped temperature ramp was applied in this growth procedure. The temperature ramps were at a predefined ramp rate in the range 100-300°C/h. The growth temperature of CuO nanowires was between 400-800°C. At each temperature step a different oxidized copper sample was obtained. These synthesis procedures allowed obtaining uniform CuO nanowires with controllable diameters in the range of 20-900 nm and with lengths of up to 30 μ m. Structural analysis by electron diffraction and high-resolution SEM were also performed. The composition and chemical bonds formed in the films after low-energy carbon ion bombardment were analyzed by x-ray photoelectron spectroscopy (XPS). XPS revealed the formation of both carbidic and graphitic bonds. Cu-C bonds were

formed up to a limiting value of 0.1 for the carbidic carbon atomic fraction. The secondary electron emission yields for copper oxide nanowires were measured before and after low-energy CH_n^+ ion bombardment. The experiments have shown that a complete suppression of multipactor can be achieved by coating the nanowires with a thin layer of gold and after carbon ion bombardment, which has a maximum secondary electron yield (SEY) lower than 1. These results lead to a higher threshold of the Multipactor breakdown for high power RF devices in vacuum or a complete suppression of the e-cloud.

NST/SS-4-Or-5

Repeated magnetization reversal in oscillating magnetic nanowires

T10 Nanoscience and Technology

#NST/SS-4-Or-5

T. Muehl, S. Philippi, H. Schlörb, A. Leonhardt, B. Büchner.

IFW Dresden - Dresden (Germany).

The interplay of mechanical and magnetic dynamics at the nanoscale and its potential for fundamental studies and novel applications still need to be fully explored. Here we present an experimental method to repeatedly reverse the magnetization of a single domain ferromagnetic nanowire with no dynamic external fields involved. The magnetization reversal is self-induced by a flexural vibration of a single-side clamped nanowire in a static perpendicular field. The vibration varies the applied field angle with respect to the nanowire axis, and causes the magnetization to reverse whenever the switching condition according to the nanowire's angular dependence of the switching field is fulfilled. Upon magnetization reversal the vibration amplitude is reduced due to the dissipation of energy associated with the magnetization reversal. The periodic driving force leads to an increase of the vibration amplitude until the following switching event occurs. This results in non-trivial sequences of transient vibrational states associated with ever-changing phase relations between the excitation force and the flexural oscillation. In our experiments, individual, freestanding Ni nanowires are used. The presence of the repeated magnetization reversal state is observable in the scanning electron microscope (SEM), as the envelope micrograph of the vibrating nanowire undergoes significant changes as compared to a steady state oscillation (see figure). The time scale between individual reversals has been estimated to several milliseconds both by calculation and SEM-based measurements.

SEM images of a Ni nanowire (a) in the idle state, (b) in a steady flexural vibration state in zero applied field at 279 kHz driving frequency, and (c) vibrating with the same driving frequency in a constant perpendicular field leading to recurring magnetization reversals. The reversals cause amplitude drops.

NST-P3-11

Potential profile of small quantum dots (QD) and the example of GaN-QD imbedded in AlN

T10 Nanoscience and Technology

#NST-P3-11

B. Sanric.

R.Boskovic Institute - Zagreb (Croatia).

It is usually assumed that the quantum well (QW) or quantum dot (QD) have rectangular potential profiles. Here we show that the potential profiles are not rectangular on nano-scale. Instead, the potential step at the interface is a smooth, gradual change of potential over a distance larger than one monolayer.[1] This is important when the size of the quantum structure is around 3-4 nm or smaller. Conclusions are obtained by calculating the electrostatic contribution to the total potential. We examine the dipole layers formed by the ions, at the interfaces in various crystal directions. Although similar to those of the Density Functional Theory, our results are obtained in a simpler and intuitive way. Remarkably, the minimal thickness of the potential barrier is not determined by the distance between the charged planes, but by the lateral spacing between ions of the same polarity. The cross-section of the potential of a narrow QW or small QD, do not have the shape of a rectangular well. A more appropriate term is the quantum valley. Due to smooth potential profiles, the energy level positions will be different in comparison to the rectangular QWs. In the example of GaN and AlN, the barrier cannot be thinner than about 3 Å. In addition, the 3D profile of a GaN-QD is not spatially uniform since it depends on the crystal orientation at the interfaces, which also effects on the effective depth (or height) of the QD potential.

Epitaxy of Mn-doped ferromagnetic bismuth chalcogenide topological insulators on BaF₂ (111) substrates

T10 Nanoscience and Technology

#NST-1-Or-4

H. Steiner¹, R. Kirchschlager¹, G. Bauer¹, O. Caha², V. Holy³, J. Sánchez-Barriga⁴, A. Varykhalov⁴, E. Schierle⁴, E. Weschke⁴, O. Rader⁴, G. Springholz¹.

¹Johannes Kepler University - Linz (Austria), ²Masaryk University - Brno (Czech republic), ³Charles University Prague - Praha (Czech republic), ⁴Helmholtz-Zentrum Berlin - Berlin (Germany).

Topological insulators have attracted tremendous interest due to their extraordinary physical properties caused by the gapless surface state with linear dispersion that is topologically protected by time-reversal symmetry [1]. Prominent examples are the bismuth chalcogenides such as Bi₂Se₃ and Bi₂Te₃, which exhibit a complicated hexagonal lattice structure consisting of three unit cells of quintuple layers stacked on top of each other. Magnetic impurities like Mn [2-4] in topological insulators are predicted to break time reversal symmetry and lift the degeneracy at the Dirac points, leading to novel phenomena like topological magneto-electric effects, quantum anomalous Hall effect and half-integer charges at magnetic domain boundaries [1].

In this work, epitaxial growth, structural and electronic properties of Mn doped Bi₂Se₃ and Bi₂Te₃ epilayers on BaF₂ (111) substrates was studied as illustrated in Fig. 1. We show that different Bi-Te and Bi-Se phases can be formed in dependence of growth conditions. Incorporation of Mn was achieved up to concentration of a few percent and these layers show ferromagnetic behavior at T_c's < 10K as revealed by SQUID magnetization and x-ray magnetic dichroism measurements. The effect of Mn on the topological surface state was studied by angular resolved photoemission (ARPES) at BESSY II after desorption of the protective Se capping layer in the ARPES chamber. ARPES spectra of Mn: Bi₂Se₃ layers with Mn content from 0 to 8% are shown in Fig. 1, demonstrating a gap opening that increases with increasing Mn content. The band gap is found to be independent of temperature and persists up to room temperature where the samples are non-magnetic. This indicates that the breaking-up of the

topological surface state is not caused by magnetism and thus, time reversal symmetry breaking but must be of different origin.

Enhanced Optical Properties of Alkylated Silicon Quantum Dots mixed with Erbium (III) Chloride

T10 Nanoscience and Technology

#NST-P1-09

K. Abualnaja, G. Bhaduri, B. Horrocks, L. Siller.

Newcastle University - Newcastle Upon Tyne (United kingdom).

There has been an increased attention on silicon quantum dots due to their enhanced optical properties. This enhancement is attributed to the quasi-direct band gap within silicon quantum dots which is indirect in bulk silicon. However, the main goal of adding erbium to silicon quantum dots is to observe the energy transfer from the excited state of the silicon quantum dots to the erbium for optical fiber technology applications. In this study, a colloidal suspension of luminescent silicon quantum dots is synthesized when porous silicon prepared at high current densities is refluxed in toluene solutions of 1-undecene under circumstances which allow hydrosilation to occur. The diameter of the Si core of the alkylated-silicon quantum dots is 2.2 ± 0.4 nm was confirmed by scanning transmission electron microscopy (STEM). Mixing alkylated-silicon quantum dots with erbium is achieved by adding aqueous erbium (III) chloride to alkylated silicon quantum dots which enhances the optical properties of silicon quantum dots. The optical luminescence of alkylated silicon quantum dots and alkylated silicon quantum dots mixed with erbium were studied under excitation 400 nm. Orange emission band was observed in the alkylated silicon quantum dots at 590 nm. Alkylated silicon quantum dots mixed with erbium exhibited photoluminescence peak at around 595 nm and 1535 nm which could be assigned to electron-hole recombination in silicon quantum dots and $^4I_{13/2} \rightarrow ^4I_{15/2}$ intra-4f transition in Er^{3+} respectively. Raman, X-ray photoemission spectroscopic (XPS) and UV-Vis analysis of the alkylated silicon quantum dots and alkylated silicon quantum dots mixed with erbium were carried out to investigate its optical and chemical properties. Raman results indicate that this method increases the Raman signals of alkylated silicon quantum dots mixed with erbium. The XPS results detect the presence of Si-O, Si-Si and Er_2O_3 which confirm the existence of Er within the alkylated silicon quantum dots lattice.

Physical systems based on Aluminum nanoparticles (NPs) have for a long time been strong candidates for extending the plasmonic response of materials towards the deep-ultraviolet (DUV) range, with important fallouts in the fields of non-linear optical spectroscopies and high-sensitivity biosensing. Despite the expectation that Al NPs exhibit a localized surface plasmon resonance (L-SPR) in the DUV range, the metal's reactivity and the synthesis difficulties have strongly hampered the research in this direction.

Employing a strict control of the fabrication process, we realized 2-dimensional Al NPs arrays with DUV-frequency L-SPR supported onto self-organized nanopatterned LiF(110) surfaces. The arrays consist of ensembles of ellipsoidal aluminum nanoparticles, either metallic or in a Al₂O₃/Al core-shell architecture, aligned along the nanometric grooves of the LiF surface. Atomic-force microscopy showed that the NPs are ordered over large areas and exhibit a coherently-aligned ellipsoidal shape with narrow size distribution in the few tens-of-nm range. High-resolution X-ray photoemission data allowed to assess the metal/oxide fraction in the nanoparticles. Polarized-light absorption measurements in the 3-12 eV range performed by synchrotron light at BEAR beamline at Elettra (Trieste) revealed the presence of the L-SPR at frequencies as high as 6.8 eV, one of the highest LSPR energy ever reported by optical spectroscopy. The experimental data are successfully compared with theoretical calculations for the L-SPR. The results show the suitability of the present method to fabricate DUV-plasmonic Al nanostructures.

Magnetism and Electronic Properties of Gold-Supported Stable pi-Radicals

T10 Nanoscience and Technology

#NST/SS-4-Or-6

S. Mullegger, M. Rashidi, M. Fattinger, R. Koch.

Johannes Kepler University - Linz (Austria).

Stable free radicals can be stored and investigated under ambient conditions, which makes them desirable for applications as polarizing agents or novel magnetic materials as well as suitable model systems for investigating sp^2 magnetism in reduced dimensions.

We have studied the stable all-organic spin-1/2 radical, α,γ -bis(diphenylene)- β -phenylallyl (BDPA), adsorbed on a weakly interacting metal support by low-temperature scanning tunneling microscopy (LT-STM). We report on the geometric structure, self-assembly, frontier orbital electronic and magnetic properties, Kondo behaviour, radical-radical, and radical-substrate interactions at the atomic-scale. [1,2]

Johannes Kepler University - Linz (Austria).

Semiconductor quantum dots (QDs) have a great potential for optoelectronic devices. The most common synthesis method is based on the Stranski-Krastanow (SK) growth mode of strained-layer heteroepitaxy. The resulting QDs have been widely employed for visible and near-infrared photonics but efficient mid-infrared (MIR) emission has been difficult to achieve. In this work, we present an alternative strain-free synthesis method based on phase separation and nano-precipitation in heterosystems with large miscibility gap. It is shown that under well defined conditions, isolated quantum dots can be produced with strong luminescence emission. With these dots, we demonstrate the first QD lasers emitting in the MIR region.

The investigated PbTe/CdTe model system is a combination of a narrow gap and wide gap semiconductor, featuring identical lattice constants but different lattice structures. Due to phase separation, ultra-thin 2D PbTe/CdTe epilayers grown by molecular beam epitaxy onto GaAs (001) transform into isolated quantum dot nanocrystals during post annealing. As revealed by in situ TEM (see Fig. 1), this process starts with formation of a 1D percolation network, which further splits up into near-spherically symmetric QDs. To reveal the underlying mechanisms, a Monte Carlo model was developed that accounts for the thermodynamics by appropriate choice of the nearest and next-nearest neighboring bond energies. The time evolution is revealed by Monte Carlo snapshots depicted in the lower part of Fig. 1. The MC movies show a remarkable agreement with the TEM images and allow to identify the key parameters for the formatio process. With the obtained QDs, microdisk lasers and light emitting diodes were produced as shown in Fig. 2.

Perrone 24 - Genova (Italy).

Alloy nanoparticles (NPs) have attracted much interest because of their unique catalytic, electronic and optical properties. In particular, the NPs localized surface plasmon resonance (L-SPR) can be tuned by controlling the alloy composition. Achieving this goal often requires complex fabrication techniques. Here we propose an extremely easy method, based on a self-organization approach, to fabricate well-ordered 2D arrays of Au-Ag alloy NPs with changing composition across the substrate. This feature makes our arrays very promising for designing surface-enhanced Raman spectroscopy (SERS) substrates, provided a precise control of the nanofabrication process.

The NPs are fabricated by the consecutive deposition of the two metals onto self-organized nanopatterned LiF(110) substrates. The preparation procedure allowed to obtain a linearly varying composition of the NPs on a single LiF substrate. The NPs plasmonic resonance blue-shifts linearly across the substrate with the increase of Ag content, as predicted for homogeneous alloys. The arrays morphology has been studied by scanning electron microscopy and atomic force microscopy. The arrays consist of NPs coherently aligned with a few nanometers interparticle spacing and narrow size distribution in the few tens-of-nm range. The arrays morphology is uniform over a several millimeters area and despite the varying composition.

These NPs arrays have been employed as SERS substrates after the adsorption of

Rhodamine-6g. The intensity trend of the Raman spectra is directly correlated to the NPs composition, i.e. to the plasmonic resonance wavelength. A strong field enhancement was found, as confirmed also by theoretical simulations, allowing to detect a nanomolar concentration of the test-molecule.

Improvement of the quality of Probes for Near-Field Scanning Optical Microscopy

T10 Nanoscience and Technology

#NST-13-Or-8

P. Dvorak, T. Šamoril, D. Škoda, M. Urbánek, T. Neumat, J. Spousta, R. Kalousek, T. Šikola.

Institute of Physical Engineering, Brno University of Technology, 682 96 Brno, Czech Republic - Brno (Czech republic).

Quality of probes for near-field scanning optical microscopy plays a crucial role in the efficiency of obtaining the near-field distribution images [1]. Commercially available probes are relatively expensive, technologically inferior and their production is time-consuming. We have improved the fabrication process and, consequently, the resulting quality of those probes. The probes are metal-coated optical fibers with a small aperture (< 100 nm).

The first step of fabrication is etching one end of a fiber in 40% HF acid for 75 min (Turner's method) which creates a tip-shape [2]. Then, the set of fibers (six together) is put in an UHV chamber and their tips sputtered by 400 eV Ar⁺ ions for 120 s. It removes impurities, provides glazing and modifies tip morphology. Afterwards, 150 nm thick aluminum layer is in situ deposited via Ion Beam Assisted Deposition (IBAD) with an optimized assisting ion beam energy of 100 eV. A 3 nm thick titanium film is used as an adhesive layer between the metal film and the glass substrate. We have studied the relation between the size of grains and ion energy. It has been found that the method provides approximately 10 times smaller grains than commercial probes. The next step is cutting the end of the tip by Focus Ion Beam (FIB). Subsequently, the metal tip is fabricated by ion beam induced deposition (IBID) of Pt. At the end, the aperture of the required geometry is milled by FIB. NSOM experimental images of calibration samples taken by the fabricated probes will be presented and discussed.

Optical scattering by dense ordered metal nanoparticle arrays produced using deposition through ultrathin anodized aluminum oxide masks

T10 Nanoscience and Technology

#NST-P3-21

J. Prikulis, U. Maļinovskis, R. Popļausks, G. Bergs, D. Erts.

Institute of Chemical Physics, University of Latvia - Riga (Latvia).

Metal nanoparticles are interesting for a variety of reasons including applications in catalysis, biosensors, solar cells, electronic devices, or use as model systems for theoretical studies of physical phenomena. Much of attention has been directed towards regular nanoparticle arrays, partly because certain properties can be greatly enhanced due to lattice diffraction effects, and partly because periodicity simplifies calculations, since all elements in an infinitely repeating system are equivalent and the surrounding fields at each site are the same. In this work we address the optical properties of aperiodic arrays, where above simplification is no longer valid and the interaction between nanoparticles results in distinct spectral features.

For array production with minimum particle size of 20 nm, and center separation of 50 nm, we employed the pore self-assembly process in anodized aluminum to produce masks for nanoparticle array deposition. The original method by Masuda and Satoh [1] was modified to use lower voltages and shorten anodization times, which resulted in ultrathin (60-100 nm) layers with high density of pores. After the transfer of the membrane to a glass substrate, a wide selection of materials can be deposited through the porous mask. Using this method we produced arrays of Ag and Au nanoparticles, which are famous for their optical activity due to localized surface plasmon resonances.

The achieved particle sizes are much smaller and packed more densely than what has been reported on similar short range ordered assemblies [2, 3]. In contrast to arrays studied in ref. [4], where disorder is introduced by random displacement of

nanoparticles from their regular grid pattern, our samples preserve no long-range periodicity at distances exceeding the wavelength of incident radiation.

The measured spectra of scattered light show resonances in visible region and vary their peak position and broadening depending on array density and particle shape, which are controllable parameters during sample preparation. We use coupled dipole model [5] to simulate the scattering spectra and obtain results which are consistent with experimental observations. We also find that the dense arrays can be treated as continuous medium with their own propagation parameters.

A high resolution Atomic Force Microscope operated at about 300 mK in up to 10 T under UHV-conditions

T10 Nanoscience and Technology

#NST-5-Or-8

H. Von Allwörden, K. Ruschmeier, A. Schwarz, R. Wiesendanger.

University of Hamburg - Hamburg (Germany).

In atomic force microscopy (AFM) and spectroscopy (AFS) force sensitivity and energy resolution scale with the temperature as \sqrt{T} . To increase the sensitivity or to observe certain phenomena, which occur below a critical temperature only, experiments have to be performed in a cryogenic environment. Up to now low temperature force microscopes are mainly operated with bath cryostats using liquid 4He, whereby temperatures down to 4.2 K can be achieved. Here, a design based on 3He evaporation will be presented that enables AFM experiments at about 300 mK in ultrahigh vacuum (UHV). First results obtained with the instrument demonstrate that (i) clean samples can be prepared, (ii) deposition of single atoms on a cold substrate ($T < 30$ K) is possible and (iii) the microscope is capable of true atomic resolution in the non-contact mode (Fig. 1). Since we are mainly interested in magnetic properties, a magnetic flux density up to 10 T can be applied perpendicular to the sample surface.

The 3He-cryostat from Oxford Instruments uses the evaporation of 3He for cooling to temperatures below 1 K [1] and is similar to an existing set-up in our group [2]. The UHV-compatible insert contains the microscope body, which is surrounded by the 10 T-solenoid. The holding time as well as the minimal base temperature strongly depends on the heat load: First, heat conduction through the electrical wires required for operation, which can be reduced by enhancing the thermal anchoring. Second, since we use a fiber-based optical interferometer, the part of the incoming light, which is not back reflected into the fiber, also contributes to the total heat load. The microscope design is based on the rigid and reliable Hamburg design [3,4]. However, for faster thermalization the body is made from phosphorus bronze instead of the glass-ceramic Macor. To gain access to tip and sample stage the microscope can be lowered from the cryogenic environment into a UHV-chamber at room-temperature. Samples prepared in two additional UHV-chambers attached to the central cryostat

chamber can be transferred and exchanged in-situ. During a typical transfer time of about 15 minutes the microscope temperature stays below 45 K. After moving the microscope back into cryogenic environment, cool down to base temperature by condensation of ^3He requires about 2 hours. Realization of the instrument, strategies to minimize the heat load and experimental results will be discussed.

Synthesis of Ag@Pt Core-shell Nanowires via Galvanic Replacement

T10 Nanoscience and Technology

#NST-6-Or-9

J. Song ¹, S.Y. Chen ², Y.L. Shen ³, I.G. Chen ⁴.

¹Department of Materials Science and Engineering, National Chung Hsing University - Taichung (Taiwan, republic of china), ²Department of Materials Science and Engineering, National Taiwan University of Science and Technology - Taipei (Taiwan, republic of china), ³Graduate Institute of Applied Science and Technology, National Taiwan University of Science and Technology - Taipei (Taiwan, republic of china), ⁴Department of Materials Science and Engineering, National Cheng Kung University - Tainan (Taiwan, republic of china).

Core-shell structure is an effective way to enhance the efficiency of precious metal electrocatalysts. In combination with the nanostructured core of less expensive or non-precious metals and the shell of Pt, high catalytic activity of core-shell bi-metallic electrocatalysts can be achieved. Previous studies have coated Pt on Pd, Au, Cu and Ag nanowires respectively using PVD (magnetron sputtering) or galvanic deposition. Excellent catalytic activity of those bi-metal NWs has also been demonstrated. Among these cases, the reports related to the synthesis of Ag-Pt core-shell nanowires are rare to our best knowledge. Zamborini et al. converted the surfaces of CTAB-protected Ag NWs into Pt by galvanic exchange reaction as shown below, however, the yield of nanowires thus produced was quite limited [1].

Without using any templates or surfactants, this study develops a high-yield process to prepare vertical Ag-Pt core shell nanowires by the thermally assisted photoreduction [2,3] of Ag NWs and successive galvanic replacement between Ag and Pt ions. The clean surface of Ag nanowires allows Pt ions to reduce and deposit on it, and forms a compact sheath comprising Pt nanocrystals. The core-shell structural feature of the NWs thus produced has been demonstrated via TEM observation and AES elemental analysis. Kinetic analysis suggests that the deposition of Pt is an interface-controlled reaction and dominated by the oxidative dissolution of Ag atoms. The boundaries in-between Pt nanocrystals may act as microchannels for the transport of Ag ions during galvanic replacement reactions.

The Nanometer Structure Consortium, Department of Physics, Lund University - Lund (Sweden).

III-V semiconductor nanowires (NWs) offer tremendous possibilities for device application in energy and information technology. It is essential to investigate their atomic surface structure and to correlate this information with electrical measurements on individual NWs. Recently, we have managed to clean InAs NWs from their native oxide and obtained first atomically resolved images of their side surfaces by using scanning tunneling microscopy (STM) [1]. Here, we present STM data covering various NW surfaces of different III-V material systems and different crystal structures, as well as scanning tunneling spectroscopy (STS) results revealing local electronic properties across the interface of NW heterostructures [2].

In order to go further in combining local surface characterization with transport measurements of NW devices, we have developed a novel STM-based setup: We are using combined atomic force microscopy (AFM) and STM/S on individually contacted NWs for mapping the atomic surface structure and the local band alignment along the NW heterostructure under device performance, as sketched in Fig. 1.

We show initial results of this unique approach on InAs-GaSb NW tunnel diodes [3], where we could prove Esaki behavior of a NW (Fig. 2b) while it was investigated by STM/AFM (Fig. 2c). From a set of STS spectra we mapped the band alignment across the broken-gap InAs-GaSb interface, and we determined the position of the Fermi level along the NW for different applied biases, showing an abrupt drop directly at the material interface (Fig. 2d). Results from additional experimental setups like scanning gate microscopy and different NW device systems will underline the versatile potential of this new method.

The interaction of graphene with a metal often perturbs the unique electronic properties of Dirac electrons in graphene. This interaction can be positively exploited to engineer the Dirac bands and obtained graphene interfaces with different functionalities. In this work we study the electronic and magnetic properties of graphene nanoislands grown on Ni(111) [1] by combining scanning tunnelling microscopy and ab-initio calculations. We show that the interaction with the Ni surface opens a gap and spin-polarizes the Dirac bands, which results in a spin filtering effect in the transport across the interface [2]. On the other hand, the standing wave pattern created around the nanoislands reveal an asymmetric potential that depends both on the spin and edge type, suggesting a lateral 2D spin-filter effect similar to that occurring across the interface.

NST/SS-6-Or-1

Bias Dependence of Tunnelling Mechanism in CoFeB/MgO/CoFeB Magnetic Tunnel Junction

T10 Nanoscience and Technology

#NST/SS-6-Or-1

R. Oksuzoglu, M. Yildirim.

Department of Materials and Engineering, University Anadolu - Eskisehir (Turkey).

Magnetic tunnel junctions (MTJs) with large tunnel magnetoresistance (TMR) at room temperature are of great importance not only for device application but also for clarifying the physics of tunnelling mechanism. Theoretically, TMR ratios over 1000% were predicted based on the coherent tunnelling of fully spin-polarized Δ_1 electrons [1]. Experimentally, the highest TMR ratio was reported as 604% at room temperature in CoFeB/MgO/CoFeB MTJ [2]. One of the important properties for application is high sensitivity, where the sensitivity generally increases with increasing of TMR ratio. An other point is the bias dependence of TMR ratio and its underlying mechanism is still discussed [3]. In spintronic devices, very thin barriers were grown, on the order of few nm or less, in order to keep the power supply within acceptable limit. Usually, very high intrinsic critical current density ($>5 \times 10^5 \text{ A/cm}^2$) [4] is passed through the thin barrier by means of large barrier voltage and high electric fields in operations; however, the TMR ratio cannot be easily increased by applying higher barrier voltages. One other point is that, during the read cycles, where the voltage is low, minimum tunnelling is desired to insure good charge retentions [5]. Consequently, an understanding of tunnelling current behaviour over a wide range of applied voltage is essential in MTJ devices with high TMR value. In this contribution, the effect of applied bias on TMR ratio and tunnelling mechanism has been systematically investigated in CoFeB(3nm)/MgO(2nm)/CoFeB(3nm) MTJ, which was deposited using a combination of the pulsed DC magnetron and RF sputtering techniques. While the thickness of junction layers and the interface roughness were determined by X-Ray Reflectometry, the structure properties were investigated by X-Ray Diffraction and Grazing Incidence X-Ray Diffraction techniques. The junction with a $25 \times 25 \mu\text{m}^2$ area indicates a giant TMR in the order of 506% at room temperature in minimum applied bias, and the TMR ratio decreases with increasing bias voltage. When the applied bias voltage is less than the average barrier height,

direct tunnelling occurs as dominant transport mechanism. In this bias regime, the TMR ratio is almost unaffected by the applied voltage, and Brinkman and Simmon formulas yield reasonable values for barrier thickness and height. If the bias voltage exceeds the average barrier height, Simmon and Brinkman formulas does not lead to correct barrier height and thickness, whereas reasonable barrier parameters could be obtained by Fowler-Nordheim Tunnelling formula, indicating a bias dependent change of the dominant transport mechanism in the investigated MTJs. The structure property correlation was also discussed.

Semiconductor nanocrystals (NCs) have found application as part of the active material in many optoelectronic and photovoltaic devices, due to their very interesting optical and electronic properties.¹ Usually, the performance of such devices is limited by the reduced charge mobility across the NC-NC and/or NC-electrode interfaces, due to the fact that the surface of the colloidal NCs is stabilized by a shell of organic ligands that are usually long and poor electric conductors. The electronic mobility and thereby the performance of such devices can be enhanced by treatments that substitute the original insulating organic ligands for halides^{2,3} or inorganic shells,⁴ what improves the electronic NC-NC interface coupling. But not many works have tackled the interface between an NC and a solid surface that might act as an electrode in the device.

In this paper we demonstrate by XPS and solid NMR that Cl is incorporated in the ligand shell of NCs decorating C-sp² surfaces; that such incorporation involves the selective substitution of anhydrides of ODPA in the organic capping shell (originally composed of ODPA²⁻ and anhydrides of ODPA); and finally that the structural changes associated with the aforementioned substitution actually strengthen the interaction of the NCs with C-sp² surfaces. These investigations have been carried out on Highly-Oriented Pyrolytic Graphite (HOPG), as a model system for general C-sp² surfaces such as CNTs or graphene.^{5,6} The one-pot sample preparation methodology that we have followed leads to long-range ordered NC monolayers with a close contact between the active NC layer and the C-sp² electrode surface. The

possibility to control the coverage degree of hexagonal ordered NCs monolayer on conductive C-sp² in one pot opens attractive alternatives to be explored in solution processed optoelectronics.

While the benefits of further miniaturization of cantilevers for AFM have been known for well over a decade, it is only in the last few years that levers as short as 10 μm long and the AFMs capable of using them have become commercially available. This talk will review the benefits of small levers and show some recent results using them.

For imaging in liquids, the biggest benefit is that the thermal noise in a given bandwidth is significantly reduced. The first part of the talk will review the theory behind this and address some common misconceptions involving thermal noise as well as show experimental results. For example, Fig. 1. shows that going from a 200 μm lever to an equivalent stiffness 10 μm lever drops the thermal force noise from 10 pN to about 2 pN. Small levers are also much faster because of the increased resonance frequency and bandwidth.

We have been using small cantilevers in liquids on a variety of sample and have been achieving ultra-high resolution. We will present results including single point defects on calcite crystals, monomer resolution on actin fibers, and resolution of the major and minor groove of the DNA double-helix (see Fig. 2).

Figure 1. Comparison of the thermal noise (left) of three levers (far right) of about the same stiffness and quality factor close to a surface. The equivalent input force noise

in a ± 1 kHz bandwidth around resonance is shown.

Figure 2. Consecutive up and down scans of a single DNA molecule in buffer taken with a 30 μm lever at an amplitude of about 8 \AA . The major and minor grooves are clearly resolved.

A new type of super intense cluster beam source based on Matrix Assembly

T10 Nanoscience and Technology

#NST-11-Or-1

W. Terry, L. Cao, F. Yin, R.E. Palmer.

Nanoscale Physics Research Laboratory, School of Physics and Astronomy,
University of Birmingham - Birmingham (United kingdom).

Over the last 10-15 years there has been much interest in clusters, due to the highly size dependent properties they exhibit [1]. So far study of the field has been unable to harness the incredible potential of size-selected clusters into viable technologies for research and industry. The low flux of pure size-selected clusters available from current cluster source technology significantly limits the availability of size-selected clusters for test tube scale tests and rules out the use of size-selected clusters in large-scale industrial applications [2,3].

We propose that using the novel method of Matrix Assembly, size selected clusters could be produced in abundance. The Matrix Assembly method pins atoms of desired cluster material (e.g. Au or Ag) within a condensed rare gas matrix (e.g. Ar). Via sputtering the matrix with atomic ions (e.g. Ar⁺), clusters are produced [4]. Experimental results from our proof of principle testing and further advances are presented here. Our results demonstrate that by carefully selecting generation conditions not only a high flux of clusters, but also a narrow distribution of cluster sizes, can be obtained. Furthermore the average cluster size is governed by the concentration of cluster material atoms in the condensed rare gas matrix.

Geometric modification of AFM probes by SEM/FIB combination

T10 Nanoscience and Technology

#NST-P2-05

T. Šamoril ¹, D. Škoda ², B. Lencova ³, J. Spousta ¹, P. Varga ², T. Šikola ¹.

¹Institute of Physical Engineering, Brno University of Technology, 682 96 - Brno (Czech republic), ²CEITEC BUT - Brno University of Technology, Technická 10, 616 69 - Brno (Czech republic), ³Tescan a.s., Libušina trída 21, 623 00 - Brno (Czech republic).

A typical method of the surface characterization is SPM. As generally known, the resulting image quality of surface structures depends on the quality of SPM probes, especially on their material, geometric shape and the radius of the tip apex curvature. However, the image quality is gradually changing during SPM measurements, due to mechanical wear of the probe tip surface. In our contribution, the modification and repair of standard AFM probes by FIB (Focused Ion Beam) milling and EBID (Electron Beam Induced Deposition), and their combination, is reported. The operation was performed in a dual-beam system TESCAN LYRA3. First, the geometry of the standard AFM tip (NT-MDT CSG 10, NSG 10) was changed using FIB milling as follows: the tip cone angle was decreased to values smaller than 10° (for cone length > 3 μm), the curvature radius was kept constant at 10 nm. To provide it, approximately 10¹⁰ ions/μm² Ga dose was used. Compared to standard Si tips (side angle 36° for tetrahedral part of the tip and 7° - 10° for the last 500 nm from tip apex, the curvature radius 6 nm – 10 nm), a smaller distortion of topography was obtained during measurements of narrow deep structures using these tips. Further, the FIB technique was also used for repairing and sharpening damaged tips and removing impurities from tip surface, additionally. Efficiency of the process depends on the degree of the tip damage. The repaired and modified AFM tips showed the same or lower level of abrasion compared to those unexposed to FIB irradiation. The big advantage of the FIB milling in the dual beam system is the monitoring of the process of tip modification by SEM (Scanning Electron Microscope) simultaneously. Modification of AFM tips was done by EBID as well. The single point-deposition of platinum carried out by decomposition of an organometallic precursor was used. The conical tip with a curvature radius about 5 nm and a small cone angle (6°) was

obtained using this method at a platinum growth rate 100 nm/s, approximately. The prepared AFM tips were successfully used during topography and conductivity (EBID tips) measurement in contact and noncontact mode of AFM.

Similar to silicon-based electronics, chemical doping offers a tool for tailoring the electrical characteristics of organic molecular compounds [1]. Contrary to inorganic semiconductors, however, controlling the position of dopants and charge donation in molecular complexes is a complicated task due to the existence of multiple doping sites, electron acceptor levels, and intramolecular correlation effects. Here we use scanning tunneling microscopy to observe the position of single Li dopants within Cu-phthalocyanine and Ni-phthalocyanine molecules in contact with a metal substrate and probe the charge transfer process with unprecedented spatial resolution [2]. We show that individual phthalocyanines can accommodate at least three stable nonequivalent doping sites and up to six dopant atoms. Ligand and metal orbitals can be selectively charged by modifying the configuration of the Li complexes. Because of strong charge-spin correlation in confined molecular orbitals, alkali atoms provide an effective way to tune the molecular spin without introducing magnetic dopants. Controlled manipulation of Li further shows that charge transfer is determined solely by dopants embedded in the molecules, whereas the magnitude of the conductance gap is sensitive to the molecule-dopant separation.

The methods of preparation and analysis of nanostructures and thin films based on gallium nitrides have been intensively studied for the last two decades. Within that time many different techniques have been tested for fabrication of nanostructures (nanocrystals, nanopillars, nanowires). Nitride semiconductors still have a great potential in the production of fundamental components of light sources, laser diodes and detectors. However, as for the future nanodevices, the ability to control their exact shape, size and position on the substrate is essential.

In our contribution, we present the results achieved by low-temperature growth of gallium nitride nanostructures on various patterned substrates. In the experiments, the nitrogen ion beam and gallium atomic beam working at the same time under UHV conditions were used.

First, the conductive Si(111) substrate was used. The significant dependence of film morphology and thickness on deposition parameters, especially on substrate temperature and N/Ga flux ratio, was confirmed. Generally, the deposited layer consists of GaN crystals and metallic Ga spherical objects with the size from tens to hundreds nanometers. The size of these objects increases when the temperature of the substrate rises. An excess of gallium under a sufficient nitrogen flux leads to the formation of Ga metallic spherical objects surrounding GaN crystallites. For an increased nitrogen ion flux, the crystalline structure predominates over metallic gallium spheres and separate GaN crystals 200-300 nm in size at 300°C can be observed. Substrate temperature influences Ga diffusion length and, therefore, also promotes the size of GaN crystals. However, above certain substrate temperature, the crystal size does not increase any more due to evaporation, which lowers gallium lifetime on the surface. Further, GaN deposition on non-conductive substrates

(sapphire, quartz) was studied as well. Charging of these substrates was reduced using an electron neutralization filament in the vicinity of the substrate holder. Thereafter, the fabrication of ordered GaN nanostructures on pre-patterned conductive and non-conductive substrates by selective growth was studied. The patterning was done by SEM lithography using standard (organic and inorganic) and carbonized photoresists [1], and FIB. Chemical composition and morphology of deposited structures will be analysed using XPS and SEM, respectively, the local chemical composition by EDS, which has been proved to be a very useful technique in detection of local composition.

Nanocarbon, such as graphene and carbon nanotubes (CNTs), is one of the hottest materials in nanoscience and nanotechnology. To control their growth, their growth process should be well understood. For this purpose, transmission electron microscopy (TEM) observation which provides the detailed structural information in atomic dimension, especially in situ TEM observation, is essential. In this talk, in situ TEM observation of graphene and CNT formation from amorphous carbon-based nanofibers by solid phase reaction will be dealt with.

Metal-included and pristine CNFs were fabricated by Ar ion irradiation of an edge of a graphite foil with and without a supply of metals at room temperature, respectively [1]. The graphite foil thus prepared was cut into small pieces to be mounted directly on a TEM sample holder equipped with a piezo-controlled nanoprobe to verify the current-voltage characteristics of the metal-included and pristine CNFs in direct current and field emission modes. Depending on the included metal element in the CNFs, different type of nanocarbon, such as graphene, ring-shaped graphene, and CNTs, was formed during the electron current flow by solid phase reaction [2]. In the talk, their formation mechanism and current-voltage characteristics will be also dealt with.

The remarkable properties of graphene, such as the very high carrier mobility at room temperature, tolerance to high temperature and inertness, make it the most promising candidate for future nanoelectronics. Several methods have been developed to produce graphene layers of various dimensions and quality, which, however, hardly match the requirements for mass production of electronic devices. From one hand, exfoliation-based techniques are time-consuming and produce small flakes or graphene of poor quality; on the other hand large-scale growth on metal substrates is capable of large-area high quality layers, but requires the transfer of graphene on an insulating support in order to guarantee the conduction through graphene.

We have developed a novel transfer-free method to electrically insulate epitaxial graphene from the metal substrate it is grown-on. This is achieved by growing an insulating SiO₂ layer of the desired thickness directly under the epitaxial graphene layer, through a stepwise reaction between intercalated silicon and oxygen [1]. Firstly, epitaxial graphene is grown on a Ru(0001) crystal surface. Subsequent exposure of the sample to a Si flux at 720 K results in Si intercalation and in the formation of Ru silicide below graphene. The final step consists of oxygen intercalation [2] at T=630 K: the Ru silicide is rapidly oxidized producing a thin SiO₂ layer over an oxygen covered Ru surface. By following the entire process by high resolution fast-XPS measurements we establish that graphene does not react with

O₂ and that during the decomposition of the Ru silicide oxygen binds exclusively to Si [3]. At the end of the process, electrical insulation of the graphene layer from the Ru substrate has been demonstrated by performing lateral transport measurements with a microscopic 12 point probe, showing a resistance behaviour characteristic of two-dimensional transport.

The transfer-free method developed in the present work might have wide application in graphene research and in the fabrication of nanotechnology devices.

Altenbergerstrasse 69, A-4020 Linz, Austria

Integration of ferromagnetic properties into semiconductor devices has become a focus of worldwide research because of the prospects for applications in a future spin- and magnetoelectronics. Of particular interest are selected compounds of the Heusler alloys that are half-metallic ferromagnets and may exhibit conduction electrons with 100% spin polarization. Our recent study of the Heusler system $\text{Fe}_{1-x}\text{Si}_x/\text{GaAs}(001)$ [1] revealed a strong interdiffusion of Fe, Si, Ga, and As at the interface region, creating intermixed layers of 2-3 nm thickness in both, film and substrate. Interdiffusion is dominant already at the moderate growth-temperatures typically required for crystallographic ordering and lithographic processing of the Heusler films, which explains the obtained low spin-injection despite of excellent abrupt interfaces indicated by transmission electron microscopy and x-ray diffraction. In view of our alarming results, the development of appropriate diffusion-barrier layers is essential for ferromagnet/ semiconductor hybrid based devices.

Here we studied the preparation of single crystal MgO films on GaAs(001) as possible diffusion and tunneling barriers. In addition to structural and morphological results we report on in-situ stress measurements that provide direct information on the strain relaxation of the MgO films, which plays a crucial role in the subsequent growth of Heusler films.

High-speed imaging in tapping-mode atomic force microscopy

T10 Nanoscience and Technology

#NST-5-Or-2

M. Balantekin.

Izmir Institute of Technology - Izmir (Turkey).

Atomic force microscope (AFM) has become an indispensable tool in the field of nanoscale science and technology. Dynamic imaging modes of AFM provide better force sensitivity over contact mode. Hence tapping and noncontact modes are the preferred operating modes in air and vacuum environments. However, imaging speeds of conventional tapping-mode AFM systems are not satisfactory for applications such as real-time imaging of biomolecular interactions and industrial scale nanometrology.

The past research on the high-speed AFM imaging has shown that two major factors that limit the scan speed are the bandwidth of the actuator and the transient response of the probe. In the recent studies, sensor and actuator sizes have been minimized to increase the system bandwidth at the expense of increased system complexity. Also, new probe structures with integrated actuators were designed. Despite these efforts, the scan speeds required for the visualization of biomolecules have not been achieved.

In this study, we present a new operating method that we developed to be used in tapping-mode atomic force microscopes. This method is developed to minimize the time spent for tapping-mode AFM imaging experiments. In addition, the real-time imaging without complex AFM systems will be possible with this operating method. We will first describe the method and present our initial simulation results showing that even with a typical tapping-mode cantilever 5 frames/second imaging speed can be easily achieved.

Magnetic nanoparticles find a variety of uses, including many devices as motors, sensors, generators, videotapes and hard disks. Iron and the magnetic phases of iron oxide have gained importance in biomedical, environmental remediation, etc[1]. Graphite-coated metal nanoparticles have been prepared by CVD using organic precursors[2].

The present work describes the synthesis and characterization of carbon-encapsulated iron nanoparticles (CEINP's), which were obtained by CVD starting from previously synthesized magnetite nanoparticles. XRD, TEM, MFM, Raman and VSM were used for characterization.

Magnetite nanoparticles were prepared by co-precipitation using a similar method as that reported in [3]. After being cleaned, they were loaded in a CVD system. The CVD process was carried out at 900 °C under an inert atmosphere comprising argon and hydrogen gas, and methane as the carbon precursor.

The nanoparticles were characterized before and after being coated. Coprecipitation produces the magnetite phase of iron oxide (Fe_3O_4) 5 nm in size nanoparticles. These particles display a superparamagnetic behavior with a 50 emu/g saturation magnetization (M_s), in agreement with values reported by Xianqiao, et al. [4]. After the CVD process, Fe_3O_4 transforms into ferromagnetic iron coated with various graphene sheets, as revealed by XRD (fig. 1). Fig. 2 shows a TEM image of CEINP's. Magnetic characterization revealed the ferromagnetic character of CEINP's with a M_s of 165 emu/g and a coercive field of 15 Oe. The MFM measurements

showed that mean size domain distribution varies from 3.5 to 2.5 nm, for magnetite and CEINP's respectively.

Its remarkable properties make graphene attractive for use in electronic devices. Yet, graphene is semimetallic and thus not directly suitable for most electronic or optoelectronic switching devices, which require a semiconductor with a specific, finite band gap. In armchair graphene nanoribbons (AGNRs), band gaps suitable for room temperature applications open at widths smaller than 3 nm. However, atomically precise control over the edges is crucial to produce AGNRs with reliable electronic transport properties. We recently developed a bottom-up method providing this level of control over the edges [1].

This allows, in particular, to grow atomically precise 7-AGNRs (7 carbon dimers across the width) for which we have determined by scanning tunneling spectroscopy (STS) and angle-resolved photoemission spectroscopy (ARPES) a band gap of 2.3 eV as well as the occupied band structure of the ribbons adsorbed on a gold surface [2].

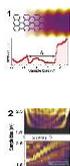

Here, we present the results of a detailed ARPES and STS of such bottom-up fabricated 7-AGNRs. GNRs of different length have been synthesized in order to explore the length dependence of the electronic band gap. STS data for ribbons of varying length reveals substantially larger band gaps for ribbons shorter than 5 nm. ARPES and Fourier transformed STS were used to determine the band dispersion of occupied and unoccupied bands. Based in these data, we determined the effective masses and energy-dependent charge carrier velocities for the frontier bands of 7-AGNRs. In addition, the experimental results are discussed by a detailed comparison with ab initio simulations of the band structure and the length-dependent band gap.

Focussed Ga Ion Beam (FIB) is a convenient method for the rapid prototyping of nanostructures in the wide range of applications. Contrary to the multistep procedure of Electron Beam Lithography (EBL), the FIB technique represents a single step mask-less technology.

One of the most straightforward applications of FIB technology is fabrication of plasmonic nanoantennas by milling their shapes out of metallic thin films. However, as the optical properties of antennas fabricated by FIB and EBL and having resonances in the visible range (called “optical antennas”) are considered to be similar, we have found that the Mid-IR Au rectangular antennas (having resonances in the Mid-IR) show different behaviour according to their fabrication origin. The Mid-IR Au antennas prepared by EBL on transparent samples (e.g. Si) possesses linear scaling of resonance frequency with their arm length. Contrary to that, those prepared by FIB revealed more complex behaviour. In principle, the resonant peak of relative reflectance of antennas is split into two sub-peaks separated by a dip at $\lambda \approx 8.2 \mu\text{m}$. The short-wavelength sub-peak was moving with the antenna arm length towards higher wavelength until its motion almost stopped at higher arm lengths. However, the long-wavelength sub-peak almost did not move with the antenna arm length for shorter arm lengths and then started to move towards higher wavelengths. Comparison with the spectra of antennas prepared by EBL and other techniques revealed that this splitting occurs just at the nanostructures fabricated by Ga FIB. This suggests that the splitting is related to the contamination of the sample by Ga atoms and so most likely to strong damping of electron oscillations [1].

¹CEITEC BUT - Brno University of Technology - Brno (Czech republic),

²Institute of Physical Engineering, Brno University of Technology - Brno (Czech republic).

The interaction of gold nanospheres with different substrates at elevated temperatures was studied in situ by X-ray photoelectron spectroscopy (XPS) and by time of flight low energy ion scattering (ToF-LEIS). Gold nanospheres were deposited from colloidal solutions on Si (100) substrates covered by native silicon oxide, thermal SiO₂ or graphene. Atomic force microscopy and scanning electron microscopy were used ex situ as complementary methods.

It was found that annealing at high temperatures leads to destruction of Au nanospheres. Au atoms can desorb from the surface or diffuse into and/or on the substrate. Depending on the substrate, chemical reactions can occur at elevated temperatures (e.g. formation of silicides) as well which naturally affects the shape stability of these nanospheres. In the contribution the mechanisms of gold nanospheres interaction with the substrates will be discussed in detail. Especially, the instabilities of the nanospheres at particular temperatures for specific substrates will be explained.

Nanoscale Mechanical Mapping at a wide range of deformation rates with Atomic Force Microscopy

T10 Nanoscience and Technology

#NST-3-Or-3

S. Minne, B. Pittenger, C. Su.

Bruker - Santa Barbara (United states).

Atomic force microscopes (AFM) can measure and map mechanical properties of materials with very high resolution. Over the years, the methods of mechanical mapping have evolved from slow force volume to multiple-frequency based dynamic measurements using Tapping Mode and contact resonance. Recently, real-time control of the peak force of the tip-sample interaction has led to a fundamental change in AFM imaging, providing quantitative mapping of mechanical properties at unprecedented resolution. During material property mapping, the time scale of tip-sample interaction now spans from microseconds to seconds, tip sample forces can be controlled from piconewtons to micronewtons, and spatial resolution can reach subnanometer. AFM has become a unique mechanical measurement tool having large dynamic range (1kPa to 100GPa in modulus) with the flexibility to integrate with other physical property characterization techniques in versatile environments. This presentation will review this recent progress, providing examples from a wide range of fields that demonstrate the dynamic range of the measurements, and the speed and resolution with which they were obtained. Additionally, the effect of time dependent material properties on the measurements will be explored.

Effects of the sudden electron-hole pair creation on the surface plasmon excitations in cylindrical nanorods

T10 Nanoscience and Technology

#NST-P1-05

J. Gervasoni ¹, J. Garcia Gallardo ¹, L. Kövér ².

¹CNEA - Bariloche (Argentina), ²Atomki - Debrecen (Hungary).

In this work we study the effect of the excitation of surface plasmons in a metallic cylindrical nanorod by a suddenly created electron-hole pair, using a classical model for the emerging electron and a quantum-mechanical model for the plasmon field in the cylinder [1]. The electron and the hole interact independently with the plasmon field, generating electron density oscillations. Two different trajectories for the emerging electron (parallel to the axis and radial) are studied in an aluminum nanorod. The average number of excited plasmons indicates how important is the role of the hole in the excitation process. We found that the results can be very different according to the trajectory of the emerging electron. We also found that the distinction between intrinsic and extrinsic process is sometimes not applicable.

School of Physics and Information Engineering, Fuzhou University - Fuzhou (China).

With a fast write/read speed, a good scaling capability as well as a good compatibility with current fabrication process, resistance random access memory (RRAM) becomes one of promising candidates for next generation non-volatile storage technology. Usually, the defects inside storage medium or on the interface determine the storage performance. As a transparent semiconductor with lots of intrinsic defects, zinc oxide (ZnO) also exhibits resistive storage capability and has potential applications in transparent storage devices. Therefore, doping some elements into ZnO seems to be a feasible way to control the defects and also adjusts its storage properties. Additionally, with the further down-scaling of physical dimension of electronic devices, the conventionally used storage medium in the form of thin film may also be replaced by its nanowire. In this perspective, doped ZnO nanowires are worth synthesis and investigation.

In this work, ZnO nanowires (ZnO_0001) were synthesized on ZnO seed substrates by zinc acetate solution with hydrothermal method. Cooper acetate was also introduced with different cooper concentration ($X=\text{Cu}/(\text{Cu}+\text{Zn})$, $x=1\%$, 2% , 4%) and the samples (CuZO_001, CuZO_002 and CuZO_003) were respectively obtained. Fig. 1 shows the SEM and HRTEM images of sample ZnO_0001. The pillar nanowires are in vertical alignments with six facets forming hexagonal cross-section, which is a typical characteristic of ZnO. The nanowire is single crystal without any visible defects inside the lattice and it is in a preferential c-axis orientation and exhibits (002) preferential growth. Fig. 2 shows the influence of cooper additive on the properties of 300°C annealed ZnO nanowires. With the increase of cooper concentration, the UV emission peak in PL spectra becomes broadened and weak,

while the visible peak is enhanced. The copper additive also produces 581.4cm^{-1} centered $E_1(\text{LO})$ Raman mode, which means the structural defects were introduced.

Figure 1. SEM image (a) and HRTEM image (b) of ZnO nanowire. The inset is the SAED image of single nanowire

Local barrier height and superconducting gap in Fe(Se,Te) by low-temperature scanning tunneling microscopy/spectroscopy (STM/STS)

T10 Nanoscience and Technology

#NST/SS-P2-03

A. Sugimoto, T. Ekino.

Graduate School of Integrated Arts and Sciences, Hiroshima University - Higashi-Hiroshima (Japan).

Recently discovered iron-based superconductors have been giving a great impact in the related field of research because of its highest critical temperature T_c of ~ 55 K among the non-cuprate superconductors. In the Fe-based superconductors, the iron-chalcogenide Fe(*Ch*) compound (the 11-type, *Ch* = chalcogen) exhibits the simplest crystal structure. Its single crystal is easy to be cleaved and the charge-neutral flat surface can be readily exposed. Therefore, the 11-type is believed to be very suitable for the STM/STS observation. For understanding the superconductivity mechanism, the superconducting gap is a very important quantity. However, the observed signal of the gap in the 11 type by STS measurement has been usually quite weak.

Therefore, it is necessary to understand the surface properties such as the distributions of work function (local barrier height, LBH) in order to clarify why the superconducting gap is hardly obtained in this compound.

Here, we examine the spatial distributions of LBH and local density of states (LDOS) by STM/STS using Fe(Se, Te) single crystals, and demonstrate how the surface properties affect the observation of superconducting gap.

The FeSe_xTe_{1-x} single crystals ($x \sim 0.3$, $T_c \sim 15$ K) were synthesized by a self-flux method using the double-sealed quartz tubes. The STM equipment used in this experiment is a modified Omicron LT-UHV-STM system. The samples were cleaved *in-situ* at $T = 2.5$ K in an ultra-high vacuum chamber of $\sim 10^{-8}$ Pa, then it was possible to obtain fresh and unaffected crystal surface. The STM measurements were carried out at $T = 4.9$ K under the UHV condition of $\sim 10^{-8}$ Pa. The STS conductance dI/dV , which is proportional to the local density of states (LDOS), was obtained by numerical differentiation of the measured tunnel-current (I) – voltage (V) characteristics, $I(V)$, with the spatial interval of ~ 0.08 nm. The values of LBH were

simultaneously obtained by measuring the dependence of I on the tip-sample distance z , $I(z)$. The average of LBH values was obtained as $\phi \sim 4.8$ eV, which is turn out to be large enough to provide ideal tunneling conditions.

The STM images show clear regular square arrangements of spots with the lattice spacing ~ 0.38 nm, together with the randomly-distributed large spots which are considered to be due to the excess Fe atoms. The LDOS maps also show the energy-dependent large spots of the excess Fe. The superconducting gap of the order of $\Delta \sim 5$ meV was observed in the vicinity of excess Fe, which is comparable to the previously obtained maximum values by the break-junction spectroscopy. It is noted that the LBH map clarifies the local area showing the larger ϕ values in the regular atomic arrangements, which correspond to the position of the excess Fe as seen in the LDOS maps and STM images. Therefore, it is considered that the local area where the gap structure could be observed is probably related to the area of large barrier height which is generated by the excess Fe.

Azobenzene molecules have become an archetype of molecular photoswitch research, due to their simple structure and the significant difference of the electronic system between their *cis* and *trans* isomers. However, a detailed understanding of the charge transport for the two isomers, when embedded in a junction with electrodes is still lacking.

With the aim of clarifying this issue, we investigate charge transport properties through single Azobenzene-ThioMethyl (AzoTM) molecules in a mechanically controlled break junction (MCBJ) system at 4.2 K. Single-molecule conductance, *I-V* characteristics, and IETS spectra of molecular junctions are measured and compared with first-principles transport calculations.

Our measured conductance traces clearly show that *cis* isomers have a larger conductance than *trans* isomers. The analysis of our simulations suggests that the difference in conductance of the isomers is due to the difference of their corresponding resonant states.

Experimental IETS spectra of Au-AzoTM-Au junctions exhibit distinct features for *cis* and *trans* isomers. The origin of such features has been elucidated based on simulated IETS spectra, which allows us to conclude that the observed differences in experimental IETS are indeed caused by the *cis-trans* conformation.

In conclusion, our studies elucidate the origin of a slightly higher conductance of

junctions with *cis* isomer and demonstrate that IETS spectra of *cis* and *trans* forms show distinct vibrational fingerprints that can be used for identifying the isomer. [1]

Since the first time a layer of graphene was isolated in 2004 [1], the interest in this material increased exponentially. The main attraction of this material lies in their unusual electronic, mechanical and magnetic properties such as the anomalous quantum Hall effect, the absence of electronic localization, high optical transparency, the high electrical conductivity, flexibility and high mechanical strength. These properties make graphene a very promising material for applications in electronics and spintronics, and therefore it is necessary to control the growth and properties at the nanoscale.

The growth of graphene layers on the nickel surface by decomposition of hydrocarbons is interesting for three main reasons. On the one hand, the lattice constant of the surface of Ni(111) coincides almost perfectly with the lattice constant of graphene, which allows it to grow in a 1×1 structure. Moreover, due to the catalytic effect of nickel surface, it is an autoterminated reaction, the reaction stops once the graphene monolayer is formed avoiding the growth of multilayers [2]. Finally, the Nickel is a ferromagnetic material, which opens the door to applications in spintronics.

Progress in the manufacture of low dimensional structures such as graphene nanoribbons has been reported [3]. It shows that the electronic properties of graphene change in a non-trivial way going to nanoscopic dimensions due to the contribution of edge effects.

In this work we study by STM the growth of graphene on a Ni (111) surface by decomposition of hydrocarbons [4]. By varying parameters such as the dosage of hydrocarbon, reaction time and temperature was possible to obtain in a reproducible manner a wide range of coverages. For low coverages the carbon atoms organize themselves into graphene nanoislands whose size and density are related to the

reaction parameters. These nanoislands, initially with irregular shapes, may, by further thermal treatment selectively acquire a triangular (Fig. 1) or hexagonal shape both with zig-zag edges. In the case of triangular islands all edges have the same packaging with the nickel surface underneath while in the case of hexagonal islands edges change alternatively the packaging. The optimum conditions to obtain nanoislands of particular size and shape are studied by systematic variation of the parameters of the hydrocarbon decomposition reaction and the thermal diffusion of carbon on the surface.

The present situation of environmental water pollution by toxic organic compound is requiring reliable analytical tool that can rapidly screen them with minimal sample handling [1]. The latest European regulations on water quality have aimed to achieve good ecological and chemical status for water bodies by 2015. Our study comes within this scope and is aimed to design a highly sensitive and specific nanosensor which would have the ability to monitor in situ the quality of environmental waters by pre-concentrating and specifically recognizing pollutants.

Surface Enhanced Raman Scattering (SERS) method has been employed to detect trace concentrations of water pollutants. This highly sensitive technique is based on the exploitation of the localized surface plasmon resonance of metallic nanoparticles for Raman scattering enhancement.

In this talk, results obtained with gold nanoparticles made by electron beam lithography [2] will be shown. In order to detect trace concentrations of pollutants, that are small and low soluble molecules, pre-concentrating systems were designed using cyclodextrins. These cyclic oligosaccharides are known to create specific host-

guest complexes with hydrophobic molecules thanks to their hydrophobic cavity. Specifically, alpha, beta and gamma-cyclodextrin, differing by the size of their cavity, were converted to thiol-derivatives and subsequently grafted to gold nanoparticles. Nanosensors with self-assembled cyclodextrins monolayer were then tested for detection of poly aromatic hydrocarbons (PAH) such as naphthalene and fluoranthenes and volatile organic compounds: toluene and xylene.

The authors want to acknowledge the ANR REMANTAS project (ANR-11-ECOT-0010) for financial support.

Efficiency of Graphene-Based Solar Cell as the Number of Graphene Layers

T10 Nanoscience and Technology

#NST-P1-10

K. Ihm, K.J. Lee.

PAL - Pohang (Korea, republic of).

Impressive optical properties of graphene have been attracting the interest of researchers, and, recently, the photovoltaic effects of a heterojunction structure embedded with few layer graphene (FLG) have been demonstrated. Here, we show the direct dependence of open-circuit voltage (V_{oc}) on numbers of graphene layers. After unavoidably adsorbed contaminants were removed from the FLGs, by means of in situ annealing, prepared by layer-by-layer transfer of the chemically grown graphene layer, the work functions of FLGs showed a sequential increase as the graphene layers increase, despite of random interlayer-stacking, resulting in the modulation of photovoltaic behaviors of FLGs/Si interfaces.

Spin-polarized STM study of Co nano islands on Ag(111) surface

T10 Nanoscience and Technology

#NST/SS-6-Or-5

Y. Hasegawa, K. Doi, S. Yamamoto, H. Kim, Y. Yoshida.

ISSP, Univ. Tokyo - Kashiwa (Japan).

Cobalt is an hcp metal in bulk, but its fcc structure can be formed as a thin film on various substrates. On fcc(111) substrates, an epitaxially grown hcp film has out-of-plane magnetization because of magnetocrystalline anisotropy that favors c-axis magnetization, whereas an fcc film has in-plane magnetization due to the shape anisotropy. Recently, surface-magneto-optical Kerr effect (SMOKE) technique revealed that cobalt thin films on Ag(111) have remnant magnetization in both in-plane and out-of-plane directions indicating the possibility of coexistence of the two structures [1]. To clarify magnetic properties of the system, we have utilized spin-polarized scanning tunneling microscopy and spectroscopy (SP-STM/S) [2], which enables us to characterize magnetization locally with nanometer-scale spatial resolution.

In STM images taken on a Co-deposited Ag(111) surface, we observed island structures with a thickness of 5~6 monolayer having a Moire pattern on their top. These Co islands are categorized into two groups depending on the Moire intensity; strong one and weak one. Using an out-of-plane magnetized tip, we found the strong Moire islands show a hysteretic variation in dI/dV under a sweep of the perpendicular magnetic fields, whereas the weak Moire islands do not. These findings support coexistence of the two structures and suggest that the strong (weak) Moire islands have a hcp (fcc) structure.

SELF-ORGANIZED AMPHIPHILIC DI-BLOCK COPOLYMER AS A GOLD NANOREACTOR

T10 Nanoscience and Technology

#NST-11-Or-3

S. Boyer ¹, C. Iwamoto ², R. Nakagawa ², K. Takahashi ², T. Yamada ², H. Yoshida ².

¹P PRIME Institute - Futuroscope (France), ²Tokyo Metropolitan University - Tokyo (Japan).

The design of advanced hybrid “hard” materials (metal or semiconductor nanocrystals) / “soft” materials (copolymers) requires to conduct constant efforts directed to gain exquisite control of the size distribution and shape of various noble metal nanoparticles (NMNPs).

The present work highlights two smart routes to manipulate the structure of hexagonally packed hydrophilic poly(ethylene oxide) (PEO) cylinders as nanoreactors. The objective is to achieve patterning of gold particles (AuPs) in the nanometer scale via a polymer structure-mediated strategy.

Eco-aware treatment dealing with the use of carbon dioxide (CO₂) or colloidal aqueous solution is reported as a way for depositing pre-formed AuPs selectively into the PEO phase-segregated nanodomains of the pre-patterned asymmetric liquid-crystalline (LC) amphiphilic di-block copolymer PEO-b-PMA(Az) scaffold [1]. The pattern deliveries are conducted through rigorous thermodynamic, diffuso-mechanic, geometric, capillary forces and chemical criteria which may be categorized under four main considerations: (i) the specific interactions of LC/solvent (liquid, gaseous and supercritical CO₂) systems as a function of pressure, temperature and annealing (time); (ii) the modulation of the surface topology concomitantly with the swelling of the CO₂-modified nanophase-separated organization; (iii) the “decorative” AuPs distribution modulation (iv) with the chemical function of the protected AuPs.

The fine thermo-diffuso-chemo-mechanical interactions would provide an essence of a two-dimensional (2D) nanometer crystal growth. Such a nontrivial study is illustrated and discussed on catalyst systems. Interest is to consider gold as a catalyst [2]. The gold ions locate inside PEO, one nucleation site giving rise to one cell growth stage.

The organization of the structure in the nanometer scale was supported by small X-ray scattering (SAXS), Transmission Electron Microscopy (TEM), and grazing incidence small-angle X-ray scattering (GISAXS).

Pure and doped copper ferrite with the $Mg_xCu_{1-x}Fe_2O_4$ ($x=0$, $x=0.02$ and $x=0.06$) structure have been successfully synthesized via co-precipitation method. The obtained precursors were characterized by thermogravimetric TG/DTA to determine the thermal decomposition and they were calcined at 600 and 800°C to obtain the ferrite spinel. The solids obtained were characterized by XRD, and BET isotherm. The TG/DTA thermogravimetric demonstrated the formation of crystalline $CuFe_2O_4$ and the $MgFe_2O_4$ ferrites, as confirmed by XRD. The X-ray diffraction (XRD) confirmed the formation of spinel structure $CuFe_2O_4$ and mixed oxide (CuO , Fe_2O_3) for all samples also the formation of the $MgFe_2O_4$ specially for the sample doping and calcined at 800°C. However, the $CuFe_2O_4$ catalysts present low specific surface BET, this last increases progressively by increasing the amounts of dopant added. The study of effects the magnesium doping in total oxidation (combustion) of ethanol over $Mg_xCu_{1-x}Fe_2O_4$ ($x=0$, $x=0.02$ and $x=0.06$) prepared by co-precipitation method, is investigated.

Table .1.

catalysts	S_{BET} (m ² /g) T _c = 600°C	S_{BET} (m ² /g) T _c = 800°C

The Interaction between Piezo Materials and Microwave Readout of Nanomechanical Resonators

T10 Nanoscience and Technology

#NST-3-Or-4

L. Hao, J. Gallop, J. Wooldridge, K. Lees.

National Physical Laboratory - Teddington (United Kingdom).

Nano-electromechanical (NEMS) resonators are an important future technology with wide ranging applications already beginning to appear. As mechanical resonators shrink towards the nanoscale two related problems emerge. The difficulty of excitation of mechanical displacement becomes greater as the length scale reduces and further the ability to detect this displacement also increases. We report on developments to minimise these problems through the use of novel piezo-electric materials for excitation and a near-field microwave resonance technique to excite and readout the mechanical resonator motion. The scale dependent properties of these methods are derived and compared, through both modelling and experiment, with a view to determining which method will be most applicable at the sub-micrometre scale length for NEMS resonators. Piezo materials may be used even at frequencies above 1 MHz, provided care is taken to minimise the high frequency impedance of the structure. But we go on to show that microwave methods are intrinsically more suited to the highest frequencies, even approaching the ability to perform up to 1 GHz.

Early results of microwave readout of the resonance of a composite mechanical resonator consisting of a 1 micron thick PZT layer on a 10 micron Si layer are shown in the figure 1. This shows the mechanical resonance of the membrane as read out by a near-field microwave probe [1] and the shift in resonant frequency from applying a d.c. voltage across the piezo layer. We also report early results on sub-micrometre drum membrane resonators made from graphene, which allow us to deduce mechanical properties of few layer graphene.

Enhancement in light emission efficiency of a Si nanocrystal light-emitting diode by indium tin oxide nanowires

T10 Nanoscience and Technology

#NST-P3-22

C. Huh, T.Y. Kim, B.K. Kim, B.J. Park, E.H. Jang, H.K. Kim.

IT Convergence Technology Research Laboratory, Electronics and Telecommunications Research Institute - Daejeon (Korea, republic of).

In recent years, Si nanocrystals (NCs) has attracted the most attention as a promising light sources for the next generation of Si-based nanophotonics [1]. The optical band gap of Si NCs can be easily tunned by changing the size of NCs due to a quantum confinement effect, meaning that Si NCs are of particular interest as a light-emitting diode (LED) covering whole visible wavelength range. We recently demonstrated a prototype Si NC LED by employing an amorphous SiC(N) film as a suitable electron injection layer [2, 3]. To further improve the light emission efficiency of Si NC LED, a conductive electrode layer that can uniformly deliver the electrons into the Si NCs should be addressed. . In addition, this layer must have a high transparency to increase the probability of photons escaping from the LED device. In this work, a new technique for improving the light emission efficiency of Si NC LEDs by employing indium tin oxide (ITO) nanowires (NWs) was investigated. The ITO NWs were grown by a Q-switched Nd:YAG pulsed laser deposition. The structure of Si NC LED investigated here was ITO NWs/ITO (100 nm)/n-SiC (50 nm)/Si NCs in SiN_x (50 nm)/p⁺-Si substrate. The Si NC LED without ITO NWs was also fabricated for comparison. The SEM image of ITO NWs grown at 500 °C is shown in Fig. 1. As the temperature decreased, the ITO NWs were smaller and less uniform in size as compared to those synthesized at 500 °C. The ITO NWs had a tendency to grow perpendicularly above the surface, even though all of them were not perfectly oriented on the surface. The I-V characteristics of Si NC LEDs with ITO NWs was improved as compared to that of Si NC LEDs without ITO NWs. This was attributed to an enhancement in the current spreading property of the ITO layer and a decrease in the dynamic resistance of the whole Si NC LED. Moreover, light output power and wall-plug efficiency of the Si NC LED with ITO NWs were also enhanced. We will

discuss on the electrical and optical properties of Si NC LED with ITO NWs in detail.

Electrochemical synthesis of CdS/ZnO nanotube arrays with excellent photoelectrochemical properties

T10 Nanoscience and Technology

#NST-P2-31

G. She, X. Qi, L. Mu, W. Shi.

Technical Institute of Physics and Chemistry, Chinese Academy of Sciences - Beijing (China).

Photoelectrochemical cell represents an ingenious approach to directly convert solar energy to electricity or chemical energy such as H₂. The main drawback of ZnO as photoelectrode material is the poor activation in the visible-light region. This issue could be alleviated by decorating ZnO with a narrow band-gap semiconductor, CdS. Meanwhile, the Type- II band configuration would reduce the probability of recombination of the photoinduced electron-hole pairs through the spatial charge separation process. In this study, a facile electrochemical method was employed to sensitize the ZnO nanotube (ZNT) arrays with CdS. The ZNT arrays were uniformly sheathed by a compact layer of CdS granular film. CdS films with the optimized thickness (40(±15) nm) can efficiently absorb the incident photons as well as restrain the recombination of the separated electron-hole pairs. Upon illumination, the photocurrent was 7.00 mA/cm² for the CdS/ZNR arrays, which is significantly enhanced compared to that of the pure ZNT arrays (0.69 mA/cm²). Furthermore, the CdS/ZNT arrays exhibited an even higher photocurrent of 10.64 mA/cm². We attribute the excellent photoelectrochemical performance to several factors. First, the CdS/ZNT arrays possessed a larger specific area and accordingly offered a larger photoelectrode/electrolyte contact area which is beneficial to the collection of the holes. Second, the nanotube arrays offering a long optical path act like lots of light-trapping wells, leading to a better anti-reflection effect. Third, the configuration of the ZnO nanotubes can result in a highly efficient charge collection. The excellent photoelectrochemical performance of the CdS/ZNT arrays making them of interest as high-performance photoelectrodes in photoelectrochemical cells.

Novel experimental investigations are currently underway to explore fundamental processes involved in the interaction between isolated nano-objects and soft X-ray radiation [1]. This kind of experiment has become possible due to advanced instrumentation that is now available, in particular at the PLEIADES beamline [2] - SOLEIL synchrotron facility.

In this study, we were able to produce a focused beam of silicon nanoparticles in vacuum from a stable suspension in ethanol. The synchrotron radiation crossed the nanoparticle beam at 90° in the focal point of an aerodynamic lens. In the interaction region, the particle beam diameter and the local particle density were estimated to be 300 μm and 10⁷ cm⁻³ respectively.

These conditions allowed us to perform X-ray Photoelectron Spectroscopy (XPS) and Near Edge X-ray Absorption Fine Structure (NEXAFS) of isolated surface-oxidized silicon nanoparticles of different sizes and different natural oxidation time. The incident photon energy was 158 eV, and Si 2p photoelectrons were recorded.

The relative chemical shifts for the various oxidation states of Si have been investigated previously for oxidized silicon wafers [3]. As in that experiment, we can observe all the oxidation states of silicon from Si⁰ to Si⁴⁺ on the surface of the nanoparticles. A systematic study of different types of particles suggests that the oxidation process and the oxide-crystal interface structure depend on the oxidation duration and on nanoparticle size.

Abstract:

Interaction in inorganic/organic interface plays decisive role on resistive switching mechanisms when current is injected. It is excited to utilize these interface effects to mimic basic functions of neural systems, one of which is synapse because using a memristor to mimic learning behavior is a very important development of highly efficient and scalable artificial neural networks. Scientists are currently engaged in the search for effective systems to realize synapse plasticity in this emergent field. We have fabricated several artificial synapses using PEDOT:PSS based memory devices. It is found that the synaptic plasticity varies extensively depending on different interface effects. A Ti/PEDOT:PSS/Ti memory device is a combined system of two readily available inorganic and organic memory materials, consisting of Ti compounds near the electrodes and PEDOT:PSS in between. These two mechanisms can be triggered under a bias with the same sign. However, the resistive switching threshold of the Ti compound is lower than that of PEDOT:PSS, higher. Memory mechanism of a Ta/PEDOT:PSS/Ag structure is the migration of Ag ions driven by redox reaction. Both potentiation and depression, in addition to spike time dependent plasticity, have been emulated using these two memory devices. Furthermore, some special features are presented in these two memory devices,

respectively. Complex memory phenomena including nonvolatile and volatile memory behavior are observed in Ti/PEDOT:PSS/Ti system because of the competition between two contrasting memory mechanisms above mentioned. Besides, metaplasticity can be realized in Ti/PEDOT:PSS/Ti system. However, good rectification and high resistivity, which is in favor of integration using crossbar model, are demonstrated in Ta/PEDOT:PSS/Ag structure. These two memory devices are complementary for each other if they are used to mimic different types of synapse in complex neuromorphic circuits. Our devices can provide the basis for Hebbian learning in the brain and facilitates diverse synaptic plasticity mechanisms in large-scale neuromorphic circuits.

VACUUM RHEOLOGY MANIPULATORS

FOR THE MULTICOORDINATE

NANOPOSITIONING AND ACTIVE

VIBRATION ISOLATION

T10 Nanoscience and Technology

#NST-7-Or-2

V. Mikhailov, A. Basinenkov, I. Zobov, A. Selivanenko.

BMSTU - Moscow (Russian federation).

The advanced vacuum equipment (for surface analysis, for micro lithography and etc.) uses multicoordinate precise positioning manipulators. The new vacuum manipulators on base of magnetic rheology (MR) liquids and MR elastomers are presented. The combination of MR loop control with elastic carriers and thin wall seals ensures small error of linear positioning (< 50 nm), small time of response (< 100 ms), total linear travel on three coordinates X,Y,Z 1 mm and load capacity more then 10 N [1,2].

It was shown, that the error of positioning of the MR manipulators with a loop control system (Fig.1) is determined by static friction force 0,1-1 N, that corresponds to error of positioning 10-100 nm. The response of the manipulators on base of MR elastomer is determined by time of response on a control signal, which value of time should not exceed 100 ms (Fig.2).

The parameters of vibration isolation systems are a cruelty and a viscose friction coefficient. The control system changes the main performances of the manipulator and reduces the oscillation amplitude that helps to move object to the check point. Because of this the MR manipulator can to operate as an active system of vibration isolation. The investigation of parameters: precision of displacement and response time of the vibration isolation system is being carried out. As a result of the work are presented: three coordinate MR hydraulic manipulator and nanopositioning manipulator on base of MR elastomer.

NST/SS-7-Or-5

One-step fabrication of few-layer graphene pattern on SiO₂ without catalyst or lithography

T10 Nanoscience and Technology

#NST/SS-7-Or-5

S. Chun.

Sejong University - Seoul (Korea, republic of).

Any electronic application of graphene needs graphene located at the desired positions on the desired materials. So far, to accomplish this many steps are required, such as graphene growth on a metallic catalyst, etching of the catalyst, transfer to the desired substrate and lithography for pattern formation. Innovative methods have been developed to slim down this process, skipping one or two steps, and these methods can also reduce the complexity and cost.[1,2] Here, we show that direct graphene growth without a catalyst enables the fabrication of arbitrary graphene patterns on SiO₂ in a single step. This one-step pattern formation is performed at temperatures as low as 500 °C using plasma enhanced chemical vapor deposition and a shadow mask (Figure 1). The pattern consists mainly of polycrystalline graphene with only a few layers and a small portion of single and double layer graphene (Figure 2). Furthermore, the nucleation of graphene could be prohibited by hydrogen plasma treatment prior to the growth, offering another way of selective growth. This catalyst-free, lithography-free method for graphene patterning, which can be applied to various substrates, would accelerate the use of graphene in processes where simplicity is preferred.

Sintered TiC-5VC-18NiCr Alloys with Nano Additions of Tungsten Carbide

T10 Nanoscience and Technology

#NST-P2-22

L. Bodrova, H. Kramar, O. Mul, I. Koval.

Ternopil Ivan Pul'uj National Technical University - Ternopil (Ukraine).

At present, it is very actual the problem of creation of new hard alloys and improvement of properties of the existing ones. This problem can be solved both by optimizing the alloys chemical composition and tungsten carbide alloying and by the use of new technological approaches in forming the structure, including nanotechnology elements [1]. In this paper it is investigated the effect of alloying fine-grained and nano additions of tungsten carbide on the microstructure and mechanical properties of the TiC-5VC-18NiCr system alloys. The alloys are obtained by the powder metallurgy method, which includes sintering in a vacuum. It is found that alloying by nano additions of WC (90-200 nm) in the amount of (5-15) % wt. leads to grinding of carbide base grains, retaining the typical core-rim structure (Fig. 1). Here, a change of the dimensional characteristics of the core and the rim of carbide grains occurs as well as a decrease in the tungsten concentration gradient between external and internal zones of the rim and an increase in the number of small homogeneous grains. With the increase of the nano-WC content, microhardness and Rockwell hardness are increasing as well as a slight drop in the crack resistance coefficient is observed. X-ray diffraction investigations of the alloys with nano-WC show that during sintering there is a certain increase in the percentage of the cubic W_2C , which has a higher microhardness in comparison with the hexagonal WC. This effects additively on the alloy hardness in whole. Besides, fine particles of nano-WC dissolve in the binder more easily that leads to the strengthening of carbide-metal bonds and the corresponding increase in hardness and microhardness. With increasing content of nano-WC, the crack resistance decreases. This can be explained by the lack of the binder, by the increase of the number of carbide-carbide contacts and by the decrease of the interphase boundaries strength. When using the nanodispersed additions, the specific surface area of carbides increases and the binder amount, which is optimal for the fine-grained carbide, becomes insufficient to ensure wettability. The values of the crack resistance coefficient for the alloys with WC nano additions ($6.2-6.8 \text{ MPa}\cdot\text{m}^{1/2}$) are

almost 20% higher compared to the fine-grained ones, while preserving the general decreasing trend with a nano-WC growth.

Spin-dependent transport properties in 1D systems: *ab-initio* studies

T10 Nanoscience and Technology

#NST/SS-6-Or-6

I. Sivkov, V. Stepanyuk.

Max Planck Institute of Microstructure Physics - Halle (Germany).

This contribution presents the results of theoretical *ab-initio* calculation of spin dependent transport properties of one-dimensional systems using Density Functional Theory and Non-Equilibrium Green's Function method.

In experimental works [1,2] authors reported the occurrence of spin injection and large magnetoresistance in systems with Co electrodes and Au contacts between them. We perform a theoretical study of conductance and I-V characteristics for Co-Au-Co nanocontacts. Co electrode is constructed as a Co pyramid on hcp Co(0001) surface. Au contact is represented by a Au atomic wire between the electrodes. Calculated conductance and current show quiet high spin polarization due to s-d hybridization of Co electrode states with the states of Au. This effect can explain the experimentally observed high magnetoresistance and spin injection.

Another way to obtain spin polarized currents is to use half-metallic materials. Motivated by results of [3], where a possible half-metallic behavior of GdN-bulk was shown, we investigate conductance and I-V characteristics of GdN atomic zigzag infinite chains. The chain is found to have a half-metallic behavior, which leads to the 100% spin polarization of conductance. Additionally, conductance and current through fcc GdN(001) films with Cu(001) electrodes in the direction perpendicular to the film is studied. It is found that GdN films show strong spin polarization of conductance and current reaching 90%, that can be used as a spin-filter for spintronic devices.

Formation of bimetallic Au-Cu nanoparticles on TiO₂(110) followed in-situ by STM and GIXD

T10 Nanoscience and Technology

#NST-11-Or-4

G. Prevot ¹, A. Wilson ¹, R. Bernard ¹, Y. Borensztein ¹, B. Croset ¹, A. Vlad ², A. Coati ², Y. Garreau ².

¹Institut des Nanosciences de Paris - Paris (France), ²SOLEIL Synchrotron - Saint Aubin (France).

The fabrication of bimetallic nanoalloys with controlled size, composition and structure attracts a wide interest for magnetic, optical or catalytic applications. The mixing of the two metals can lead to various structures such as alloyed phases, core-shell or janus configurations. In the field of catalysis, Au based nanoalloys are of special interest, due to the specific properties of Au at the nanoscale. Among them, Au-Cu nanoparticles attract a growing interest. Such nanoparticles have been recently shown to be active for various chemical reactions, especially oxidation reactions. Au-Cu nanoparticles supported on oxide substrates have been shown to be active for CO oxidation, preferential oxidation of CO in H₂ environment or propene epoxidation.

Using in-situ scanning tunneling microscopy (STM), we have studied the growth of Au-Cu nanoparticles on TiO₂(110). We show that successive evaporation of Au and Cu leads to the synthesis of alloyed nanoparticles whereas Cu evaporation followed by Au evaporation leads to the renucleation of pure Au nanoparticles. Starting from pure Au NPs of mean size 1.5 nm grown at 300K, we have followed by grazing incidence X-ray diffraction and small angle scattering (GIXD/GISAXS) the change of the NPs during Cu evaporation at room temperature. Alloying occurs instantaneously and the lattice constant of the NPs shifts gradually towards lower values during evaporation. The epitaxial relations with the substrate remain unmodified, with a main relation given by Au(112)//TiO₂(110) and Au[1-10]//TiO₂[001]. After deposition, no chemical ordering could be evidenced in the NPs (of size around 2 nm). However, after annealing at 400°C, AuCu NPs present a L10 chemical ordering, whereas Au₃Cu and AuCu₃ NPs remain FCC disordered. No significative variation of the mean size of the NPs is observed. The formation of an ordered phase for such small NPs is

unexpected since it is usually observed for larger NPs (above 10 nm) on amorphous substrates. This specific behaviour could be related to the interaction with the substrate and the specific geometry of the (112) interfacial plane.

STM observation during growth. a) and d) bare TiO₂(110) surface. Steps are shown (black lines). Observation of the same area as (a) after 0.01 ML Cu evaporation (b) followed by 0.01 ML Au evaporation. Fabrication and study of C₆₀-Co_x complex using low temperature scanning tunneling microscopy and spectroscopy

T10 Nanoscience and Technology

#NST-7-Or-3

P. Yang, J. Lagoute, V. Repain, C. Chacon-Carillo, Y. Girard, S. Rousset.

MPQ, Université Paris Diderot - Paris (France).

Profound understanding of the electronic process at the metal/molecule interface and the interaction between the organic molecule and metal at atomic scale is critical to fabricate the new generation molecule electronic devices. Moreover, atom manipulation using scanning tunneling microscopy (STM) allows the formation of atomic controlled artificial molecule-metal conjugate [1–3]. As the interface between C₆₀ and magnetic material holds promises for molecular spin electronics [4,5], we studied the interaction between C₆₀ and Co atoms. Using a low temperature (LT) STM we performed atomic and molecular manipulation to build and study C₆₀-Co_x complex.

The Co atoms and C₆₀ molecules are deposited in-situ on a clean Au(111)/mica surface in ultra-high vacuum ($<10^{-10}$ mbar) at low temperature (5K). We show that it is possible to move a C₆₀ above a Co adatom and then manipulate the molecule-atom ensemble as a single object, suggesting that we formed a Co-C₆₀ complex. Moreover C₆₀-Co_x entities with $x>1$ can be formed by a combined lateral manipulation of C₆₀ and Co adatoms in two different ways: the molecule is successively moved towards individual adatoms, or a Co_x cluster is built by atomic manipulation and the molecule is moved towards the cluster. We have been able to add up to 9 Co atoms to a C₆₀, which is, to our knowledge, the largest number achieved in such molecule-metal atom complex.

We performed dI/dU spectroscopy using the lock-in technique in order to measure the influence of Co on the molecular spectrum. Although possible doping effect still

need to be clarified, the C_{60} - Co_x spectrum exhibit the main features of the C_{60} single molecule suggesting that the pi states are at most only slightly affected by the interaction between the molecule and the Co atoms.

Nanoparticles are becoming increasingly important in a wide range of different fields including optics, catalysis, energy, mechanics and biomedical. The exceptional properties of these materials are a direct function of their small size, but also their composition, structures, morphologies and crystallinity. Among all the possible compositions of such materials, lanthanide fluorides receive specific attention. Conventional methods for preparing nanoparticles of lanthanide fluorides are most often difficult to implement (for entire series) for further use on industrial scale. Current processes often lead to compounds with unsatisfactory purity or to nanoobjets with low crystallinity. Additionally, some of these processes use binding temperatures and pressure conditions and/or use expensive raw materials with synthesis routes that are not practical for industrial applications. The present study provides a novel process for a simpler preparation of lanthanide fluoride nanoparticles for all of the lanthanide series, as well as for solid solutions between fluorides. The objects obtained may be isolated as powders or colloidal solutions in a large number of solvents. The method also covers the preparation and shaping of different materials (thin films, monoliths and powders) out of these nanoparticles. The magnetic and emission properties of nano-objects as well as materials obtained will be presented. The figure below shows examples of nanoparticles of lanthanide fluorides prepared using the new process.

Tuning Surface Stiffness with Thin Oxide Films

T10 Nanoscience and Technology

#NST-3-Or-5

S. Cohen ¹, E. Kalfon-Cohen ¹, D. Barlam ², K. Gotlib-Vainshtein ³, O. Girshevitz ³, C. Sukenik ³.

¹Weizmann Institute of Science - Rehovot (Israel), ²Ben Gurion University - Beer Sheva (Israel), ³Bar Ilan University - Ramat Gan (Israel).

Controlling and tuning surface and interfacial mechanical properties is the starting point for many scientific and engineering problems and applications. In this work, surfaces with tunable stiffness have been designed and created by coating a soft polymer (polydimethoxysilane) by a layer of amorphous titanium oxide with thickness varying between 8 and 70 nm. This protocol allows control of surface stiffness, while preserving the bulk material properties as well as composition and chemical reactivity of the interface. The surfaces were characterized by a variety of techniques, and AFM-based nanoindentation was applied to deduce the mechanical characteristics. Finite element analysis was used to investigate the modes of deformation, as well as respective contribution of substrate and film to the overall mechanical response. It is shown that knowledge of only the film thickness, and elastic modulus of film and substrate allows accurate prediction of the observed load vs. deformation characteristics.¹ These results show promise in design and creation of surfaces with independently customized chemical and mechanical properties.

Temperature dependence of a graphene growth on a stepped iridium surface

T10 Nanoscience and Technology

#NST/SS-7-Or-6

P. Pervan, I. Šrut, V. Mikšić Trontl, M. Kralj.

Institut za fiziku - Zagreb (Croatia).

Many of the desirable properties of graphene are related to its electronic structure with linearly dispersing π and π^* bands merging at the Fermi level in a single point. This makes graphene a gapless semiconductor which is a limiting factor for some applications of graphene in electronics where a sizeable band gap at the Fermi energy is required. For that reason, a lot of research effort is directed towards manipulation of the electronic structure of graphene around the Fermi energy. One possible route, which is subject of this work, relies on altering the graphene band structure by means of an additional periodic potential, i.e. graphene superlattice. Calculations indicate that superlattice structures may lead to unexpected and potentially useful charge carrier behavior, e.g. gap openings or Fermi velocity anisotropy [1].

Graphene superlattices have been already realized on well defined monocrystalline substrate surfaces as a consequence of the mismatch of graphene and substrate lattices which leads to the so called moiré superstructures. For graphene on Ir(111) it has been shown that the moiré superstructure adds a long range superperiodic potential to the graphene, which opens minigaps in the Dirac cone [2].

In this work [3] we have used scanning tunneling microscopy to study the growth of graphene on a periodically stepped Ir(332) substrate surface, which is a promising route for modification of graphene properties. We have found that graphene continuously extends over iridium terraces and steps. Moreover, new distinctive mesoscopic features of the underlying surface are formed involving large, flat terraces accompanied by groups of narrower steps. The distribution of the newly formed terraces is sensitive to the preparation temperature and only below 800°C terrace width distribution closer to the intrinsic distribution of clean Ir(332) are found. We propose that the microscopic shape of steps found after graphene formation is

strongly influenced by the orientation of graphene domains, where graphene rotated by 30° with respect to the substrate has a prominent role in surface structuring.

Since their discovery by Iijima [1] carbon nanotubes (CNTs) attract great interest due to their unique physicochemical, electric and mechanical properties, such as hardness, emission and others, which imply CNTs applications in electronics, and a variety of other properties promising their possible practical applications in other fields.

Carbon nanotubes are produced by chemical vapor deposition (CVD) at 800, 850 and 900 °C from benzene and ferrocene in the flow of argon (50, 80 and 110 ml/min) in the reactor constructed by [2], based on [3]. CVD synthesis proceeds at the atmospheric pressure during one hour. The amounts of CNTs obtained are 0.5-1.7 g. Field Emission Scanning Electron Microscopy, Energy Dispersed Spectroscopy (EDS) and X-Ray Diffraction are used to characterize the obtained CNTs. The observed lengths of the CNTs are 70-412 µm and diameters 15-133 nm. EDS demonstrated about 0.4 of Atomic percentage of Fe in the CNTs. The numbers of CNTs walls are estimated by Scherrer's equation [4]. The different flow of argon produced various numbers of walls: 50 ml/min-41 walls, 80 ml/min-36 walls and 110 ml/min-32 walls average.

The epoxy resin series 2040 with aluminum load by Epolyglas (which is designed to manufacture vacuum molding and structural elements) is used for the preparing of composite. The epoxy resin comes in two components: epoxy aluminum bearing and hardener clear amber liquid. The mixing contained 20 ml of hardener liquid per 0.1 Kg epoxy resin. The obtained nanotubes are dispersed in the epoxy resin using a

solution blending technique to obtain a carbon nanotubes-polymer composite with 3% weight of CNTs. The solidification time was 4 hours. Later the samples were thermally treated in a muffle for 1h, raising the temperature from 30 °C to 150 °C in order to improve the major mechanical resistance.

The obtained composites materials are analyzed with a Micro Vickers Hardness Tester, Mitutoyo 810-129E equipped with Vickers and Knoop indenters. The hardness is evaluated by a force application of 0.05 and 0.1 Kg during 10 s. It can be observed that the higher values of hardness are presented in the composites produced from CNTs with lower number of walls obtained with argon flow of 110 ml/min and temperature 850 °C. The range of Hardness Vickers for obtained composites is 880-1150 Kg/mm². It is important to mention that these values exceed more than 4 times the hardness of steel 1018, and far much more the hardness of epoxy resin without CNTs. So the addition of just 3% weight of CNTs allows providing high hardness to CNTs-epoxy resin composite.

Nano-additives Reinforcing of Binders for Diamond Cutting Tools

D. Sidorenko, E. Levashov, V. Kurbatkina, A. Zaitsev, S. Rupasov
National University of Science and Technology "MISIS"

Currently, the diamond cutting tools are becoming more widely used in build industry. Advantages of using it are obvious: low noise and vibration, which can destroy the integrity of building structures; increase in productivity in several times, because this type of cutting tools does not have difficulties with the notch of armature and other metal parts; and after cutting there are clean smooth holes which do not require additional processing. The most important characteristics of cutting tools are the cutting speed and wear resistance, which, in turn, depend on the physical and mechanical properties of a binder.

The incorporation to metal matrix composite (MMC) of even a small amount of reinforcing nanoparticles can significantly increase hardness, bending strength, impact strength, and decrease of friction coefficient, simultaneously, without increasing of the sintering temperature, duration and hot-pressing pressure. This work demonstrates effect of the dispersion strengthening by nanoparticles of tungsten carbide, zirconium dioxide and carbon nanotubes on mechanical and tribological properties of MMC based on iron and copper. Nanoparticles doped conventional MMCs show higher values of hardness and bending strength.

Besides, diamond/binder adhesive force is of great importance for cutting performance. Adhesion between diamond grains and the binder strongly depends on diamond graphitization. Raman spectroscopy studies of WC, ZrO₂ and Mo nanoparticles influence on this process are presented. Mo and ZrO₂ additives accelerate graphitization, while WC nanoparticles decrease graphitization level up to 30%.

Industrial tests of diamond cutting wheels and drills with disperse strengthened by nanoparticles MMC have shown the increase of life time up to 2 times without

reduction

of

cutting

speed.

Yttrium niobate (YNbO₄) phosphor is a perspective efficient material generally used in X-ray intensifying screens. The blue light emission from yttrium niobate phosphors is associated with groups host crystalline lattice [1]. Such luminescent properties can be shifted towards longer wavelengths when doped with other rare-earth ions that partly replace yttrium ions in the host lattice. In the case of Eu³⁺ emission centers red luminescence can be generated.

Yttrium niobate is usually synthesized by solid state reaction method, using a ball mill to grind precursors for tens of hours [2,3], while nanocrystalline yttrium niobate is often obtained by sensitive soft-chemical methods [4]. Here we prepared single-phase Eu³⁺-doped YNbO₄ phosphor nanopowder i.e. nanophosphor, using fast and energetically efficient mechanochemical method followed by annealing. The precursors were mixed in a ball-mill at 100 rpm for 3h, pre-sintered at 800°C for 2h, then ball-milled again and finally annealed at 1200°C for 2h.

The sample crystalline structure is confirmed by XRD measurements. The crystallite size of 42 nm was estimated using Debye Scherrer's equation by determining the line broadening of the main intensity peak. Scanning Electron Microscopy was used to observe microstructure and particle size of the powder. High-resolution photoluminescence measurements were performed at room temperature. The sample exhibits very intense red emission, coming from specific ⁵D₀ → ⁷F_J (J = 1, 2, 3, 4) transitions of the Eu³⁺ ion, with the lifetime around 0.6 ms. Compared to previously reported [5] photoluminescence emission of the microcrystalline YNbO₄:Eu phosphor, emission of the nanocrystalline sample is almost twice as strong.

Nanowires, nanotubes, nanoalloys : a phase diagram story

T10 Nanoscience and Technology

#NST-11-Or-7

I. Braems, F. Berthier.

CNRS - Orsay (France).

The bimetallic submonolayer is the scene of many kinetic processes including deposition, aggregation, surface diffusion and segregation, most of participating in nucleation-growth kinetics whose complete evolution is beyond the capabilities of atomistic-scale simulations. Derived from bulk alloys precipitation, the cluster dynamics is therefore an efficient tool to reach larger time and space scales, at the condition that cluster-scale parameters are consistently derived from atomic-scale quantities measured via Monte Carlo simulations (1).

In this talk we present a comprehensive view of a bimetallic submonolayer described as a collection of bimetallic clusters. For kinetics that tend towards equilibrium such as deposition and ageing, cluster-scale parameters must depend on the thermodynamical equilibrium of the submonolayer in order to satisfy microreversibility. Hence the submonolayer equilibrium first depends on the vacancy mobility and density (2), the latter being here non negligible as compared with 3D bulk counterparts. Second, the atomic phase is to be described as a size distribution of bimetallic finite-size objects, each of them being subjected to edge segregation. We show how segregation in particular affect both morphologies and size distribution of clusters at equilibrium, the thermodynamical properties of each class of clusters depending both on the size to be considered and the average composition of the monolayer (3). We also illustrate the variety of observed configurations within the collection of bimetallic clusters and in particular coexisting configurations with strongly different edge concentrations that can lead to different kinetic routes in modelling surface kinetics.

In the second part of the talk we describe the nucleation kinetics for two codeposited species as a function of their interaction energies and their partial coverage. The key parameters that assess consistency between atomic-scale and cluster-scale simulations are distinguished and the influence of a second species onto atomic

deposition is quantified and illustrated. Extension to size-mismatched systems is discussed.

Single Molecule Fluorescence from Tetraphenyl-Porphine on GaAs(110) in a STM

T10 Nanoscience and Technology

#NST-P3-23

S. Mühlenberend, N.L. Schneider, R. Berndt.

IEAP, University of Kiel - Kiel (Germany).

The tip of a STM can be used to excite luminescence from atomic scale structures. A major difficulty in STM induced luminescence experiments has been the coupling between molecules and a metallic substrate that largely inhibits molecular fluorescence. Therefore molecules have been decoupled by, e. g., multilayer arrangements. Here we use the semiconductor GaAs(110) as a substrate. Even for very low coverages of Tetraphenyl-Porphine of less than 5% of a monolayer and without injecting electrons into the molecular orbitals, we observe fluorescence. Spectral and polarization analysis show clear evidence of a plasmon at the STM tip inducing intramolecular Q-band transitions. The processes involved in exciting this molecular fluorescence over lateral distances of several nm will be discussed.

The understanding of the coupling between a molecule and a ferromagnetic electrode is one of the key issues in the promising field of molecular spintronics. Among various molecules, C60 has a particular interest considering its high symmetry and the absence of nuclear spins. In this framework, we have investigated the adsorption of C60 on chromium and cobalt surfaces, studying both the change of magnetism in the magnetic layer and the induced spin polarization on the molecules. The comparison of the experimental data with ab initio calculations allows a good understanding of the specific hybridizations giving rise to a significant molecular spin polarization for certain molecular orbitals.

In a first step, we have measured by in situ magneto-optical Kerr effect how the deposition of a C60 layer can influence the magnetism of underlying Co ultrathin films grown both on Au(111) and Pt(111). For a certain range of thickness, we observe a magnetization reorientation transition, favoring a perpendicular magnetic anisotropy with the organic layer. More interestingly, in a second step, we have performed spin polarized scanning tunneling spectroscopy of individual C60 molecules on a Cr(001) surface (cf. figure) and on Co/Pt(111). On chromium, we have found a tunnel magneto-resistance through single molecules that changes sign depending on the energy, related to the complete spin polarization of the lowest unoccupied molecular orbital of the free C60. These results arise from a statistical analysis over more than 500 molecules and are particularly well reproduced by ab initio calculations, despite of the complexity of the chromium magnetism [1]. On cobalt, the coupling between the molecules and the metal seems to be less important, giving rise to a smaller molecular spin polarization. These results are of particular importance for the future design of organic spintronics devices as they

illuminate the complex interplay between ferromagnetic electrodes and molecular layers on model systems.

III-V semiconductor nanowires (NWs) are promising candidates as components for future solar cell designs, if a controlled distribution of dopants along NWs can be achieved. To generate a homogeneous axial dopant profile, p-doped GaAs NWs were grown on an n-doped GaP(111)B substrate by Au-assisted metal-organic vapor-phase epitaxy (MOVPE), with Au-particles that had previously been saturated with Zn as dopant. For electrical characterization these free-standing NWs were contacted using a multitip STM. Four point probe measurements with variation of the probe distances reveal their electrical transport properties. The conductance profile along the NWs and the diode characteristics of the pn-junction to the substrate were measured. We show that the resistivity is constant over most of the NW length of 8 μm , while the base, up to about 1.5 μm , has an increased resistivity. The contact between the n-GaAs NW and the p-GaP substrate forms a diode. Using the SEM integrated into the multitip STM setup, an electron beam induced current (EBIC) generated in the pn-junction from substrate to NW can be mapped. Furthermore, the NWs exhibit high mechanical elasticity. They can be deformed by the STM tips and revert to their original shape when released. Even extreme bending of a NW did not show a significant influence on its conductivity.

Magnetic properties of iron nanocrystals

T10 Nanoscience and Technology

#NST/SS-P2-04

D. Li, C. Barreateau, A. Smogunov, F. Silly.

CEA - Gif Sur Yvette (France).

We have investigated the electronic and magnetic properties of iron nanocrystals by means of electronic structure calculations using both the Quantum-espresso package [1] based on density functional theory as well as an efficient tight-binding code [2]. The nanocrystals studied are in shape of truncated square pyramids (see Fig. 1) since it has been shown experimentally that such crystals can be grown on SrTiO₃(001) surface[3]. We analyze the atomically resolved magnetization of systems of various sizes. It is found that the spin moments are indeed reinforced on low coordinated (surface, step, edge) sites: (001) facets have larger magnetic moments than (110) facets. We have also performed non-collinear calculations including spin-orbit coupling and determined the magneto-crystalline anisotropies of such objects which is essential to characterize their magnetic stability.

Development of field effect transistors based on graphene using dielectrophoretic deposition and tantalum nitride electrodes

T10 Nanoscience and Technology

#NST/SS-P1-13

A. Pascon De Marque, J. Fernandes De Souza, J.A. Diniz.

Center for Semiconductor Components, State University of Campinas - Campinas (Brazil).

For devices based on graphene, usually, non-refractory metallic electrodes of Ti/Au or Ti/Pd are used. However, to reduce the contact resistance between metal and graphene, an annealing process in vacuum environment at temperature of 700°C is a requirement [1]. Therefore, refractory metallic electrodes, such as tantalum nitride (TaN), must be studied. Graphene in large quantity can be obtained by dielectrophoretic (DEP) assembly [2] of a few layers of insulating graphene oxide, which become metallic after thermal reduction at 450°C. In this context, tantalum nitride (TaN) electrodes (deposited by DC reactive sputtering in N₂/Ar environment) are used as metallic contacts with the graphene. In our FET devices, the graphene sheets are deposited between TaN electrodes of source and drain and above the high-k gate dielectric of TaO_x formed on n⁺ silicon substrate, which is used as back gate. These sheets were obtained in suspension of DMF (dimethylformamide) with four different graphene concentrations and were deposited using DEP process: ac signals were applied between electrodes with voltage of 3 to 5 V_{pp} and frequencies ranging from 5 to 50 MHz for periods of 25 up to 180 sec. Scanning electronic microscopy (SEM) analyses and current-voltage (I-V) measurements were carried out to get the physical and electrical characteristics of our devices. Our best results, which are presented in Figure1 are for DEP process carried out using frequency of 50 MHz and period of 180 sec. The resistance values measured before and after annealing differ in three orders of magnitude, in agreement with [2]. The Dirac point near V_{BG}=0 results in a low I_{on}/I_{off} ratio (Figure2).

Development and investigation of an atmospheric microplasma jet for generation of silicon nanocrystals

T10 Nanoscience and Technology

#NST-11-Or-5

B. Barwe, J. Benedikt.

Group Coupled Plasma-Solid-State Systems, Faculty of Physics and Astronomy, Ruhr-Universität Bochum - Bochum (Germany).

Silicon nanocrystals (SiNC) offer new opportunities in a wide range of electrical and optical devices including solar cells and single-electron transistors. Other fields of applications are nanoelectronic circuit elements, luminescent markers in biomedicine and thermoelectric energy generation because of their spectral tunability and photoluminescence efficiency.

The production of SiNC is connected with several challenges. It is difficult to reach crystalline particles and to avoid particle agglomeration during the generation process. Moreover, it is important to prevent the oxidation of the crystals by providing them a surface passivation. This surface passivation can be performed in a liquid phase, but it is usually a lengthy and demanding process.

We produce SiNC with the help of a dual microplasma jet system, where the SiNC are first synthesized in a DC-microplasma jet using Argon as working gas (as already shown by Sankaran et al. [1]), followed by a passivation step in a second atmospheric pressure plasma to avoid agglomeration, to passivate their surface and to incorporate them in a thin film.

The HRTEM, FTIR, and photoluminescence measurements of SiNC prepared under various experimental conditions and plasma diagnostic results will be presented.

Gd decorated ZnO nanoparticles to obtain high fluorescence quantum yield and enhanced MR relaxivity; potential multimodal nanoprobe for bioimaging applications

T10 Nanoscience and Technology

#NST-6-Or-12

L. Selegård, M. Ahrén, A. Skallberg, K. Uvdal.

Molecular Surface Physics and Nanoscience, Linköping University - Linköping (Sweden).

Gd decorated ZnO nanoparticles are potential candidates for future multimodal nanoprobe imaging applications, such as fluorescence imaging and MR signal enhancement. When combining Zn and Gd in this type of nanoparticles, novel properties are obtained, which enable design of nanoprobe for these two complementary imaging techniques. Decoration of ZnO nanoparticles with Gd-acetate enhances both the fluorescence emission and the MR signal, compared to earlier investigations of plain ZnO and Gd alloyed ZnO nanoparticles. In this study, Gd decorated ZnO nanoparticles are synthesized and investigated as a function of Gd/Zn relative ratio, ranging from 1- 0.07. The full set of nanoparticle variations was characterized by means of PEEM, XPS, TEM, Fluorescence spectroscopy and MR, to obtain chemical composition, size, crystallinity, quantum yield and relaxivity values. The results clearly show that presence of Gd acetate surface states induces increased fluorescence emission and MRI signal enhancement.

The discovery of topological insulators has inspired research on a new class of topological materials. Topological crystalline insulators (TCIs) have recently been introduced as new states of quantum matter, with gapless metallic surface states protected by mirror symmetry of the crystal lattice [1]. Tin telluride (SnTe), with a rocksalt structure having four equivalent points in the Brillouin zone, is predicted to be a TCI [2,3]. When indium (In) is doped on the Sn site of SnTe, superconductivity is found with a higher critical temperature and lower carrier concentration relative to pristine SnTe [4].

In this work, we use ultra low temperature scanning tunneling microscopy to investigate the superconducting properties of indium-doped tin telluride ($\text{Sn}_{1-x}\text{In}_x\text{Te}$). In a sample with a critical temperature of ~ 1.6 K, the tunneling spectra show a superconducting gap of 0.2 meV, which is continuous throughout the surface of the cleaved crystal. The superconducting gap is completely suppressed above a critical magnetic field of $B=0.50$ T, and dI/dV conductance maps reveal a vortex lattice in perpendicular applied magnetic fields. We will discuss the dependence of In concentration on topological superconductivity in this material in relation to previous experiments and predictions [5].

The discovery of topological insulators has triggered the search for new topological states of matter. A topological superconductor is one such state, characterized by the existence of an unconventional superconducting pairing in the bulk, and gapless Andreev bound states (Majorana fermions) on the surface. Recently, Cu intercalated Bi_2Se_3 ($\text{Cu}_x\text{Bi}_2\text{Se}_3$) was found to be superconducting with a $T_C \approx 3.8$ K [1], and is considered a prime candidate for topological superconductivity due to its band structure symmetry properties and strong spin-orbit coupling in this material. Angle resolved photoemission spectroscopy has revealed the preservation of the topological surface states at the Fermi level after Cu intercalation, while recent point contact measurement observed zero-bias conductance peaks, suggesting these as evidence of surface Andreev bound states [2, 3].

In this work, we use an ultra-low temperature scanning tunneling microscope [4] to investigate the superconducting properties of a cleaved $\text{Cu}_{0.2}\text{Bi}_2\text{Se}_3$ bulk crystal. The crystal was synthesized by electrochemical intercalation of Cu atoms into a previously synthesized Bi_2Se_3 bulk crystal. Resistance versus temperature measurements of the bulk crystal show a superconducting transition at 3.65 K, consistent with previous reports. A superconducting gap is observed in scanning tunneling spectroscopy (STS) measurements. The tunneling spectrum shows that the density of states at the Fermi level is fully gapped without any in-gap states. Fitting the spectrum to BCS theory yields a superconducting gap of $\Delta=0.4$ meV. When a

magnetic field is applied, the tunnel spectrum shows a complete suppression of the superconducting gap at a critical field of ≈ 1.65 T. In addition, spatially resolved measurements of the superconducting gap under an applied magnetic field revealed no bound states in the vortex cores. The spectrum is well described by the BCS theory with a momentum independent order parameter, which suggests that $\text{Cu}_{0.2}\text{Bi}_2\text{Se}_3$ is a s-wave superconductor and not a topological superconductor, contrary to previous expectations and measurements. We will discuss these observations and current work examining the Cu concentration dependence in the context of recent theories of topological superconductors.

Enantioselective Separation on Chiral Au Nanoparticles Measured by Optical Rotation

T10 Nanoscience and Technology

#NST-8-Or-7

N. Shukla, N. Ondeck, N. Khosla, A. Gellman.

Carnegie Mellon University - Pittsburgh (United states).

The surfaces of chemically synthesized Au nanoparticles have been modified with D- or L-cysteine to render them chiral and enantioselective for adsorption of chiral molecules. Their enantioselective interaction with chiral compounds has been probed by optical rotation measurements when exposed to racemic propylene oxide. The ability of optical rotation to detect enantiospecific adsorption arises from the fact that the specific rotation of polarized light by R- and S-propylene oxide is enhanced by interaction Au nanoparticles. This effect is related to previous observations of enhanced circular dichroism by Au nanoparticles modified by chiral adsorbates. More importantly, chiral Au nanoparticles modified with either D- or L-cysteine selectively adsorb one enantiomer of propylene oxide from a solution of racemic propylene oxide, thus leaving an enantiomeric excess in the solution phase. Au nanoparticles modified with L-cysteine (D-cysteine) selectively adsorb the R-propylene oxide (S-propylene oxide). A simple model has been developed that allows extraction of the enantiospecific equilibrium constants for R- and S-PO adsorption on the chiral Au nanoparticles.

The figure illustrates the reversible equilibrium adsorption of R- and S-PO on Au nanoparticles modified with L- or D-cysteine. The equilibrium constants are enantiospecific.

The presence of internal electric fields in quantum confining structures, like quantum wells and discs (QDiscs), has a major effect on their optical properties.[1] Indeed, upon excitation, additional carriers, in out of equilibrium conditions, will partially screen the electric field within the QDisc. This causes a reduction of the quantum confined Stark effect (QCSE) and shifts energy levels towards higher energies, depending on the carrier concentration.[2] Cathodoluminescence (CL) in a Scanning Transmission Electron Microscope (STEM) allows the deployment of very local excitation probes and the assessment of single QDiscs.[3,4] Here we show a direct observation of very local emission of light from single GaN QDiscs formed between AlN barriers in the growth axis of GaN nanowires. Indeed, due to the height of AlN barrier, the diffusion length of carriers is as short as about 5 nm in this system.[4] Moreover, we show that the internal field can be screened by CL-generated charge carriers inside these QDiscs. CL spectral imaging with nanometre resolution tracks the emission of QDiscs as function of the electron probe position, allowing the creation of different concentrations of carriers in QDiscs. It is then possible to study energy shifts in individual QDiscs by observing different emission rates.

Enabling the study of nanoscale Graphene physics using nanoconfined, large momentum IR light

T10 Nanoscience and Technology

#NST/SS-P1-14

G. Andreev, S. Minne.

Bruker Nano Surfaces - Santa Barbara (United states).

Mid-infrared light confined to nanoscale volumes, as done in the technique of IR-sSNOM, is a powerful and versatile probe of Graphene physics. For instance, recent IR-sSNOM experiments show that one can excite, image, and spectrally characterize Dirac plasmons in Graphene with nanoscale sensitivity^{1,2}. Due to the uncertainty principle: $\Delta x \Delta k \geq 0.5$, conventional IR microscopy lacks both the spatial momentum and spatial resolution necessary to launch and simultaneously image such surface waves. In the IR-sSNOM technique, nanoconfinement of IR light between a sharp metallic tip (<10nm radius) and the sample surface can reduce Δx to <10nm and consequently increase Δk by as much as 3 orders of magnitude. The IR frequency of the excitation, however, remains unchanged. Beyond the recently demonstrated plasmonic applications, the potential for using IR light with such a large spatial momentum is not yet fully recognized by the Graphene community. We experimentally demonstrate some additional applications that also greatly benefit from the much larger IR momentum. For instance we show a greatly enhanced optical sensitivity to material thickness which enables counting the number of Graphene layers on both suspended and supported regions. We also demonstrate the ability to spectrally determine the carrier density and scattering rate with < 10 x 10 x 1nm spatial resolution. The results of both experiments are confirmed using other techniques such as confocal Raman spectroscopy (layer counting) and Scanning Capacitance Microscopy (conductivity mapping). With these experiments, we hope to raise awareness to previously unattainable characterization capabilities enabled by the use of nanoconfined IR light.

MicroRNA Detection with Double-helix Bio-Barcode Assay

T10 Nanoscience and Technology

#NST-P3-13

J. Park, H. Lee, J.M. Nam.

1 - Seoul (Korea, republic of).

MicroRNAs (miRNAs) are short non-coding RNAs, consisting of very few nucleotides, average of 22. miRNAs bind to target messenger RNA (mRNA), resulting in translational repression or target degradation. Thus, they can act as gene regulators. Most miRNAs have been found to related with various types of diseases, especially cancer. The expression level of miRNAs could be very different from RNA to RNA and disease to disease, and miRNA can be a biomarker for cancer for this reason. Although northern blot, microarray, and qRT-PCR are considered as the standard methods for detecting miRNAs, these protocols require extrinsic labels, complicated procedure and expensive reagents, and show difficulties in probe or primer design.

For theses reasons, we developed double strand (ds) bio-barcode-based miRNA detection method with gel electrophoresis. We demonstrate that this method allows to detect low abundant miRNAs with high sensitivity and selectivity. Furthermore, multiplexed miRNA detection capability is also shown with this approach. This finding could offer a straightforward and inexpensive way of miRNA detection in disease diagnosis on a conventional gel platform.

BI/NST-1-Or-5

Molecular-scale visualization of biomolecules and their biochemical functions by frequency modulation atomic force microscopy

T10 Nanoscience and Technology

#BI/NST-1-Or-5

H. Yamada, I. Shinichiro, U. Kenichi, S. Kazuhiro, K. Kei.

Kyoto University - Kyoto (Japan).

Significant progress has been made in frequency modulation atomic force microscopy (FM-AFM) in liquids over the past several years, which allows us to directly investigate "*in vivo*" molecular-scale biological processes [1-3]. In fact this development has opened the way to high spatial resolution analysis of biomolecules such as membrane proteins and DNA molecules in liquids [4]. In this study, submolecular-resolution imaging of biomolecules has been conducted for the molecular-scale analysis of various biochemical functions. In addition, three-dimensional (3D) hydration structures on the biomolecules have been visualized by 3D force mapping method based on FM-AFM for exploring the roles of water molecules in the biological functions. Furthermore, the molecular-scale distributions of surface charge density on molecular assemblies at solid-liquid interfaces were successfully measured by fitting the force mapping data to a modified DLVO theory. We recently succeeded in FM-AFM imaging of sub-molecular structures of a monoclonal immunoglobulin G (IgG) antibody molecule such as protein domain structures (Ig domains). We newly revealed that the IgG antibodies spontaneously assembled into hexamers and successively formed into a two-dimensional (2D) crystal in an electrolyte solution, as shown in Fig. 1(a). Figure 1(b) shows an FM-AFM image of the 2D antibody crystals interacted with antigenic serum albumin molecules. Although the image shows the surface covered with many irregular structures, we can still see regular crystal pattern in some areas below the irregular adsorbents, directly indicating the specific binding of the antigenic molecules to the antibody crystal.

Local surface potential measurements of organic field-effect transistors having a submicron crystalline grain channel by Kelvin-probe force microscopy

T10 Nanoscience and Technology

#FMMM/NST-1-Or-2

T. Kimura ¹, K. Kobayashi ², H. Yamada ¹.

¹Department of Electronic Science and Engineering, Kyoto University - Kyoto (Japan), ²Office of Society-Academia Collaboration for Innovation, Kyoto University - Kyoto (Japan).

The electric characteristics of organic field-effect transistors (OFETs) are governed by not only electrical properties of organic molecules but also those of grain boundaries and organic/metal interfaces. It is difficult to investigate these local effects only by macroscopic electrical measurements. Frequency modulation Kelvin-probe force microscopy (FM-KFM) is a useful technique for the elucidation of these local properties in OFETs, which provides simultaneous imaging of sample topography and surface potential on a nanometer scale without contact damage [1]. In this study, an OFET having submicron-scale electrodes and an alpha-sexithiophene (α -6T) crystalline grain as channel was investigated by FM-KFM in order to reveal the local electronic properties in OFETs.

We first fabricated 10-nm-thick Pt electrodes on a heavily doped n-type Si substrate with a surface oxide layer. α -6T molecules were deposited on it, such that two electrodes were connected with a high-crystalline film (Fig. 1). We applied a drain (V_D) and a gate bias voltage (V_G) to the lower electrode and Si substrate, while upper electrode is grounded as source. Then we performed FM-KFM measurements of this OFET during operation. At $V_G = 0$ V, we found a large voltage drop at the edge of drain electrode, while potential was linearly changed in grain, which implies pinch-off at reverse-biased drain electrode. On the other hand, no voltage slope in grain was found at $V_G = -6$ V and source electrode turned to be the main voltage drop site. We measured current-to-voltage characteristics and also found a current increase from around $V_G = -6$ V. These results suggest that its FET characteristics were limited by

injection barrier at source electrode. We will also discuss the results of the OFET in which the source and the drain electrodes were interchanged.

We report on studies concerning contribution of the cantilever on the accuracy of surface potential imaging of heterogeneous surfaces in Kelvin probe force microscopy, working in frequency modulation mode (FM-KPFM), performed in ultrahigh vacuum. The system under investigation consisted of a set of electrically isolated Pt nanowires (of 100 nm in width) lithographically deposited on SiO₂/Si substrate. The metallic nanowires were externally biased, with respect to the Si substrate, with dc voltage ($V_{ext,dc}$). Then, with the standard FM-KPFM imaging of the Pt/SiO₂/Si system, the spatial distribution of the contact potential difference (VCPD) signal as a function of the dc voltage applied to the Pt nanowires, was measured. A CPD-gradient i.e. ($dVCPD/dV_{ext,dc}$) measured at specific surface location allowed to evaluate the effect of parasitic capacitance between the cantilever and the sample on the accuracy of surface potential imaging. For this case, the experimental findings are compared with the predictions of theoretical calculations based on a realistic model for the cantilever-sample geometry.

Departments of Mechanical Engineering,^a and Chemical Engineering,^b Technion,
Israel

A promising organic conductive system is the Tetrathiafulvalene-Tetracyanoquinodimethane charge-transfer complex (TTF-TCNQ CTC). In this work a conductive organic nanofibers were produced by manufacturing core-shell nanofibers made of poly(vinylidene hexafluoropropene) (PVDF-HFP) with embedded TTF and TCNQ in the shell and in the core respectively, using co-electrospinning process [1] to produce conductive CTC crystals. The fibers diameter was found to be between 100 to 500 nm. X-ray analysis showed strong equatorial reflections (110,200) of oriented copolymer PVDF-HFP crystals (β -form) with copolymer chains oriented along the fiber axis, along with unreacted TCNQ and TTF crystals on surface, and reflection of the CTC (001) indicating that the CTC molecular planes (ab plane of the monoclinic form) are aligned parallel to the nanofiber axis (Fig. 1, 2) [2-5]. The electrospun nanofibers were collected to form a fiber mat which was measured as a working electrode in a three-electrode-cell system, to give differential conductance of 5.23 $\mu\Omega$.

Structural Analysis of Carbon Nanotubes by STM Tip Enhanced Raman Imaging with a few Nanometers Resolution

T10 Nanoscience and Technology

#NST-13-Or-1

C. Chen ¹, N. Hayazawa ¹, S. Kawata ².

¹RIKEN - Wako (Japan), ²RIKEN; University of Osaka - Suita (Japan).

TERS (tip enhanced Raman spectroscopy) opens a new horizon for nanoscale characterization. Atomic force microscopy (AFM) combined with near field Raman spectroscopy is generally used for hybrid imaging and chemical analysis. However, for higher spatial resolution, we constructed a scanning tunneling microscope (STM) based TERS targeting at Raman spectroscopy of single wall carbon nanotubes (SWNT).

SWNT is selected as our sample for TERS because it exhibits very unique optical properties depending on its clear nanometric morphology/chirality. We simultaneously obtained STM topographic image and TERS spectroscopic images at D-, G- and 2D-bands. Different Raman bands show characteristic distributions with a few nanometers resolution. Local defect is visualized in real space through D band imaging while G band and 2D band provide different structural variations. To the best of our knowledge, our result showed the highest spatial resolution on carbon nanotubes ever that has been obtained by optical spectroscopy.

In summary, TERS is a difficult experiment, which requires sophisticated techniques from both optics and scanning probe microscope. However, now it is possible to make it a more practical research tool for nanoscale chemical analysis. We will show our recent progress and detailed issues in the conference.

Manufacturing of Cantilever Probes with Sub-100nm Pt-Electrodes Integrated in a Sharp Tip for Scanning Electrochemical Microscopy

T10 Nanoscience and Technology

#NST-7-Or-4

C. Richter ¹, P. Weinzierl ¹, D. Graf ¹, S. Beuer ², M. Rommel ².

¹Nanoworld Services GmbH - Erlangen (Germany), ²Fraunhofer Institute for Integrated Systems and Device Technology (IISB) - Erlangen (Germany).

Since the introduction of micron-sized ultramicroelectrodes (UMEs) in the early 1980s scanning electrochemical microscopy (SECM) has become a powerful tool for investigating small electrochemically active structures and processes, from characterizing of ion channels in living cells to in situ observation of metal corrosion [1, 2]. Although SECM is a well-known method for years [3], its application is limited by the insufficient availability of sensors which can fulfill the requirements. Commercially available probes for scanning electrochemical microscopy as well as those realized by several scientific groups suffer either from a poor lateral resolution or an inadequate stability under commonly used measurement conditions, i.e. a degradation of the insulating layer can often be observed during probing in liquids. Furthermore the fabrication scheme is generally very complex and, thus, either not applicable for mass production or it is very expensive [4]. Hence we have developed a reliable probe fabrication process suitable for mid-volume production to realize different types of combined atomic force microscopy (AFM) and SECM probes. The probes combine the potential of outstanding lateral resolution and stable ion sensitivity by using an insulated Platinum nanoelectrode on the tip apex which features an exposed area of less than $1\mu\text{m}^2$ (compare Figure.1). The geometry of support chip, cantilever and tip preserve the dimensions of typical AFM-probes. To characterize the functionality and performance of the developed SECM sensors, we have built up a measurement setup for cyclic and differential pulse voltammetry. Corresponding measurements will be presented and critically discussed.

The Quadratic Stark Effect In the Fullerene C₆₀

T10 Nanoscience and Technology

#NST/SS-2-Or-6

A. Tuchin, L. Bityutskaya, E. Bormontov.

Voronezh State University - Voronezh (Russian federation).

Fullerenes and their derivatives are promising for applications in the fields of energetics, materials science, nanotechnology, optoelectronics and molecular electronics, memory devices [1-3]. Hybrid structures based on fullerenes are actively studied due to their high hardness, breakdown voltage, the gain on the field, wide band gap, which allow to create devices that emit in the optical range [1]. The field devices based on fullerene and fullerite are of a particular interest due to the possibility of the field doping, metallic conductivity and, in some cases, superconductivity [3]. Therefore, studies of the effect of strong local electric fields on the electronic structure of fullerenes are relevant and allow to identify ways to manage the basic electrical and optical properties of carbon nanomaterials. The fullerene C₆₀ causes huge interest because of the high stability, the mass production and the high symmetry of the truncated icosahedron I_h. A distinctive feature of the molecule of this symmetry, which is not found in other systems of lower symmetry, is the existence of the electron shells g_N and h_N with degeneracy 4 and 5 at the ground state of the fullerene. The external electric field leads to the polarization and the orientational deformation of fullerenes. Wehrli et al. in [4] showed the splitting of t_{1u} and h_u levels of neutral C₆₀ due to the Stark effect. However, the calculations do not take into account the change of the fullerene C₆₀ geometry in an electric field. In this paper the density functional theory was used to investigate the splitting of t_{1u} and h_u levels of the neutral C₆₀ depending on the magnitude ($E = 0 \dots 1.2 \text{ V/\AA}$) and the direction ($\mathbf{E} \parallel \mathbf{C}_{2v}$, $\mathbf{E} \parallel \mathbf{C}_{3v}$, $\mathbf{E} \parallel \mathbf{C}_{5v}$) of an applied electric field with the consideration of the orientational deformation of the molecule. It is shown that the σ -electron system of the molecule is stable in the entire range of fields. Notable changes in the electronic structure occurs at the fields of $E > 0.01 \text{ V/\AA}$, which is accompanied by the splitting of the degenerate levels by the quadratic Stark effect. The nature of the splitting of the lowest unoccupied (t_{1u}) orbitals is almost independent of the field direction. The result consists with the calculations conducted by Wehrli [4]. The splitting of the highest occupied molecular orbital (h_u) strongly depends on the direction of the field. At the field of $E = 1.2 \text{ V/\AA}$ and $\mathbf{E} \parallel \mathbf{C}_{2v}$ levels are

shifted up relatively to the ground state by 0.018, 0.065, 0.138, 0.169 and 0.200 eV; at $\mathbf{E}||\mathbf{C}_{3v}$ h_u is splits into three levels shifted upward by 0.035, 0.12 and 0.19 eV; for $\mathbf{E}||\mathbf{C}_{5v}$ two closely spaced energy levels are shifted up by 0.142 and 0.150 eV, the stabilization of one of the split levels on the value of 0.022 eV is unexpected. Destabilization of h_u - split levels and a decrease of t_{1u} - split levels lead to the quadratic reduction in the energy gap between the lowest unoccupied (LUMO) and the highest occupied (HOMO) molecular orbitals. The Modulation $E_{\text{LUMO-HOMO}}$ by the electric field can be widely used in molecular opto-and nanoelectronics.

There is a general interest in the study of the physical and chemical induced effects by grinding in solids. Dry grinding is most intensive than wet grinding when acting on solids. It originates mechanical stress which are quite diverse, producing important changes such as lattice distortions, amorphization, decrease in particle size, formation of nanostructures and an increase in surface area, besides the formation of new phases by mechanical alloying. Thus, the reactivity of ground solids is enhanced and, therefore, it leads to mechanochemical reactions. The effects of dry grinding on layer silicates have been extensively studied. It is associated to their relevant importance in some industrial applications as ceramic raw materials and processing of advanced ceramics. In the present research, samples of kaolinite (1:1 layer silicate), pyrophyllite and talc (2:1), and vermiculite (1:2:1) have been selected. Dry grinding experiments, using planetary or vibratory milling, have been performed. Several techniques were used to follow the evolution of the layer silicates, mainly XRD, surface area (nitrogen adsorption), SEM, TEM, MAS-NMR, DTA, TGA, FTIR, XPS and particle size analysis.

Modifications of surface area, particle size and shape of short and prolonged grinding

on the crystal structure of the layer silicates have been evaluated. The observed changes have been related to a progressive delamination and structural breakdown during grinding, with final formation of a turbostratic-type structure. However, short grinding times resulted in the breakdown and drastic size reduction of relatively thin particles. On the other hand, it should be noted that the rate of size reduction decreased with time and a limit is reached for each sample producing more rounded particles and aggregates, with a decrease of surface area. These changes also affected the pore size distribution and surface modifications as deduced by XPS. TEM and SEM allow to examine the formation of nanometer size ground powders and further particle agglomeration. It can be also observed an increasing in amorphization as a consequence of the loss of long-range order. It is explained considering that grinding produces a loss of periodicity perpendicular to the layer silicate plane, and the dimensions of the crystallites along the c-direction resulted too small to produce coherent X-ray scattering. On the other hand, it has been found an inverse relationship between coherent X-ray domain and microstrains in the ground powders. Modifications in the coordination of Si and Al nuclei have been also deduced from MAS-NMR spectroscopy, demonstrating a short-range order. The present results are interesting to analyze the formation of nanostructured powders when grinding layer silicates and further to examine the reduction of dehydroxylation temperature when the ground samples are heated.

Oscillations of the band gap of single-walled carbon nanotubes depending on their length and diameter

T10 Nanoscience and Technology

#NST-2-Or-6

A. Ganin, A. Tuchin, L. Bityutskaya, E. Bormontov.

Voronezh State University - Voronezh (Russian federation).

Carbon nanotubes and fullerenes can be viewed as ideal quantum wires and dots, having unique optical, electrophysical and chemical properties. However their broad application in nanoelectronics is impeded by difficulties of control of their properties which strongly depend on structure of every particular nanoobject. General classification of single-walled carbon nanotubes (SWCNT) is based on their chirality indices n, m . According to a well known rule infinite SWCNTs of large diameter exhibit metallic properties or zero band gap if $|n-m|$ is a multiple of three (the “3k” rule) and are semiconducting otherwise. Decrease of length and diameter of SWCNTs leads to changes in their electronic structure and violation of the above mentioned rule. Transition from nanowires to quantum dots is insufficiently studied and appears to be interesting both fundamentally and practically [1]. We have theoretically investigated band structure of infinite and finite-length SWCNTs and calculated values of their band gap, ionization energy and work function. A cylindrical unit cell was used. We employed the ab initio method of density functional theory for infinite nanotubes (with periodic boundary conditions) and semiempirical methods for finite-length SWCNTs. Relevance of the method and basis was verified in previous calculations for SWCNTs [2] and also by a direct comparison with experimental and theoretical values. [3] Electronic structure of finite-length SWCNTs with fullerene caps and chirality indices (5, 5) and (0, 9) was investigated in the length range from 0.7 nm (single fullerene molecule – C_{60}) to 6.1 nm (C_{500}). It was found that the additional confinement of electrons along the axis of the tube leads to a non-zero band gap value. Dependency of the band gap versus number of atoms for SWCNT (0, 9) has monotonic character while for SWCNT (5, 5) this dependency has oscillating character with a consistent pattern. Increase of the length of SWCNT (5, 5) from 0.7 nm to 6.1 nm leads to decrease of the band gap from 4.88 to 1.06 eV. Electronic structure study was also performed for 30 infinite zigzag and armchair

SWCNTs. The dependency of the band gap versus diameter for semiconducting nanotubes has nonmonotonic oscillating character with a global maximum and a period of $\frac{3\sqrt{3}d_0}{\pi}$ (here d_0 is a distance between two carbon atoms in SWCNT). For tubes (0, 4) and (0, 5) we have obtained zero band gap values (while they are semiconducting according to the “3k” rule). We have also confirmed metallic conductance in armchair SWCNTs. The results obtained shed light on the intrinsic properties of quantum 0D and 1D systems and open new opportunities for application of SWCNTs in cold cathodes, x-ray machines, photovoltaic panels and elements of electric circuits.

The mass production of graphene (GR) based electronic devices requires the synthesis of high quality, i.e. with low defects concentration, and large area layers. This can be achieved by different routes, among which the epitaxial growth on transition metals surfaces is one of the most promising ones. Interaction with the substrate, however, is the major drawback of epitaxial GR [1]. In some cases, e.g. GR layers grown on Ru(0001), Rh(111) or Re(0001), this interaction can be sufficiently strong to prevent the typical electronic properties of GR from being established. On the other hand, a very weak interaction, e.g. GR on Pt(111), leads to the formation of GR domains with different orientations. GR/Ir(111) is a representative example of a weakly bound interface: GR-like electronic properties are observed but the moiré pattern due to the lattice incommensurability between GR and its substrate gives rise to replica bands and minigaps near the Fermi level. It appears thus difficult to achieve a weak interaction with high structural quality at the same time. A possible solution is the epitaxial growth of GR on a sufficiently interacting substrate, such as Ir(111), and the subsequent decoupling by the intercalation of metals, silicon, fluorine or hydrogen in order to restore, at least partly, the pristine linear band dispersion. Oxygen intercalation appears as a viable route to decouple GR/metal interfaces, but so far intercalation has been demonstrated only for incomplete monolayers or islands [2]. Here, using photoemission spectroscopy with synchrotron radiation, we show that

oxygen intercalation is achieved on an extended layer of epitaxial GR on Ir(111), which results in the “lifting” of the GR layer and in its decoupling from the metal substrate [3]. The oxygen adsorption below GR proceeds as on clean Ir(111), giving only a slightly higher oxygen coverage. Upon lifting, the C 1s signal shows a downshift in binding energy, due to the charge transfer from GR to the electronegative oxygen. Moreover, the characteristic spectral signatures of the GR-substrate interaction in the valence band are removed, and the spectrum of strongly hole-doped, quasi free-standing GR with a linear π -band dispersion is observed. Abrupt oxygen deintercalation with a slight carbon etching occurs around $T=600$ K. After deintercalation, GR restores its interaction with the Ir(111) substrate. Additional intercalation/deintercalation cycles readily occur at lower oxygen pressure and temperature, consistently with an increasingly defective lattice. Our findings demonstrate that oxygen intercalation is an efficient method for fully decoupling an extended layer of GR from a metal substrate. They pave the way for the fundamental research on GR, where extended, ordered layers of free-standing GR are important and, due to the stability of the intercalated system in a wide temperature range, also for the advancement of next-generation GR-based electronics.

Obtainment and properties of self-organized gallium antimonide superclusters

T10 Nanoscience and Technology

#NST-4-Or-4

T. Kutcelyk.

Bitvutskaya L.A. - Voronezh (Russian federation).

At the present time structures consisting of semiconductor quantum dots (QD) and nanofibers(nanowires), based on GaSb, which may be used in unique optoelectronic devices applications, are intensively studied. [1,2]. When using the planar technology, concentration of QD on the substrates has physical limitations, and because of this fact this the possibilities of these devices are restricted.

Nanostructures with a different way of organization can solve these and many other problems. The current work deals with aspects of the research of the morphology and properties of 3D fractal self-organized GaSb structures, obtained by non-equilibrium crystallization from the melt.

A conglomerate of spheroidal globules in size of 0,1-0,001 sm formes in the reaction volume. Microscopic methods, allowing to obtain images in macro-, micro- and nanoscales, were used to investigate the morphology of the surface and the volume of the globules.

Cleaved GaSb globules in size of 0,01 sm were examined by AFM microscopy. To receive AFM topographs of the volume of the GaSb globules the following procedures were done: obtaining of the GaSb cleaves in the liquid nitrogen, scanning in situ the globules cleaves with increasing resolution: 2*2, 1,6*1,6, 0,8*0,8, 0,4*0,4 um., with the fixed position sonde-substrate. On all scales we observed the self-similarity effect — the system of spheroidal fractally associated particles-modules. This type of structures was predicted by Mackay A.L. in the works and is classified as superclusters [3].

The hierarchy of size scales of spheroidal particles in the volume was defined by the processing of AFM topographs by the method of wavelet analysis [4].

Wavelet-analysis of the AFM topographs was made for following sizes of scans: 0,4*0,4, 0,8*0,8, 1,6*1,6 and 2*2 um with the use of the basic function Gauss8, which provides high resolution in determining the limit of the structural unit. Hierarchical scales of the sizes of the particles amounting to the GaSb supercluster were

specified: 20, 60, 130, 260, 330 and 700 nm. The fractal organization of the GaSb supercluster leads not only to unusual morphology, but to appearance of the new physical and optical properties: the hardness of GaSb nanoparticles is higher, than of crystalline material and it is equal to 105 GPa, density is reduced and it depends nonlinearly on the size of the supercluster, in the visible range at room temperature the cathode luminescence is observed.

Investigations of the effect of CdZnS nano-structures incorporation on performance of P3HT based hybrid solar cell

T10 Nanoscience and Technology

#ESD/ASS-1-Or-9

L. Kumar, R. Sethi, M. Mall.

University of Allahabad - Allahabad (India).

Two different nanostructures of cadmium zinc sulphide (CdZnS) viz. nanorods and quantum dots have been synthesized and incorporated in poly(3-hexyl thiophene) (P3HT) to investigate the effect on photovoltaic properties of polymeric solar cell. Different techniques were used for the shape and size controlled synthesis of nanostructures and was confirmed by electron microscopic studies. The device performance were elaborated in terms of the parameters like open-circuit voltage (Voc), short-circuit current density (Jsc), fill factor and power conversion efficiency (PCE). We have further demonstrated the morphological strategy to explain the difference attained in the photovoltaic behavior using two different kinds of nanostructures.

Molecular conformational flexibility is widely recognized to be important for molecular self-assembly, but relatively few studies have addressed this explicitly and systematically [1, 2]. Here, we focus on the degrees of freedom introduced by molecular conformational flexibility in a molecular system that displays a number of distinct conformational states after adsorption on the surface (Figure 1). For this purpose we have synthesized a class of rod-shape molecules that consist of two or three naphthalene units connected by ethynylene spokes and functionalized by systematically varied terminal moieties, including bulky tert-butyl and hydrogen bonding carboxyl groups [3]. Using high-resolution STM measurements to identify molecular conformations on the surface (Figure 1c), we investigate adsorption structures formed by UHV thermal deposition on a range of metal surfaces. The structures are systematically compared based on careful statistical analysis, focusing on molecular tiling patterns and the distribution of molecular conformations, allowing us to determine how the conformational degrees of freedom of the single molecules are manifested in the global structures and how intermolecular interactions may lead ordering/selection of molecular conformations. By optimizing the molecular functionality, a highly-ordered lamella-type packing is achieved which is suitable for amplification of molecular conformational information. Differences in the distribution of molecular conformations between molecules individually adsorbed and embedded in the ordered network indicate that the growth of ordered structures may involve dynamic conformational adaptation; to directly elucidate the details of such dynamic processes, we performed time-resolved STM investigations. The STM movies reveal that the evolution of the highly-ordered structures involves propagation of conformational order within the network and dynamic conformational adaptation at the domain boundaries.

The on-surface synthesis scheme for forming molecular surface nanostructures where the molecular building blocks are joined by strong covalent bonds has received tremendous recent interest¹. In this context there is a need to identify suitable chemical reactions that will readily proceed under Ultra High Vacuum conditions. "Click"-chemistry, in particular the 1,3-dipolar Huisgen cycloaddition² reaction between azides and terminal alkynes (CuAAC reaction) is a widely used reaction in organic chemistry and is potentially very interesting for on-surface synthesis. However, it remains to be shown, if the CuAAC reaction can be performed in an on-surface synthesis scheme with the reacting groups adsorbed directly on a surface and in the absence of a solvent and the solvated Cu(I) ions normally catalyzing the reaction. Here we study on-surface click chemistry on a Cu(111) surface using scanning tunneling microscopy (STM) and X-ray photoelectron spectroscopy (XPS)³. The adsorption structures of the reactants 9-ethynylphenanthrene (alkyne) and 4-azidobiphenyl (azide) were characterized by STM. The alkyne adsorbed individually with distinct orientations believed to result from interaction of the alkyne group with the Cu surface. The azide formed a range of small clusters (involving 2-5 molecules) that express distinct motifs. To perform the on-surface click reaction, the reactants were co-deposited onto the Cu(111) surface held at RT. This procedure led to distinct new features showing an excellent structural correspondence to the expected 1,4- triazole reaction product regarding the bent molecular shape and the positions/appearance of the assumed diphenyl and phenanthrenyl groups. The reaction was confirmed by control experiment using an equivalent ex-situ prepared 1,4-triazole. Quantitative evaluation of the C/N atomic

ratio from XPS measurements showed significant degradation of the azide upon adsorption, which was found to be the limiting factor for the reaction. The apparent yield calculated from the number of reactant and product molecules observed on terraces of the Cu(111) surface is ~2%. The observed click-reaction products must, however, stem from the small fraction of intact azide molecules present on the surface and the reaction yield based solely on intact azides was at least 15% suggesting that the cycloaddition reaction proceeds quite readily on the surface.

Hetero-epitaxial interfaces of graphene and hexagonal boron nitride on Ir(111)

T10 Nanoscience and Technology

#NST/SS-8-Or-2

F. Schulz, R. Drost, S. Hämäläinen, P. Liljeroth.

Department of Applied Physics, Aalto University - Espoo (Finland).

After almost a decade of intensive research, the interest in graphene is unabated. The material's many exceptional properties make it very attractive as a candidate for industrial and technological applications, while fundamental researchers are especially fascinated by the rich electronic structure of graphene [1]. Hexagonal boron nitride (h-BN), a large bandgap insulator structurally similar to graphite, has emerged as a promising support material for graphene, with electron mobilities of graphene samples on h-BN approaching those measured in suspended graphene [2]. Furthermore, the combination of h-BN and graphene within a single layer, both in the form of domain structures as well as the use of B and N as dopants, offer routes to engineer the graphene band structure [3 - 5]. It is clear that the interface of graphene with h-BN in a hetero-epitaxial monolayer will play an important role in its electronic properties. In order to fully understand the possibilities offered by mixing the two materials, a detailed study of the interface region is necessary.

Both graphene and h-BN samples of high quality can be readily grown by chemical vapour deposition (CVD) on transition metal surfaces under ultra-high vacuum conditions. The growth of graphene has been studied in depth especially on the Ir(111) surface, making it a good testing ground for hetero-epitaxial layers of graphene and h-BN. We grow sub-monolayer coverages of hetero-epitaxial layers of graphene and h-BN on the Ir(111) surface in a two-step process. In a first step, islands of graphene are formed from an ethylene precursor by temperature-controlled growth. Following the deposition of graphene, h-BN is formed in a second step by thermal cracking of borazine on the Ir(111) surface. At the interface between graphene and h-BN islands, the two films hybridize. The resulting hetero-epitaxial interfaces are investigated by tuning-fork-based low temperature scanning probe microscopy. Combining point spectroscopy and high-resolution imaging, we are able to determine structural as well as electronic properties of the interfaces.

Near infrared emitting Quantum dots has gained great interest recently for biotechnology and energy applications^{1,2}. Bulk Ag₂S with band gap of 0.9 eV is a best candidate for Near IR emission blend as well as has a great potential for both applications. However, Ag₂S QDs are usually synthesized by organic preparation methods. Hence, They are hydrophobic in nature which is not suitable for bio-applications³. Those quantum dots are emitting in the range of 700-1100 nm wavelength with the very low quantum yields up to 2%⁴. There are few studies in the literature on aqueous preparation of Ag₂S QDs and these are quite complicated⁵. We have synthesized Ag₂S NIRQDs in a very simple one step aqueous synthesis with thiolated capping agents. Particles showed near band-edge emission (Figure 1). Those Ag₂S NIRQDs are highly luminescent emitting in the range of 800- 900 nm with quantum yield between 7-39%. Thiolate coated Ag₂S NIRQDs are cytocompatible. Ag₂S-NIR QDs showed almost no toxicity in NIH3T3 and HeLa cell lines. Cellular uptake and intercellular localization of Ag₂S-NIRQDs study by a confocal laser scanning microscopy was reported (Figure 2). Besides, The surface of these can be easily functionalized. Hybrid nanoparticles are prepared from these QDs and SPIONs. These particles have both luminescent and magnetic properties, demonstrating a great potential for in vivo bio-applications.

Nucleation control of self-organized vertical nano-graphenes using inductively coupled plasma enhanced chemical vapor deposition

T10 Nanoscience and Technology

#NST/SS-8-Or-3

M. Hiramatsu ¹, R. Tsukada ¹, H. Kondo ², M. Hori ².

¹Meijo University - Nagoya (Japan), ²Nagoya University - Nagoya (Japan).

Carbon nanowalls (CNWs) are self-organized network of vertical standing few-layer graphenes. The large surface area of vertically standing CNWs is useful as templates for the fabrication of other types of nanostructured materials, electrodes for energy storage devices and biosensors. In view of the practical application using CNWs, further investigations should be performed to clarify their growth mechanism as well as to enable their nucleation control. Here, CNWs were grown by inductively coupled plasma enhanced CVD (ICP-CVD). We have investigated the early growth stage of CNWs on the catalyst-free substrate and the Ti-nanoparticle-catalyzed substrate.

Growth experiments were carried out at substrate temperature of 700°C, RF power of 500 W, total pressure of 20 mTorr, and flow rates of CH₄/Ar of 50/100 sccm, respectively. Figs. 1(a) and (b) show typical SEM images of CNWs grown on SiO₂ by ICP-CVD employing a mixture of CH₄ and Ar for 30 min. These images show that two-dimensional carbon sheets with a relatively smooth surface were grown vertically on the substrate. A TEM image of CNW shown in Fig. 1(c) reveals that graphene layers are clearly observed at the folded edge of the CNW.

There was an induction period of 1–5 min before the onset of vertical nanographene growth and the height of CNWs almost linearly increased with the increase of growth period in the steady-state condition. An interface layer existed between CNWs and the surface of SiO₂ substrates. The existence of interface layer enables us to grow CNWs on a variety of substrates without a catalyst. Furthermore, ion bombardment on the surface would play an important role in nucleation by creating active sites for neutral radical bonding. By controlling the substrate biasing to decrease the ion flux

incident on the substrate, it became possible to suppress the nucleation of CNWs on the SiO₂ substrates. CNW growth was not observed after 10 min on the substrate biased at +50V. In contrast, nanographene nucleation was enhanced by using Ti nanoparticles. In this case, SiO₂ substrate was coated with Ti nanoparticles 1–2 nm in size using the arc plasma deposition. In the case of growth on Ti nanoparticle-coated SiO₂ substrates, planar nanographenes were directly nucleated from the Ti nanoparticles without forming base layer, even when the substrate was positively biased to suppress the nucleation of CNWs. These results indicate the possibility of area-selective growth of CNWs for the device application such as biosensors or electrochemical sensors in micro-total analysis system (μ -TAS).

The potential of magnetic nanoparticles for the use in medicine

T10 Nanoscience and Technology

#BI/NST-1-Or-6

N. Ciobanu.

Technical University of Munich - Munich (Germany).

At present, numerous studies are evidencing the tremendous advantages of magnetic nanoparticles to treat a large class of diseases, from the more simple ones up to complicated forms of cancers. For their use in medicine, magnetic nanoparticles have to prove certain physiological parameters besides their optimal magnetic properties. One class of therapies with magnetic nanoparticles is represented by the magnetic drug targeting. It has novel advantages in the local deposition of chemostatics especially in the cases of cancers that are too critical to be treated by the conventional therapies. The magnetic nanoparticles have to be thoroughly characterized prior to any preclinical and clinical phase tests.

Transmission electron microscopy is a convenient tool to image magnetic iron oxide nanoparticles and to inspect their size and morphology (Fig. 1). Large nanoparticles of about 100 nm with a magnetic moment of interest for the medicine are revealed to be formed by subunits of 3 nm single crystals grown together. The magnetic single crystals usually of maghemite $\gamma\text{-Fe}_2\text{O}_3$ and magnetite Fe_3O_4 . are obtained through the polyol method and are adapted at their surfaces for the in vivo conditions. The optimal saturation magnetic values of such magnetic nanoparticles are situated within the range of 40-65 emu/g (Fig. 2). Physiological suspensions of fluorescently labelled magnetic iron oxide nanoparticles charged with mitoxantrone have been imaged by confocal fluorescence microscopy when submitted to external magnetic fields of 0.5 T. The magnetic nanoparticles show immediate magnetic collection and reversible chain formation which eliminates any danger of embolism.

Development of field effect transistors based on carbon nanotube (CNTFET) using standard lithography, dielectrophoretic deposition and tantalum nitride (TaN) electrodes

T10 Nanoscience and Technology

#NST/SS-P1-15

J. Fernandes De Souza ¹, C. De C. C. E Silva ², J. A. Diniz ³, I. Doi ³, P. J. Tatsch ³.

¹School of Electrical and Computer Engineering, University of Campinas, Center for Semiconductor Components (CCS), University of Campinas, Center for Information Technology Renato Archer (CTI) - Campinas (Brazil), ²Center for Semiconductor Components (CCS), University of Campinas - Campinas (Brazil), ³School of Electrical and Computer Engineering, University of Campinas, Center for Semiconductor Components (CCS), University of Campinas - Campinas (Brazil).

Devices based on carbon nanotube (CNT) are promising candidates for future field-effect transistors (CNTFETs), because of its high carrier mobility, low defect structure and intrinsic nanometer scale. However, on-off current ratio is small owing to the absence of bandgap. A number of approaches have been implemented to create a bandgap, but the mobility is degraded consequently [1]. Current saturation is not observed in devices with high contact resistances of source and drain. The total resistance is a series combination of the channel resistance and the contact resistance [2]. Usually, CNTFETs are fabricated using e-beam lithography to choose the best region with better quality of CNTs on the substrate. Thus, the better characteristics of CNTFETs are obtained, but it cannot be a reproducible method [3]. In this study, we fabricated sets of CNTFETs with sub-micron channel length using standard lithography (a reproducible method), dielectrophoretic deposition (DEP) and TaN electrodes. In a single 3 in. wafer, over 100,000 devices were produced (Figures 1A, B, C, D e E). Random CNT networks were deposited on electrodes by DEP [4] (Figure 1F). Our TaN electrodes are refractory metal structures and present electric

resistance with thermal stability. The physical characteristics of TaN electrodes, such as surface roughness and structural crystallization, were extracted using atomic force microscopy and micro-Raman spectroscopy, respectively. These electrodes present very smooth surfaces (3.0 nm rms roughness), high work function values (~4.4 eV) and low resistivity (~180 $\mu\Omega\cdot\text{cm}$), which allow the low channel and contact resistance values, when it compared with resistance values from Pt, Au and W electrodes, which are often used in CNTFETs. Thermal annealing process was carried out to get the low resistance of CNT/TaN contacts. Also, scanning electron microscopy was carried on the fabricated CNTFETs. The electrical characteristics, such as sub-threshold slope ($S=64$ mV/dec) and ambipolar characteristics, were extracted.

Instituto de Química -Universidade Estadual de Campinas - Campinas (Brazil).

The human brain is affected by many diseases, including cancer and infections. Drugs must pass through the blood brain barrier to achieve therapeutic effect. Permeation of drugs through it can be increased by Polysorbate 80-coated nanocarriers [1]. Phytantriol-based nanocarriers are receiving increased attention due to their tunable nanoscale internal structure and resistance to esterases [2]. Despite their advantages, there is a lack of studies concerning brain targeting. The liquid crystalline phase behavior of phytantriol could be influenced by Polysorbate 80 due to its hydrophobic anchor and relatively low molecular weight. Determining this influence is a key part of the nanoparticle design using phytantriol for brain targeting because the kind of liquid-crystalline phase can affect drug loading and release kinetics [3].

In this work, the effect of Polysorbate 80 was investigated in bulk and dispersed liquid crystals. Bulk samples were prepared by co-melting (70°C) phytantriol and Polysorbate 80 into glass ampules and then adding water. The ampules were sealed and centrifuged up and down at 5000 x g several times. SAXS curves of phytantriol presented Bragg peaks indexed as a gyroid-type (Ia3d space group) inverted cubic phase. This structure was not altered by adding up to 1 % w/w (Polysorbate 80:phytantriol) of stabilizer. With higher Polysorbate contents (10 to 45 % w/w) SAXS curves displayed a single broad correlation peak centered at q ranging from 1.72 nm⁻¹ (10 %) to 2.19 nm⁻¹ (45 %). The disorganized structure observed for those samples indicated penetration of stabilizer and disorder of the liquid crystalline phase. Correlation distances from 2.77 nm (10 %) to 2.21 nm (45 %) were found and can be related to the fluctuations of the phytantriol aggregates. The nanocarrier dispersions were prepared by a fragmentation method where preformed liquid crystals were highly sheared (27700 rpm) into an aqueous phase containing Polysorbate 80. Only

Polysorbate 80 content of 45 % w/w provided monomodal (180 nm) and narrow size distribution (PI < 0.2). SAXS curves of dispersions up to 34 % w/w Polysorbate 80 showed Bragg reflections indexed as double diamond-type (Pn3m space group) inverted cubic phase. A broad peak was also observed in all samples indicating the coexistence of a disordered structure. The highest Polysorbate 80 concentration used (45 %) presented only the broad peak. The stabilizer was probably located at the nanocarrier surface and also penetrated its internal phase.

From these results, we conclude that Polysorbate 80 interacts with phytantriol both in bulk and in the internal phase of the dispersion. A higher concentration of Polysorbate 80 in the dispersions provided monomodal distribution and changed the internal phase of the particles from inverted cubic bicontinuous to a disordered phase, which probably can lead to increased drug loading and faster release.

There are experimental evidences of metallic nanoparticles (NP) shape dependence on chemical environment [1-3]. On the other hand, shape and structure of NP are crucial for many applications [2,4]. For a set of metals two significantly different structures with similar potential energies are known – face-centered cubic crystal (fcc) and non-crystalline structure with five-fold symmetry (5fs). To these structures the following shapes respectively correspond: fcc produces octahedral, cuboctahedral, sometimes cubic NPs and 5fs structure produces icosahedral and decahedral shapes. It is known, that for small sizes the most stable structure is 5fs, yet for large NPs and bulk metals the most stable is fcc [5]. In different studies for different metals the crossover size was predicted to vary from hundreds to tens of thousands atoms. Taking into account small energy difference of fcc and 5fs structures in the vicinity of crossover size we suppose that chemical environment significantly affects equilibrium shape and structure of the NP. Therefore we have investigated an influence of adsorbed molecules on relative stability of different NP structures and shapes with Monte Carlo simulations.

Simulations were conducted in a grand canonical ensemble, in a lattice gas model framework. The model we employed considered several possible types of adsorption sites on (111) and (100) faces (e.g. a-top, in-hollow, on-bridge). This approach was previously successfully used for simulation of CO adsorption on supported Pt nanoparticles [6]. Adsorption isotherms and dependency graphs of crossover size on chemical potential were plotted using putative equilibrium shapes and structures obtained in simulations. Example of cuboctahedral Pt NP with adsorbed CO molecules is shown in Figure 1.

MWCNTs are prepared by aerosol-assisted catalytic chemical vapor deposition. N precursor are introduced as gaseous NH₃ with different experimental conditions. The synthesized nitrogen-doped carbon nanotubes present very reproducible XPS responses with typical multi-contributions N1s core levels and well defined C1s peaks whose FWHM are totally correlated to the N concentration. The XPS responses are compared to sample obtained by other grow methods. The multi-component N1s can be described with different N environments. These environments can be modified more or less by thermal annealing in UHV at different temperatures. Using this opportunity we prepared different sets of MWCNT which are studied about their electrocatalytic oxygen reduction performances. We demonstrated electrochemically that ORR mechanism can be completely modified by the actual N/C ratio. This demonstration about correlation between electrochemistry and photoelectron spectroscopy will be discussed about ORR mechanism understanding at a local level.

Vertically Aligned Carbon Nanotube carpets (VACNT) are potential candidates for a large range of applications in nanotechnology. Particularly, they can be considered as building blocks for the design of multifunctional composite materials containing anisotropic nanomaterials [1]. Such an interest absolutely requires the reproducible production of various well controlled VACNT carpets in terms of purity, size and surface chemistry, as well as their controlled processing.

In this communication, we will focus on the Aerosol-Assisted Catalytic Chemical Vapour Deposition (AA-CCVD) method based on a simultaneous feeding of the CVD reactor with both the carbon source and the catalyst metallic source and enabling to produce VACNT carpets (see figure a)) [2, 3]. This one step process is versatile, low cost and easily scalable. However, in order to control this process and to adjust it to different technical requirements for applications, it is necessary to understand nanotube formation and the main parameters controlling CNT growth. The effect of different synthesis parameters such as the nature of the reactive atmosphere, the catalyst source concentration, the reactor location, on catalyst and nanotubes formed will be presented, revealing a gas phase homogeneous nucleation phenomenon for the formation of metal-based catalyst nanoparticles [4] and the importance to adjust the nature and composition of the reactive gas phase in order to control the nanotube diameter. These results have strong impact on the extension of this process to several growth configurations, while controlling the carpet height (e.g. nanotube length) and CNT diameter distributions.

In a second part, our approach of scale-up of VACNT carpet homogeneous growth (see figure b)) will be detailed. In particular, we will emphasize on the reactor configurations, either horizontal or vertical depending mainly on the substrate nature and size. Finally, we will present how to get macroscopic 1D composite sample exhibiting controllable thickness. The properties of such nanomaterials are under

evaluation [5], and a large variety of applications such as space or aerospace materials, filtration or separation, are envisaged.

NaYF₄:Yb³⁺,Er³⁺ nano upconversion phosphors (NUCPs) are required for biological imaging, security, and manufacturing coupled nanosystems. We report two innovations to improve power conversion efficiency: (1) synthesis of highly efficient NUCPs passivated by undoped or Yb-doped layers; (2) use of surface plasmon enhancement.

Platelets (hexagonal section ~20-35 nm, thickness ~ 10 nm) were synthesized, with X-ray measurements confirming β -phase and TEM core size and layer thickness. The photoluminescence (PL) was excited by 980 nm radiation. To investigate surface passivation undoped and Yb (20%) doped shells¹ were grown on Yb:Er (18%:2%) co-doped cores. Figure 1 shows that the green 546 nm PL from undoped- and Yb-shell coated particles normalized to the core PL, increases as a function of shell synthesis time with both showing an enhancement of ~3.5 after 36 and 10 min, respectively. The undoped shell passivation behaves conventionally; however, for shell doping excited Yb ions transfer energy with equal probability to the surface or Yb + Er doped core to activate PL. Thicker shells progressively lose energy to the surface and the PL decreases enabling a measure of the diffusion length.

To investigate surface plasmon enhancement, silver gratings were fabricated tuned to the excitation wavelength. A Si₃N₄ spacer layer alleviates quenching of NUCPs deposited layer-by-layer using amphiphilic polymer coatings. The gratings showed well-defined plasmon absorption and after NUCP deposition, strongly enhanced PL peaks at 546 and 662 nm, Fig. 2(a). PL enhancement varied with Si₃N₄ spacer thickness indicating two effects in play: the spacer layer alleviates quenching but shifts the plasmon resonance. A thickness of 38 nm minimized quenching while maximizing field enhancement. Since up-conversion efficiency depends on excitation power, and absolute up-conversion efficiency decreases with

decreasing power: the enhancement increases. As shown in Fig. 2(b), the enhancement monotonically increases with decreasing power to 30x at 9.4 mW. Even at high power, gains of 10x and 6.3x for red and green emission were observed. Theoretical models will be presented.

Nanocomposites of metal nanoparticles dispersed by oxide nanoparticles display a variety of interesting chemical and physical properties which can be modified by varying the particle size and metal volume fraction. Mechanical alloying (MA) has been considered as a powerful and practical process for synthesis of compounds and nanocomposites using the mechanochemical reactions. In the present work, the mixtures of α -Fe₂O₃ and (Cr / Si) powders have been milled for various times up to 15 h, in a planetary ball mill (P7) in air atmosphere. The as-milled powders were structurally and magnetically characterized by X-ray diffraction (using the MAUD program based on the Rietveld method) and magnetic measurements in dc magnetic fields up to 10T at room temperature. The refinement of the X-ray diffraction patterns (α -Fe₂O₃/Cr) shows that the reduction of hematite by chromium is gradual with the formation of nanoparticles of α -Fe. The final phases α -Fe and Cr₂O₃ are formed, with a nanometric grain size ~ 20 nm and 23 nm at 15 h respectively. The saturation magnetization (Ms) of Fe-Cr₂O₃ nanocomposites jumps from 6 Am²/kg at 1h to 76 Am²/kg at 15h. This value of Ms is in relationship with the change in the computed fraction of iron nanoparticles. The value of coercive field (Hc) is about 0.02 T. In the milled mixture of (Fe₂O₃/Si), there is no change up to 5 h of milling. After 15h of milling, α -Fe nanoparticles are formed in an amorphous SiO₂ phase. All phases have

nanometric size (~ 25 nm, 19 nm at 15 h respectively). The calculated lattice parameter of the iron nanoparticles is $a_0 = 2.8687 \text{ \AA}$. The magnetic measurements of Fe-SiO₂ nanocomposites show that the (Ms) reaches 70.6 Am²/kg at 15h. The increase of Ms is expected since this parameter depends on the total mass of material embedded into silica matrix. The values of coercive field (Hc) decreases first then increase reaching a stationary value above 10 h of milling time (about 0.03 T at 15 h).

In addition to the grain size effects, the reduction of the particle size toward the size region of single domain and matrix nature can explain the above structural and magnetic variations.

Since their discovery, carbon nanotubes (CNTs) are emerging as novel nanomaterial for large variety of applications, particularly as electronic material owing to their mechanical, thermal and unique electrical properties [1]. In order to understand the transport phenomenon through CNTs networks, electrical characterization is of key importance. One way to progress in the comprehension of CNTs behaviour is by improving the deposition method.

Inkjet printing is considered as a promising technology, which gives the possibility to readily control the pattern geometry, location, film thickness, and uniformity of the films. In this present study, CNT ink was used to print films on coplanar waveguides (CPWs) lying on Glass substrate. Scanning Electron (SEM) of used Multi-Walled CNTs (MWCNTs) solution and individual CNT features were observed by Transmission Electron microscopy (TEM) Microscopy images are shown in Fig. 1. MWCNT presents 8 walls, a length and a diameter of approximately 10 μm and 15 nm, respectively. Afterwards CNT Ink is prepared using the method described in [2] to correspond to physico-chemical characteristics required for performing printing using inkjet equipment Fujifilm-Dimatix DMP 2831. Four layers of MWCNTs solution, shown in Fig. 2, were successively deposited and followed by a 40°C drying. The diameter and spacing between drops are around 50 μm and 25 μm , respectively. A stable carbon nanotube (CNT)-based ink has been prepared and printed. Consequently their electrical could be investigated with easy and precise control, which is of great interest for developing accurate models that are required to design new and novel devices based on CNTs.

¹GE GRC - Niskayuna, NY (United states), ²Bechtel - Niskayuna, NY (United states).

Analytical solutions to a simple 1D model of a nano-scale filament-like field emitter show quite high temperatures can be reached during modest current flow. Current of 1 μA and material properties of CNT show non-linear temperature as a function of length along the emitter. Adsorbed gas species are bound to the surface of the emitter with a range of energies: 1 - 10s kcal/mole. Desorption of gas during current emission contributes a background gas that can be ionized by the emitter current and contribute to ion backbombardment a life-limiting mechanism. Pressure as a function of time, $P(t)$, can be predicted and is compared to RGA measurements. Sparse (low density) emitter densities (1 to 10 μm center-to-center spacing) on a substrate yield modest change in pressure; the decay time of the pressure spike depends on pumping, gas species, and geometrical factors. The high effective pumping speed of nearby solid state getters, surface and bulk, and the like, can reduce the effect of this background and limit the damage to the emitter. Analytical solutions will be presented and a calculation will show the effect of the advantageous changes to pump disposition and geometry. These solutions suggest strategies for longer emitter lifetime. Applications include displays, addressable multi-emitter current sources, and x-ray sources.

Recently various nanowire/nanotube based two terminal nanoelectromechanical (NEM) switches [1-3] has been reported. The operation of these devices is depending on adhesion forces in nanocontacts. Strong elastic and/or electrostatic forces have to be applied to the active element to surpass adhesion force in the nanocontact. High elastic force causes large distance between elastic active element and contact caused in increase of dimensions of NEM device. To apply strong electrostatic field high voltages has to be applied in system. For two terminal devices high applied voltages causes high currents in nanocontacts after jump in contact leading often to degradation of switches [2,3].

Here we present implementation of DC and AC field to reduce force needed for operation switching *off* events. Experiments were carried out *in situ* by using nanomanipulation systems inside SEM. Ge nanowires were used as active element and etched gold tips was used as contact electrodes.

Switching *off* voltages in NEM switches can be reduced when combined AC+DC electric field is applied. Effect is observed when AC frequency the nanowire resonance frequency.

Structure and thermal stability of mechanical properties of Al–TiB₂ composites alloyed with Mn and Zr

T10 Nanoscience and Technology

#NST-P2-32

E. Kurbatkina, N. Belov.

National University of Science and Technology “MISIS” - Moscow (Russian federation).

Composite materials based on system aluminum - boron have attracted great attention of scientists and researchers nowadays. They can be widely used in nuclear industry because of good combination of properties, such as low specific density, good thermal conductivity as well as the ability to absorb neutron radiation. Aim of this work was to obtain aluminum matrix composite material (AMCM) based on Al-B-Ti-Cu-Mn-Zr-Sc system and the study of its structure and properties. The object of research was an experimental alloy Al-2,5B-1,5Ti-1,5Cu-1Mn-0,2Zr-0,2Sc. AMCM was prepared using liquid-phase technology. Thermo-Calc software was used to calculate the phase composition of this alloy at various temperatures. TiB₂ particles formed as endogenous phase during holding at 900°C. AMCM ingots were rolled at 200°C to the thickness of 3 mm and annealed. Metallographic analysis showed that annealing at temperatures of 300-450°C led to the separation of Al₂₀Cu₂Mn₃ and Al₃(Zr,Sc) dispersoids. No secondary Al₂Cu precipitates were detected. Such structure is the most favorable for creep resistance as Mn- and Zr, Sc-containing dispersoids have a higher thermal stability than the Al₂Cu precipitates. We measured mechanical properties, thermal conductivity, corrosion resistance, coefficient of thermal expansion. Analysis of the mechanical properties showed a high thermal stability up to 350°C due to the formation of polygonized structure, which resulted from large amount of Al₂₀Cu₂Mn₃ and Al₃(Zr,Sc) dispersoids that effectively pinned down dislocations. Therefore, replacing the lxxx,5xxx, 6xxx series by Al-Cu-Mn-Zr-Sc alloy as the matrix would be of interest.

Dysprosium nanooxide has been obtained two methods.

1- method Erbium nanooxide preparation method with chlorides: the corresponding metal amount was dissolved in hydrochloric acid and chloride was obtained. Distilled water +NaOH+NaCl was added to obtained chloride. It was heated at pH=3.6-3.8 and evaporated. Hydrate DyCl₃ + H₂O= Dy₂O₃+ 3HCl was prepared. This mixture was roasted at 440°C, washed and filtered using Bruchner filter, the sediment was dried. The second sample was roasted at 540°C, the third one at 640°C. Roasting time for all samples was similar- 1hour.

X-ray phase analysis shown that in the process of roasting the reflex intensity is growing corresponding to cubic Dy₂O₃ structure. Size value of coherent-scattering region calculated using the Sherrer formula for the samples were 80-120nm.

2- method of preparation of Dy₂O₃ with use organic compounds, which consisted of several steps:

1step: Synthesis of sodium oleinate.

2step: Synthesis of dysprosium chloride.

3step: Synthesis of dysprosium olenate.

4step: Dyr₂O₃ nanocrystal preparation.

X-ray phase analysis has shown single phase nanooxide have been obtained with 49nm size.

IR, Raman spectras have been investigated. As it results from IR spectra that there

are groups containing C-O bound (adsorption bands 1530 and 1430 cm^{-1}) in the studied samples. Concentration of these groups can be significant – several percents. Roasting in the air reduces concentration of these groups.

Stochastic resonance (SR) is a phenomenon where the noise can enhance the transmission of signal which lied below threshold level. The SR phenomenon can be found in sensory organ of living creatures [1]. This phenomenon also can be reproduced in electronic device [2,3]. According to the previous studies, we need multiple junctions, independent noise, and non-linear response to realize the SR device [2-4]. The large numbers of junction drastically improve the SR effect. However the numbers of junctions in previous electronic device were limited by the fabrication method [2]. To solve this problem, we propose the use of single walled carbon nanotube (SWNT) as we can easily build multiple junctions. The SWNT is a one-dimensional nanomaterial and thus has the possibility to be a source of independent noise due to its Tomonaga-Luttinger liquid behavior [5].

We succeeded to fabricate the device which consist multiple junctions of individual SWNTs. The channel length and width are 0.2 μm and 1 μm , respectively. Our device showed good p-type field effect transistor (FET) behavior since we used semiconducting SWNT. In the SWNT-based FET, the current flows through individual SWNT is strongly affected by the gate voltage. The response of each junction to the external electric field might be different each other. Therefore, we utilized this field effect behavior as a noise generator by applying noise signal to the gate electrode. Increment of the noise signal amplitude yielded different quality of signal transmission. We calculated correlation coefficient of the signal transmission as shown in figure 1. We concluded that this result is the effect of SR phenomenon, though the effects of multiple paths have not been defined yet. In the future, we will vary the channel length and width to increase the number of SWNT junction.

Omsk State Technical University - Omsk (Russian federation).

Controlled production of self-assembled nanostructures of complex organic molecules on metallic surfaces is now the constantly growing field of researching and attracts great interest. It has promising potential for electronic and electro-optic devices [1]. Controlled assembly also can be used for creating templates for the accommodation of guest molecules [2, 3]. These systems have potential application in molecular recognition, selective catalysis, and molecular storage.

In this work we have investigated the lattice gas model of 5, 10-bis (4-carboxyphenyl)-15, 20-bis (3,5-di-*t*-butylphenyl) porphyrin (cis-BCaTBPP) adsorption on a square lattice taking into account the directional interactions between adsorbed molecules. We consider that cis-BCaTBPP molecule occupies only one site of two-dimensional square lattice. The model was studied with transfer-matrix and Monte Carlo techniques in grand canonical ensemble.

In the framework of constructed model we calculated adsorption isotherms, internal energy and phase diagram. All structures of self-assembled adlayer appearing in our model are analogous to real ones.

Biomimetic Au/TiO₂ with hierarchical structures from butterfly wings (Peacock butterfly)

T10 Nanoscience and Technology

#NST-P2-27

S. Mihai ¹, A. Dinescu ².

¹Petroleum - Gas University of Ploiesti - Ploiesti (Romania), ²National Institute for Research and Development in Microtechnologies - Bucharest (Romania).

In nature, biologic systems shows a wide variety of structures that can be used in nanotechnology. Peacock butterfly wings have been used as templates for the formation of the Au/TiO₂ inorganic structures. The reticular hierachical structure of butterfly have been synthetized by sol-gel technique by subsequent calcination. The morph - Au/TiO₂ possesses an enhanced light absorption property in visible light region owing to its hierarchical structures, which would be favorable for high photocatalytic activity.

Synthesis of nano-CeO₂ and degradation of dye in indoor lighting

T10 Nanoscience and Technology

#FMMM/NST-P3-5

R. Li, B. Zhao, M. Gu, C. Li, X. Song.

Key Laboratory of Aerospace Materials and Performance (Ministry of Education), School of Materials Science and Engineering, Beihang University - Beijing (China).

Azo dyes are an abundant class of synthetic, organic compounds which contain one or more azo bonds (-N=N-). Large amounts of these dyes are produced for use in different applications.

However their complex structure makes them difficult to biologically degrade. We sought to degrade acid orange 7 (AO7) using nitrogen-doped (N-doped) and carbon-nitrogen (C-N) co-doped nano-CeO₂. N-doped monocrystalline CeO₂ nanoparticles was synthesized by solvothermal method using triethanolamine as a nitrogen source at 120 °C for 24 h. C-N co-doped monocrystalline CeO₂ nanoparticles was synthesized by solvothermal method using hexamethylenetetramine as both nitrogen and carbon source at 140 °C for 24 h. For purposes of comparison, a sample of undoped CeO₂ was synthesized using the dopant of neither triethanolamine nor hexamethylenetetramine. The doped and undoped CeO₂ monocystals were all less than 10 nm in diameter. Nitrogen and carbon-nitrogen were shown to be incorporated into CeO₂ lattice from the results of both XRD and X-ray photoelectron spectroscopy analyses.

The degradation of AO7 in water was investigated using a domestic 10 W compact fluorescent lamp. The results showed the degradation ratios of AO7 in the presence of nano-CeO₂ in the sequence of: C-N co-doped CeO₂ > N-doped CeO₂ >> undoped CeO₂, corresponding to magnitudes of 98.8%, 97.6%, and 48.2%, respectively.

NST-12-In-1

THE CHIRALITY INDUCED SPIN SELECTIVITY (CISS) EFFECT- FROM SPINTRONICS TO ELECTRON TRANSFER IN BIOLOGY

T10 Nanoscience and Technology

#NST-12-In-1

R. Naaman.

Department of Chemical Physics, Weizmann Institute - Rehovot (Israel).

Spin based properties, applications, and devices are commonly related to magnetic effects and to magnetic materials. Hence, most of the development in spintronics is currently based on inorganic materials. Despite the fact that the magnetoresistance effect has been observed in organic materials, until now spin selectivity of organic based spintronics devices originated from an inorganic ferromagnetic electrode and was not determined by the organic molecules themselves. In several studies, however, it was found that chiral organic molecules can act as spin filter for photoelectrons transmission, in electron transfer, and in electron transport. Results will be presented from several recent experiments and some implications and applications will be discussed.

NST/SS-4-In-1

SELF-ORGANIZED EPITAXIAL NANO-ALLOYS ON METALLIC SURFACES: GROWTH AND NANOMAGNETISM

T10 Nanoscience and Technology

#NST/SS-4-In-1

S. Rousset.

MPQ, CNRS and University of Paris Diderot - Paris (France).

The use of spontaneously nanostructured substrates as templates allows growing a very high density of ordered nanostructures over macroscopic scales [1]. This opened up studies of both individual and collective physical properties by means of usual spatially averaging techniques.

Taking advantage of our former work on magnetic nanostructures [2, 3, 4], we present here results on more complex systems, namely small magnetic nano-alloys epitaxial dots, which are not yet published. We used the Au(111) surface, since the growth and the characterization of ordered nano-alloys on such a template is still a challenging issue, together with their magnetic properties. The CoPt alloy is one of the most studied bimetallic compounds, due to its potential application for magnetic recording. First we investigate the morphology and the chemical composition of CoPt ordered nano-alloys as a function of the alloy stoichiometry and the size of the dots. Then, their magnetic behavior can be understood by hybridization effects between Co and Pt. We will compare nano-alloys islands with bimetallic core-shell structures [5]. Eventually, we will discuss how to predict the elaboration of 3D magnetic nanostructures stable at room temperature and with a very high density at surfaces, which can have important consequences for magnetic storage.

NST/SS-6-In-2 SPIN LEGOS - BOTTOM-UP FABRICATION OF MODEL MAGNETIC SYSTEMS

T10 Nanoscience and Technology

#NST/SS-6-In-2

A.A. Khajetoorians.

Institute of Applied Physics, Hamburg University - Hamburg (Germany).

With the development of sub-Kelvin high-magnetic field STM, two complementary methods, namely spin-polarized scanning tunneling spectroscopy (SP-STs) [1] and inelastic STs (ISTS) [2-3], can address single spins at the atomic scale. While SP-STs reads out the projection of the impurity magnetization, ISTs detects the excitations of this magnetization as a function of an external magnetic field. They are thus the analogs of magnetometry and spin resonance measurements pushed to the single atom limit. We have recently demonstrated that it is possible to reliably combine single atom magnetometry (SAM) with an atom-by-atom bottom-up fabrication to realize complex atomic-scale magnets with tailored properties [4]. As a first such example of this, we demonstrated that it is possible to realize an all-spin based atomic logic gate comprised of coupled Fe atoms on a metallic surface [5]; a demonstration of a fundamental nano-spintronic concept. In this talk, I will address novel developments illustrating advances in the realization of artificially constructed magnetic nanostructures, like complex two-dimensional indirect-exchange based nanomagnets, as well as investigations of the magnetization dynamics [6] of single and coupled spins as probed with spin-resolved STM techniques.

NST-10-In-1 ELECTRON BEAM INDUCED DEPOSITION OF NANOSTRUCTURES: A SURFACE SCIENCE PERSPECTIVE

T10 Nanoscience and Technology

#NST-10-In-1

H. Fairbrother ¹, S.G. Rosenberg ¹, J.D. Wnuk ¹, J.D. Wnuk ², J.M. Gorham ¹, M. Barclay ¹, C.W. Hagen ³.

¹Department of Chemistry, Johns Hopkins University - Baltimore (United states), ²Intel Cooperation - Hillsboro (United states), ³Delft University of Technology, Faculty of Applied Sciences - Delft (Netherlands).

Electron beam induced deposition (EBID) is a minimally-invasive, lithographic strategy that uses the electron stimulated decomposition of volatile organometallics under low vacuum conditions to fabricate and prototype three-dimensional metallic nanostructures (Figure 1). One of the limitations of FEBIP lies in the often unacceptably high level of organic contamination in the deposits which adversely affects properties and restricts their value (e.g. as catalysts and biosensors). At the heart of EBID are the electron stimulated reactions of the surface bound organometallic precursors which are responsible for deposition and the ultimate chemical composition of the deposit. In this presentation I will describe the current status of EBID and in particular how surface analytical techniques have been used to provide mechanistic and kinetic insights into the influence that ligand architecture, substrate temperature and electron fluence have on the surface reactions and molecular level processes that underpin EBID.

Figure 1: Electron beam induced deposition of metal nanostructures from organometallic precursors.

Epitaxial graphene on Ir(111) – a playground for the fabrication of graphene hybrid materials

T10 Nanoscience and Technology

#NST-1-In-2

T. Michely.

Physikalisches Institut, Universität zu Köln - Köln (Germany).

Highly perfect graphene layers on Ir(111) can be used as a laboratory to construct new types of graphene based compound materials. Due to the inhomogeneous binding of graphene to its substrate a plethora of pattern formation processes is observed: arrays of clusters and molecules, patterned intercalation and the formation of a nanomesh upon ion irradiation. The resulting changes in graphene allow one to tune its properties in a wide range and to locally functionalize it.

NST/SS-3-In-1 SPIN SPIRALS AND MAGNETIC SKYRMIONS STUDIED WITH SPIN- POLARIZED STM

T10 Nanoscience and Technology

#NST/SS-3-In-1

K. Von Bergmann.

Institute of Applied Physics, University of Hamburg - Hamburg (Germany).

Magnetism in low-dimensions is a versatile topic and broken inversion symmetry due to the presence of a surface can induce the formation of non-collinear magnetic states. In such systems the spin rotates from one atom to the next resulting for instance in spin spirals with nanometer sized magnetic periods [1-3]. In the case of the monolayer Fe on Ir(111) competing interaction lead to a lattice of skyrmions on the atomic scale [4,5]. By changing the interface of this system we obtain an ultrathin film system with a spin spiral ground state that can be driven into a skyrmion lattice phase by the application of an external magnetic field. Depending on temperature and measurement parameters we find reversible or hysteretic behavior.

Electronic properties and electron dynamics in quasi free standing graphene

T10 Nanoscience and Technology

#NST-1-In-1

P. Hofmann.

Aarhus University - Aarhus (Denmark).

Epitaxial graphene grown on SiC as well as on transition metal surfaces has successfully been used as a model system to study the electronic properties and many-body effects in graphene by angle-resolved photoemission spectroscopy and scanning tunnelling spectroscopy. Over the last years, it was shown that the intercalation of hydrogen between graphene and SiC, or oxygen between graphene and a transition metal, can decouple the graphene from its substrate, leading to an electronic structure that resembles that of pristine graphene even more [1-4]. In this talk, I will review the electronic properties and many-body effects in such quasi free-standing graphene. I will also discuss recent results on the ultrafast dynamics of the excited carriers near the Dirac point in quasi free standing graphene, as studied by time and angle-resolved photoemission spectroscopy. Direct access to the Dirac cone in such an experiment is only possible with sufficiently high laser photon energies as provided by the Artemis setup at the Rutherford Appleton Laboratory.

NST-5-In-1

Towards an atomistic understanding of molecule-metal interfaces

T10 Nanoscience and Technology

#NST-5-In-1

F.S. Tautz.

Peter Grünberg Institut, Forschungszentrum Jülich - Jülich (Germany).

Contacts between metals and large π -conjugated molecules are of central importance for organic and molecular electronics. Highly ordered monolayers of electrically active molecules on single-crystal metal surfaces are excellent model systems for metal-molecule contacts. They can be used to study fundamental properties of metal-molecule contacts at the atomistic level. In my talk, I will give examples of our recent work, including precision measurements of adsorbate geometries, comprehensive experiments revealing how observables such as vertical adsorption height, charge reorganization and charge transfer emerge from a complex interplay of different factors, and investigations of the role played by van der Waals interactions at metal-organic interfaces.

NST/SS-3-Kn-1 MOLECULAR QUANTUM SPINTRONICS

T10 Nanoscience and Technology

#NST/SS-3-Kn-1

W. Wernsdorfer.

Institut Néel - Grenoble (France).

A revolution in electronics is in view, with the contemporary evolution of three novel disciplines, spintronics, molecular electronics, and quantum computing. A fundamental link between these fields can be established using molecular magnetic materials and, in particular, single-molecule magnets, which combine the classic macroscale properties of a magnet with the quantum properties of a nanoscale entity. The resulting field, molecular quantum spintronics aims at manipulating spins and charges in electronic devices containing one or more molecules. The objective is to fabricate, characterize and study molecular devices in order to read and manipulate the spin states of one or several molecules and to perform basic quantum operations. The most important results in this new research area will be presented.

NST-9-In-1 CONTROLLED SYNTHESIS OF HETEROSTRUCTURES OF 2D MATERIALS

T10 Nanoscience and Technology

#NST-9-In-1

E. Sutter.

**Center for Functional Nanomaterials, Brookhaven National Laboratory - Upton
(United states).**

The ability to combine materials in heterostructures with controlled interfaces has become one of the foundations of modern materials science. Heterostructures of 2D materials promise tunable properties and new functionality, and raise fundamental questions on interface formation, intermixing, strain, etc., in a new context at reduced dimensionality. I will discuss progress toward meeting key challenges in the controlled formation of 2D heterostructures: atomically precise thickness and stacking control in superlattices, and the creation of atomically sharp line interfaces in heterogeneous monolayer membranes. Our combined findings establish a powerful toolset for the scalable fabrication of 2D heterostructures for research and applications.

Grain boundaries [1] are a common feature of polycrystalline graphene grown by chemical vapor deposition on transition metal substrates [2, 3]. The simplest model of the boundaries connecting two rotated graphene domains consists of a series of dislocation cores made up of nonhexagonal rings such as pentagons and heptagons. Such grain boundaries have to date been mostly measured by transmission electron microscopy. AFM and STM, being uniquely suited to the study of defects in graphene, have only recently been used to measure grain boundaries in CVD grown graphene [3, 4]. Using scanning tunneling microscopy (STM) and STM spectroscopy (STS), combined with modeling, we present evidence that grain boundaries in graphene grown on copper incorporate a significant amount of disorder and the simplest dislocation core model cannot fully describe these structures. Beyond characterization, STM in lithographic mode (STL), is a versatile tool for the nanopatterning of graphene [5]. Possibilities of STL [6] and difficulties associated with the nanopatterning of CVD graphene grown on Cu will be discussed.

PST-P3-01 ELECTRIC ARC PLASMA REACTOR FOR FLUID ORGANIC COMPOUNDS DECOMPOSITION

T11 Plasma Science and Technology

#PST-P3-01

L. Szymanski.

Lodz University of Technology - Lodz (Poland).

The aim of the paper is to study a stream rate and quantity of organic fluid waste production by an average analytic chemical laboratory, to find out the required conditions of its thermal treatment in electric arc plasma and to demonstrate a concept of compact system able do utilize from one to a few kilograms of reagent per hour. The main part of the device is the plasma reactor equipped with the electrode spacing adjustment actuator and the power and flow control unit. The collected wasted solvents must be filled in the container feeding the reactor. The gasified waste is heated in the reactor space and must pass across the plasma column going to the compact chlorine absorber and catalytic oxidizer. In a chemical analytic laboratory practice small amounts of diverse reagents, mostly liquid organic substances are used for many purposes such as chromatography. They are the chlorinated solvents, solvents from the group of alcohols, esters, and aliphatic or aromatic hydrocarbons. The avoidance of stockpiling and transportation of those waste is the economic challenge in the procedure of utilization of the used reagents. So far any device able to utilize those wastes "in situ" where they are produced had not been offered [1]. Such device had to be placed in/or close to the laboratory and may be working in measure of the need (batch mode) on principle how the office document shredder. The aim of the paper is to study a stream rate and quantity of organic fluid waste production by an average analytic chemical laboratory, to find out the required conditions of its thermal plasma treatment and to demonstrate a concept of compact device PDU CR - Fig. 1 (Plasma Destructor of Used Chemical Reagents) able do

utilize from one to a few kilograms of reagent per hour. The main part of the device is the plasma treatment reactor equipped with the adjustment actuator and the power and flow control unit. The collected wasted solvents must be filled in the container feeding the reactor. PDUCR will be supplied in the inert gas delivered from the bottle in the slow rate and atmospheric pressure. To optimize the conditions of the reaction the calculated decomposition of solvents within the range of temperatures from 400 to 3000K using the CHEMSAGE program based on the minimization of Gibb's free energy will be presented.

PST/SE/TF-1-Or-1

Influence of type of gas on the properties of SiO_x coatings by cold atmospheric plasma

T11 Plasma Science and Technology

#PST/SE/TF-1-Or-1

H. Hamze ¹, M. Jimenez ¹, D. Deresmes ², A. Beaurain ³, N. Nuns ⁴, M. Traisnel ¹.

¹UMET, ISP-PERF, CNRS 8207, Université Lille Nord de France - Lille (France), ²IEMN, CNRS 8520, Université Lille Nord de France - Lille (France), ³UCCS, CNRS 8181, Université Lille Nord de France - Lille (France), ⁴Institut Chevreul, Université Lille Nord de France - Lille (France).

In this study, thin layers of SiO_x were applied on glass substrates, using two different gases (air and nitrogen), by a cold atmospheric plasma torch (ULS, AcXys technologies, France). Looking at the literature, the extreme surface of such thin films is usually only analyzed by X-Ray Photoelectron Spectroscopy (XPS) [1-2]. The aim of this work is to investigate on one hand the influence of the gases used during plasma process on the extreme surface composition and morphology of the layer by XPS and Atomic Force Microscopy (AFM) and on the other hand the whole thin film composition, using Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS).

A Hexamethyldisilan (HMDS) precursor was injected in post-discharge in an air or nitrogen plasma, using a carrier gas (air or nitrogen) and applied on the substrate previously pre-treated by an air or nitrogen plasma. The carrier gas and plasma gas flows, the distance between the substrate and the plasma torch, the scanning speed and the precursor flows were held constant during the study.

The gas used during activation pre-treatment shows no further influence on the characteristics of the deposit. When air is used both as plasma and carrier gas, the coating layer is thicker (96 nm) than when nitrogen is used (64 nm). It was also evidenced that the carrier gas precursor has little influence on the hydrophobicity of the coating, on the contrary of the plasma gas. The latter significantly influences the surface characteristics of the coatings. As it can be seen in the figure 1, the layer morphologies are completely different depending on the plasma gas used. Moreover,

the surface contact angles are different: 82° and 100° for the layers respectively obtained with air and nitrogen. This increase of hydrophobicity could be correlated to the increase of Si–O–C bonds in the upper surface layers evidenced by XPS analyzes. This observation was then confirmed by ToF-SIMS analyzes carried out on these thin layers. A uniform distribution of Carbons in the SiO_x coating could also be observed using ToF-SIMS 2D reconstruction images of cross sections of the deposited layers.

The Effects of Pressure and Boundary Layer on the Propagation of Plasma Jets

T11 Plasma Science and Technology

#PST-P2-01

M. Laroussi, M.A. Akman, S. Mohades.

Old Dominion University - Norfolk, Va (United states).

In this paper we report on the effects of ambient pressure and background gas on the formation and propagation of plasma jets. In the experiments reported in this paper a plasma jet is introduced into a Pyrex chamber where the pressure and gas mixture can be controlled. In this way the plasma plume/jet is launched inside the chamber [1]. The pressure in the chamber is regulated by controlling the gas flow and the rate of evacuation. We discovered that there are three operating phases: A first phase, the stagnant phase, where the plume length remains approximately constant. This is followed by a second phase where the jet inside the chamber rapidly increases in length (up to 28 cm) as the pressure decreases. Then at a pressure around 70 Torr an operational mode transition suddenly occurs where the plume length decreases dramatically. Further lowering the pressure in this third phase, to around 20 Torr, the plasma starts expanding in all directions starting from the point where the plume enters the chamber. At pressures below 2 Torr, the entire volume of the chamber gets filled with homogeneous plasma.

Our most recent studies indicate that the behavior of the plasma jet is not limited to the pressure alone but also to the presence of a physical boundary that confines the gas flow. It is observed that in a chamber filled with only helium, no plasma jet is created and therefore no bullet propagation occurs; however inside the connecting tube in which the helium is flown into the chamber, plasma bullet propagation is visible. This is attributed to the existence of the physical boundary of the wall of the tube. However, we find that this boundary does not need to be an object that surrounds the gas flow. This is evidenced by the introduction of a gas different than helium into the chamber. In this case, the diffuse plasma transitions into a jet as a result of the formation of a helium channel in which the plasma bullets propagate. Therefore, we conclude that in order for plasma bullets to propagate, there needs to be a boundary surrounding the gas channel. In addition to this visual observation, emission profile in VIS range also shows distinct transitions, specifically at 587.4nm.

In this paper, experimental evidence supporting the observations explained above will be presented.

Generation of Homogeneous Dielectric Barrier Discharge in Atmospheric Air without Preionization

T11 Plasma Science and Technology

#PST-P2-02

E. Shershunova, M. Malashin, S. Moshkunov, V. Khomich.

**Institute for Electrophysics and Electric Power RAS - Saint-Petersburg
(Russian federation).**

Physical properties of dielectric barrier discharge (DBD) and its simple realization make this discharge very attractive to many technological applications: from widely known purifying of gases and liquids to surface treatment, plasma medicine, plasma chemistry and aerodynamics. DBD can exhibit as a filament mode as a uniform one [1, 2]. In 1988 Okazaki and his colleagues realized the homogeneous atmospheric DBD in helium [3]. Later the uniform atmospheric DBD was generated also in other noble gases. But it is a difficult task to get the uniform DBD in air under atmospheric pressure. The nitrogen metastables are considered to play a dominant role in generating the uniform discharge in air, since they create seed electrons due to Penning ionization. However, the activity of the metastables is neutralized in gases, containing oxygen, because the oxygen molecules capture electrons due to their electronegative properties. Therefore, the typical method for generating the uniform DBD in air is use of preionization [4].

According to our experimental results the uniform DBD mode can be realized in atmospheric air without preionization, if the DBD is supplied by voltage pulses with nanosecond rise time.

The experimental setup is shown in figure 1. The discharge was initiated in the discharge gap (DG) between two plane-parallel electrodes in atmospheric air. One of the electrodes was insulated from air by 2 mm alumina ceramic plate. The gap length was fixed to 2 mm. Square unipolar pulses, generated by the solid-state high voltage pulse generator (HVPG) [5], were applied to the DG. The pulse repetition rate was constant during all experiments – 30 Hz. The voltage at the DG was measured by high voltage probe Tektronics P6015A. The discharge current was measured by low inductance resistance detector Rcs. The waveforms of the voltage at the DG and the discharge current were recorded by means of oscilloscope LeCroy WaveRunner 104Xi-A 1 GHz 10 GS/s. The photo registration of the glow in the DG was conducted

by use of photo camera Canon EOS 500D with EFS 18-200 mm objective under the following conditions: exposure time – 2 sec., aperture – 1/5.6, photosensitivity – 3200 ISO. We investigated the dependence of a DBD mode on a value of resistor R, which determined the voltage pulse rise time t.

As a result, we found that at voltage at the DG of 14 kV, the uniform DBD was initiated at pulse rise time of 40 ns and less ($R < 100 \text{ Ohm}$) (fig.2). At $t = 40 - 70 \text{ ns}$ ($100 \text{ Ohm} < R < 4000 \text{ Ohm}$) the uniform DBD turned into a mixed mode, a filamentary discharge with a volume glow around filaments. The filamentary discharge was initiated at pulse rise time of 70 ns and more.

We suppose that the uniformity of the DBD in atmospheric air is attributed to the growth rate of the electric field strength in the DG. The homogeneous volume DBD in atmospheric air exists at the growth rate of the electric field strength of 1.1 kV/cm·ns and more.

PST-P3-02

White Paper for Developing Fast Lithium Pellet Injection System Using High Pressure Gas for Disruption Mitigation on EAST

T11 Plasma Science and Technology

#PST-P3-02

H. Zhuang, X. Zhang.

Institute of plasma physics, Chinese academy of sciences, - Hefei.

In large tokamaks, disruptions of high current plasma would damage PFCs or other inner components due to high heat load, electromagnetic force load and runaway electrons. It would also have influence on the following plasma discharge due to impurities production during disruptions.[1] So the avoidance and mitigation of disruptions is essential for next generation tokamaks, such as ITER. Massive gas injection and pellet injection are two promising methods for disruption mitigation. Most of the tokamak devices in the world have had research on disruption mitigation by injection massive gas and pellet injection.[2,3] By injecting suitable amount of massive gas or pellet, the harmful effect of disruptions could be mitigated. In the first case(massive gas injection), the high heat load, electromagnetic force and runaway electrons all could be mitigated, but the injected particles could only get the boundary of the plasma due to ionized. In the second case(pellet injection), the injected pellet couldn't provide enough particles for RE(runaway electrons)mitigation, but the injected pellets could achieve the core of plasma.

In order to optimizing the methods of disruption mitigation, a new method has been proposed on EAST, and the new system is developing, which will be tested in the next round campaign of EAST. The system consist of two parts, the first part is a fast valve which was driven by eddy current[4], the work chamber was filled with high pressure noble gas, and the pressure in the fast valve could reach 50bar .The second part is the supply system of lithium pellet, the lithium is made into strip shape, the blade which was pushed by cylinder could cut the lithium strip into suitable length that needed which is controlled by a stepping motor After a trigger signal, the valve could be opened within 0.5ms, so the high pressure gas in the work chamber could spurt out, and the lithium pellet in the pipeline could be accelerated to a few hundred meters, so both the high pressure gas and lithium pellet could be injected into the

plasma, the injected gas could cooling the edge of plasma ,at the same time the lithium pellet could penetrate into the central area of plasma. So both the boundary and central area of the plasma temperature could be cooling down to a safety level at the same time, which is very important for disruption mitigation.

Lithium is a kind of promising coating material in tokamaks, so the injection of lithium pellet couldn't have bad influence on following discharge. The system will be tested in next round campaign of EAST in 2013. If the project was confirmed feasible, which will be a good news for ITER.

PST-P3-03

Investigation of the plasma density feedback control experiment by gas puff and SMBI on EAST

T11 Plasma Science and Technology

#PST-P3-03

X. Zheng, J. Li, J. Hu, J. Li, B. Cao, J. Wu.

8605515593616 - Hefei.

To achieve stable and desirable plasma density on EAST tokamak, plasma density feedback control was investigated by both of gas puffing and new developed Supersonic Molecular Beam Injection (SMBI) fueling system. And some meaningful results were obtained.

There are two modes using gas puffing for plasma density control. It was found that the pulse width modulation mode [1] seemed much better than voltage modulation mode for plasma density control. If using voltage modulation mode, the plasma density seems difficult to meet the set value due to this mode doesn't meet the fast change of plasma density. However, one disadvantage of gas puffing is its long delay of fueling, the others is that it would lead a high retention on walls, which makes density feedback control difficult.

In 2011, a new core fueling system- SMBI has been also successfully employed as a fast density feedback tool to maintain plasma density for steady-state operations, and it seems much better than gas puffing. SMBI produces a rapid travelling gas jet with a speed exceeding 1 km/s and pulse length ranging from 2 to 20 ms. This leads to a much shorter density response time (2-4 ms) than the conventional gas puffing (16 ms and 77 ms for LHS and HFS, respectively). And SMBI has a higher fueling efficiency of 15~30% with a lower fuel retention on walls [2]. Using SMBI for feedback control, the plasma density is agreed with the set value very well. It is been testified that SMBI is a more feasibility method than gas puffing for plasma density control, especially during performing the discharges with long pulse and high parameters on EAST in the near future.

This research was funded by National Magnetic confinement Fusion Science Program under Contract No.2010GB104002 and No.2013GB114004 and National Nature Science Foundation of China under Contract No.11075185 and No.11021565.

PST/SE/TF-P1-01

Effect of Heat Exposure Conditions on the APS-W Layer coated on Molybdenum Substrate

T11 Plasma Science and Technology

#PST/SE/TF-P1-01

G. Cho, K. Choe.

Korea Institute of Industrial Technology - Incheon (Korea, republic of).

Pure molybdenum(Mo) possesses a unique combination of physical properties including excellent high-temperature strength, high thermal conductivity, a high elastic modulus and a low thermal-expansion coefficient. Because of these outstanding properties and high melting point (2620°C), technically pure Mo sheet has been used in a wide range of applications, including hot-zone materials such as heating element, heat shield and crucible for high-temperature furnace construction [1]. But, the Mo alloy was vaporized in a vacuum atmosphere and chemically reacted with heating element in a high-temperature furnace. Also, hot-zone Mo alloy degraded on their high-temperature mechanical properties under prolonged exposure to thermal radiation due to the embrittlement of large recrystallized grains [2]. So, plasma sprayed tungsten(PS-W) coatings have been successfully fabricated and studied to protect metallic substrate. It was reported that tungsten seems a promising candidate material for plasma facing components in next fusion experimental devices due to its low sputtering yield and good thermal properties [3]. Vacuum plasma spraying (VPS) process is done in the controlled low pressure of inert gas, which reduces the interaction between plasma jet and oxidative environment. VPS process needs high cost equipment and operation maintenance cost, so a relatively inexpensive air plasma spraying(APS) process has been adopted for limited coating applications. In this work, an effort was made to investigate the influence of heat exposure conditions on the APS-W coating layer on Mo substrate. Thermal exposure experiment was carried out in three atmosphere conditions. After heat exposure, their microstructure and composition changes were characterized by field emission scanning electron microscopy, X-ray diffraction, energy dispersive spectrum. Mo strip of 160mm(L) x 8mm(W) was coated by the air plasma spraying technique. Tungsten coatings were successfully deposited by air plasma spraying technique on Mo substrate. Fig.1 shows the surface photographs of a tungsten thick(775um) coating on 1.0t Mo substrate. The APS-W coating layer was tightly bonded with Mo

substrate. Air plasma spraying W coating layer could be a good thermal radiation protection candidate material for the hot-zone parts application.

Preparation of silica and borosilicate permeation barriers by magnetron sputtering for Laser Megajoule gaseous targets

T11 Plasma Science and Technology

#PST-5-Or-1

P. Rodriguez, S. Le Tacon, C. Chicanne, V. Brunet.

CEA, Valduc - F-21120 Is-Sur-Tille (France).

In order to prepare first fusion experiments performed with the Laser Megajoule (LMJ), some will be realized on a gaseous deuterium – tritium (DT) mixture. The target consists in a doped CH_x microshell containing the gas mixture. Glow discharge polymerization (GDP) is an appropriate technique to produce doped CH_x microshells compatible with LMJ specifications. The capsule has then to be filled with DT mixture of several megapascal and hold for several days at ambient temperature in order to allow laser experiments. However, plasma polymer is highly permeable to light gases in general and DT mixture in particular. We therefore studied the possibility to include a thin film coating as semi-permeable barrier. This functional layer is made of amorphous silica or borosilicate and is obtained by magnetron sputtering onto CH_x microshell. The permeation layer is then buried under a final CH_x layer. A schematic representation of the gaseous target is shown on figure 1.

One of the originality of the present work is the use of magnetron sputtering in order to obtain functional thin layers not on flat substrates but on CH_x capsules with a mean diameter less than 2 mm. We studied the influence of the permeation barrier nature (borosilicate or silica) and the deposition parameters (i.e. pressure, RF power...) on the permeation properties of the targets. These latter are studied by mass spectrometry using deuterium (D_2) as filling gas. The optima thin film coatings exhibit permeable properties at high temperature (e.g. 200 °C) which are useful for the filling step and quasi-blocking properties at ambient temperature with a D_2 permeation coefficients as low as $1 \cdot 10^{-20} \text{ mol} \cdot \text{m}^{-1} \cdot \text{s}^{-1} \cdot \text{Pa}^{-1}$ for silica layers (amorphous silica theoretical limit) and few $10^{-21} \text{ mol} \cdot \text{m}^{-1} \cdot \text{s}^{-1} \cdot \text{Pa}^{-1}$ for borosilicate layers. As function of the permeation barrier thickness and the number of barrier layers

incorporated, pressurized targets over 3 MPa with half-life of several weeks are obtained.

Figure 1: Schematic representation of the future LMJ gaseous target.

Carbon facing plasma in fusion devices: erosion study under argon/hydrogen radiofrequency plasma treatment

T11 Plasma Science and Technology

#PST-5-Or-2

X. Glad, L. De Poucques, J.L. Vasseur, M. Belmahi, R. Hugon, J. Bougdira.

Université de Lorraine, Institut Jean Lamour, CNRS UMR7198 - Vandoeuvre-Lès-Nancy, F-54506 (France).

The new stellarator Wendelstein 7-X, currently under construction in Greifswald, Germany, will include a 10-unit divertor. The plasma-facing material (PFM) selected for this component is grain graphite for the test divertor which, after two-years of operation, will be replaced by a carbon-fiber composite (CFC) high-heat flux divertor^{1,2}. These compounds exhibit interesting properties as fusion devices PFMs such as an excellent thermal shock resistance and absence of melting compared to metals. However, carbon raises the critical issue of erosion. This phenomenon generates porous dust polluting the fusion reaction and retaining radioactive elements, leading to efficiency loss and safety concerns. A better understanding of the different erosion processes is thus an essential issue to solve in order to improve the quality of the carbon components. The study presented here focuses on the erosion of flexible graphite, highly ordered pyrolytic graphite (HOPG) and CFC tile samples undergoing plasma treatment under different conditions. The influence of pressure, gas mixture, radiofrequency coupling modes and plasma exposure duration has been investigated in order to characterize etching and re-deposition growth kinetics.

All experiments were conducted in a standard two-chamber helicon reactor³ allowing four different coupling modes and conditions close to a fusion device scrape-off layer plasma, i.e. electron density and temperature around 10^{11} cm^{-3} and below 5 eV, respectively⁴. Hydrogen/argon discharges are initiated by a new 13.56 MHz RF 2 kW power supply coupled to a Boswell-type antenna surrounding the source chamber. Two sets of copper coils generating a static magnetic field up to 200 G allow the

transition from inductive to wave coupling modes.

Several diagnostics were carried out for the characterization of both the plasma and the carbon samples. Langmuir probe, optical emission spectroscopy and two-photon absorption laser-induced fluorescence were used to evaluate electron and H relative densities. We observed the erosion outcomes with mass loss measurements, Raman spectroscopy, and scanning and transmission electron microscopies in order to estimate the erosion rate and compare structure modifications.

The highest erosion rate obtained is 6 $\mu\text{m/h}$ at a pressure of 10 mTorr in a pure hydrogen inductive discharge. The facts that increasing the pressure limits the plasma transport and that the substrate-holder is at floating potential explain these results. Furthermore, the erosion rate does not seem to be affected by the plasma exposure duration, unlike the re-deposited structures size and porosity, which increase with the latter. Also, the non-increasing re-deposited structure density shows that radicals resulting from the etching tend to be deposited on the already present structures. In fusion devices, such porous structures would allow significant tritium retention. Finally, pure argon discharges, i.e. physical etching, reveal interesting highly-ordered graphite structures that deteriorate with the addition of hydrogen in the gas mixture.

PST-P2-17b

Characterization of discharge in heptane by optical emission spectroscopy

T11 Plasma Science and Technology

#PST-P2-17b

A. Hamdan, C. Noël, G. Henrion, T. Belmonte.

Institut Jean Lamour - Nancy (France).

Electro-discharge machining, treatment of biomaterials, nanoparticles synthesis, plasma electrolytic oxidation, gases production, etc. are some applications of discharges in liquids. Indeed, because of its short lifetime (several hundreds of nanoseconds) and small dimensions (several micrometers), the plasma cannot be characterized easily by conventional techniques. However, radiations emitted during the discharge are very intense. In the present work, nanosecond time-resolved Optical Emission Spectroscopy (OES) is used to characterize the plasma (temperatures, species, densities ...) during its expansion and decay phases. A positive high voltage (+15 kV) is applied to a Pt pin-electrode (anode) located 100 μm above an aluminum plate electrode (cathode), the two electrodes being immersed in heptane ($n\text{-C}_7\text{H}_{16}$). Using a Jobin-Yvon TRIAX 550-spectrometer (gratings: 100, 1200 and 1800 grooves mm^{-1}) coupled with an ICCD detector, spectra averaged from 50 to 1000 discharges are acquired in the range [200-1000] nm. Because of the random nature of discharges in time, we have used a nanosecond-switch with a voltage rise-time of 130 V/ns. Therefore, it is possible to breakdown the plasma with a time-resolution of 50 ns. This time-step is used for this study. Although each discharge event is not perfectly reproducible, the reproducibility of the measurements is very satisfying. Using a grating with 100 grooves mm^{-1} , global spectra are acquired. Black-body emission is observed with a maximum centered at ~ 400 nm. By fitting the spectrum with a black-body behaviour, one can estimate the temperature of the plasma and its time evolution from 0 to $t=1000$ ns with a step of 50 ns. An important emission of Balmer-lines (especially H-alpha, 656.3 nm) is observed. Using the temperature values determined before, we can fit rigorously the H-alpha line (Doppler, van der Waals and Stark broadnings) and then, determine the electronic density and gas temperature.

Gratings with 1200 and 1800 grooves mm^{-1} are used to identify the atomic lines and

rovibronic bands of molecules presents during discharge. Atomic lines start to appear when the intensity of the black-body emission decreases. Auto-absorption is also observed in several lines of Pt atoms. Swan-band of the C₂ molecule is also observed after the decrease in the black-body emission. By modeling the spectra of C₂, we can determine a characteristic temperature and its time evolution. This information is directly related to the synthesis of carbon nanoparticles during the discharge, what opens new perspectives in their control.

PST-1-Or-5

Determination of N, O and N₂(A) metastable density in the afterglows of N₂ and N₂-O₂ RF discharges

T11 Plasma Science and Technology

#PST-1-Or-5

A. Ricard ¹, S.G. Oh ².

¹laplace - Toulouse (France), ²Ajou Univ - Suwon (Korea, republic of).

Afterglows of N₂ and N₂ – O₂ flowing RF discharges are characterized by emission spectroscopy. The N and O atoms and the N₂(A) metastable molecule densities are determined after NO titration for N and measurements of NO and N₂ band intensities for O and N₂(A) .

The experimental setup showing only the early afterglow, between 32 and 45 cm from the discharge at z=0, is reproduced in Fig.1. The late afterglow appeared after 45 cm. The early and late afterglows have been analysed at z = 37 cm (maximum of the early afterglow) and at z= 55 cm in a dominant late afterglow . At these 2 positions , it has been determined by the method of ref.1 a contribution of the N+N recombination of 10% in the early which is mainly a pink afterglow and 70 % in the late afterglow(still 30% of pink).

The N-atom density is determined by NO titration which allows to calibrate the N₂(580 nm)intensity .

The O-atom density is obtained by comparing the NO(320 nm) intensity resulting from the N+O recombination to the N₂(580 nm) intensity.

The N₂(A) density is deduced from the N₂(316 nm) intensity which mainly comes from the N₂(A)+N₂(A) pooling reaction , also compared to the N₂(580 nm) intensity .

By introducing O₂ into N₂, at 8 Torr , 1 Slm , 100 W, it is found as shown in Fig.2 less N and O atoms in the early (pink) than in the late afterglow with a density slowly decreasing for the N-atoms and inversely increasing for the O-atoms with O₂ into N₂. The N₂(A) density is higher in the pink afterglow at less than 0.1%O₂ and become important in the late only at more than 0.5 %O₂.

Small quantities of O₂(10⁻⁴ – 10⁻²) are introduced before the N₂ discharge.Ar-1.5 % NO is introduced before the early afterglow.

Fig.2 – Density of N ,O-atoms and N₂(A) metastable molecules versus O₂ percent into the early and late afterglows of N₂ at 8 Torr , 1 Slm , 100 W.

PST-P2-03

Combined gas temperature study in continuous and pulsed He ICP discharges

T11 Plasma Science and Technology

#PST-P2-03

N. Britun ¹, N. Kang ², S.G. Oh ², R. Snyders ³.

¹Chimie des Interactions Plasma Surface, Univ. de Mons - Mons (Belgium),

²Division of Energy Systems Research, Ajou University - Suwon (Korea,

republic of), ³Chimie des Interactions Plasma Surface, Univ. de Mons, Materia Nova Research Center - Mons (Belgium).

Recent results on continuous and time-resolved gas temperature (T_g) diagnostics in He inductively coupled plasma (ICP) discharges are presented. The ICP discharges working at 13.56 MHz in continuous and pulsed mode ignited by a spiral coil in a vacuum chamber have been operating at 100 mTorr of working pressure (with repetition frequency 0.5 and 1 kHz, 50% of duty ratio in the pulsed case). The applied power (P_{RF}) is ranged within 50-400W (continuous) and was about 250W/pulse (pulsed). Fabry-Perot interferometry (FPI), rotational emission spectra analysis, as well as thermocouple measurements are utilized for T_g determination.

The Doppler broadening of one of the component of He 587.56 nm emission line is used for T_g study by FPI. The developed and built interferometer with a typical finesse of ~ 30 and resolution of ~ 1 pm is utilized for this purpose. The FPI results show that, in the continuous mode T_g grows linearly with P_{RF} remaining in our case in the range of 300-600 K. In the pulsed mode at $P_{RF} = 240$ W/pulse T_g increases during ~ 150 μ s at the beginning of pulse and later saturates at ~ 470 K level (see Fig. 1).

The obtained FPI results are verified by the time-averaged measurements of N_2^+ rotational temperature (T_{rot}) using the First Negative System of N_2^+ [1]. T_{rot} is determined by the Boltzmann plots drawn for corresponding rotational population in the $N_2^+(B)$ state. A good agreement between the T_{rot} of N_2^+ and the FPI data is obtained within the error of measurements ($\pm \sim 40$ K) in the continuous mode. In the pulsed mode T_{rot} data represents T_g values after saturation in the plasma pulse owing to the fact that the contribution to the rotational spectra coming from the beginning of the plasma pulse is negligible due to the low emission intensity (Fig. 1). The total T_g elevation during the pulse under our conditions is found to be equal to ~ 150 K.

The time-averaged temperature values measured by a thermocouple attached to a Cu plate located in plasma bulk correlate well with both FPI and T_{rot} results, showing the high level of thermal equilibrium in this type of discharges in the considered pressure range.

The obtained results establish the usability of high-resolution Fabry-Perot spectral analysis for ICP discharges, and can be applied for characterization of the actual ICP plasma processes involving He, as well as the other gases/mixtures, especially where addition of the molecular species for rotational spectral analysis is limited.

Keywords: ICP discharge, Fabry-Perot interferometry, helium, gas temperature

Capacitively coupled rf discharges in N₂-H₂ at low-pressure

T11 Plasma Science and Technology

#PST-P2-04

L. Alves ¹, L. Marques ², A. Mahjoub ³, C. Pintassilgo ⁴, A. Gouveia ⁴, N. Carrasco ³, G. Cernogora ³.

¹Instituto de Plasmas e Fusão Nuclear, Instituto Superior Técnico - Lisbon (Portugal), ²Instituto de Plasmas e Fusão Nuclear, Instituto Superior Técnico and Centro de Física da Universidade do Minho, Universidade do Minho - Braga (Portugal), ³Université Versailles St-Quentin, CNRS, LATMOS - Guyancourt (France), ⁴Instituto de Plasmas e Fusão Nuclear, Instituto Superior Técnico and Departamento Engenharia Física, Faculdade Engenharia, Universidade do Porto - Porto (Portugal).

Capacitively coupled radio-frequency (ccrf) discharges can be used in planetary studies to simulate, in laboratory environment, the reactivity of ionospheres. The present work is part of a research strategy, involving both simulations and experiment, to analyse the N₂-CH₄ ionospheric chemistry of Titan, the biggest satellite of Saturn. The first step was the study of ccrf discharges in pure N₂ [1], which now pursues with the analysis of N₂-H₂ discharges, considering that the original atmosphere contains hydrogen resulting from the dissociation of methane. N₂-H₂ ccrf discharges are also used for the etching of low-k organic materials and to enhance the plasma-assisted nitriding process.

Simulations use a hybrid code that couples a 2D (r, z) time-dependent fluid-type module, describing the transport of the charged particles, to a very complete 0D kinetic module, for the nitrogen-hydrogen mixture. The fluid module solves the charged-particle continuity and momentum transfer equations, the electron mean energy transport equations, and Poisson's equation for the rf electric potential. The kinetic module solves the two-term homogeneous and stationary electron Boltzmann equation (accounting for inelastic collisions from ground-state molecules and atoms, and inelastic and superelastic collisions involving vibrationally excited states) and the rate balance equations of the ground-state vibrational excited states and the main electronic excited states with the N₂ and H₂ molecules, the most relevant electronic excited states with the N and H atoms, and the most relevant N_xH_y radicals resulting

from interactions between the two excited systems [2,3]. The space-time map of the electron transport and rate coefficients is obtained from the electron mean energy profile using the local mean energy approximation.

The experimental setup is described in detail in [4]. A system of parallel-plate electrodes (driven at 13.56 MHz frequency) is surrounded by a cylindrical metallic grid, which confines the discharge. The resulting closed reactor acts as a resonant cavity in the microwave range, used to measure the electron density. Optical emission spectroscopy diagnostics are used to study the evolution, with the work conditions, of the First Negative System with N_2^+ . The effective rf power coupled to the plasma is determined using the subtractive method [1], hence accounting for the circuitry power losses.

The study analyse the modifications induced in pure N_2 ccrf discharges, running at low-pressure (0.5–1.5 mbar) and low-power (5–20 W, corresponding to 110-220 V applied voltages), by the addition of small amounts of H_2 (up to 5%). The discussion is particularly focused on the evolution of the electron density and the population of N_2^+ .

Non-invasive Process Diagnostics of Nanoparticle synthesis in an inductively coupled plasma reactor.

T11 Plasma Science and Technology

#PST-4-Or-6

C. Delval, M. Leparoux.

Empa, Laboratory for Advanced Materials Processing, Feuerwerkerstrasse 39, CH-3602 Thun, Switzerland - Thun (Switzerland).

In the last decades, nanoparticles synthesis using thermal plasma technology has been widely spread [1]. High flexibility of the precursor phase (gas, liquid, solid), high enthalpy of thermal plasmas, and ability to control the chemistry of plasmas (flexible gas mixture), allow the production of almost all materials including those with a high melting point [2] at high production rates (kg/h). In the process, precursors are vaporized in the thermal plasma leading to a supersaturated gaseous phase with nanoparticles subsequently forming upon cooling. Fine-tuning of targeted stoichiometry is achieved by injecting additional reactive gases. Among thermal plasmas, Inductively Coupled Plasma (ICP) processing is a powerful technique to produce nanopowders of oxides, metals and hard ceramics such as TiCN or SiC [3]. ICP is a technique of choice to produce nanoparticles with well-defined properties thanks to a longer residence time of the precursor (axial injection), a rapid condensation of the supersaturated gas phase (quenching) and the absence of contamination generated by the electrodes. In the Laboratory for Advanced Materials Processing of Empa (Thun – CH), the expertise has been focused on the understanding and the precise control of the whole synthesis process which is the key to the development of advanced nanoparticles with tailored and reproducible properties. In thermal plasma, to obtain high quality nanoparticles with high production yield, the complexity of the subsequent steps of the synthesis implies a systematic study of the influence of the processing conditions and parameters, and a thorough understanding of the interaction plasma-particle. At Empa Thun, a RF-ICP setup, based on a Tekna PL-35 torch linked to a 13.56 Mhz generator ($P_{max}=35$ kW), has been dedicated to the investigation of plasma

synthesis and in-flight functionalization of nanoparticles [4] since years. The reactor is equipped with many viewports enabling the observation and characterization of the overall process including plasma properties, gas phase characterization and plasma/particles interactions. Enthalpy probe measurements have been performed to characterize the plasma properties depending on the process parameters. The synthesis chamber is equipped with non-invasive optical diagnostics (FTIR, light extinction spectroscopy, Optical Emission Spectroscopy) to gain insight into the plasma-particles interactions. High speed imaging is assessed to observe the instabilities of the plasma tail and follow the trajectories of the inlet micron-sized precursor particles. Based on case studies, we will present here the state of the art of the plasma characterization of synthesis of nanoparticles at Empa.

Poly(lactic acid) (PLA), derived from renewable resources, is a (bio)degradable polymer accepted as a good alternative to conventional polymers for packaging applications. Nevertheless, as for other polymers, it presents too high water and gas permittivity. In order to improve its barrier properties and, as a consequence, its degradation rate, we are developing a cross-linked ethyl lactate-based plasma polymer film (ELPPF). The control of both chemical composition (hydrolysable ester bonds density) and cross-linking degree would allow tuning the degradation rate of the polymer by ester bond hydrolysis.

In this work, our objective is to correlate the plasma and film chemistries and, ultimately, to propose a clear picture of the plasma-surface interaction during the process.

ELPPF have been synthesized by PECVD using both continuous and pulsed RF power (PRF) through an ICP copper coil ($5 \text{ W} < \text{PRF} < 400 \text{ W}$). The ELPPF chemistry, especially the ester function density, has been evaluated by the combination of chemical derivatization and XPS measurements and compared to the plasma phase composition measured by using RGA mass spectrometry and in situ infrared spectroscopy. These plasma diagnostic data are discussed in view of DFT calculations.

Our data reveal that, in the defined experimental window, by increasing PRF, the

ester content in the ELPPF increases from 1.4 at.% to 18 at.% which is perfectly correlated to the in situ FTIR spectroscopy data revealing the loss of the degradation of the ester function in the gas phase with a similar rate. On the other hand, the mass spectrometry data supported by DFT calculations allow proposing a clear fragmentation pattern of the precursor as a function of the experimental conditions. Altogether, this set of data paves the way for a reproducible and controllable synthesis of ELPPF with defined chemical composition.

Surface Temperature Measurement using Fraunhofer Diffraction via Photoacoustic Waves for Laser Irradiation Process

T11 Plasma Science and Technology

#PST-P2-05

F. Mitsugi ¹, T. Ikegami ¹, T. Nakamiya ², Y. Sonoda ².

¹Kumamoto University - Kumamoto (Japan), ²Tokai University - Kumamoto (Japan).

Pulsed laser irradiation is used for treatment of a solid surface and ablation to fabricate nanoparticles or anneal thin films. When a pulsed laser irradiates a solid surface, photoacoustic waves are caused. For solids, photoacoustic wave generation involves photothermal expansion via thermoelastic expansion, as well as shockwaves induced by ablation plasma. Detection of indirect photoacoustic waves is important because it enables us to obtain maximum surface temperature indirectly. In this research, we introduced an optical wave microphone for detection of indirect photoacoustic waves and shockwaves. The optical wave microphone works based on Fraunhofer diffraction. We reported on waveforms and frequency analysis of photoacoustic waves from Si in air for surface temperature measurement.

Fig.1 shows experimental setup of an optical wave microphone to detect photoacoustic waves. The working region of the microphone is between the diode laser and the lens1. A Si wafer is set within the working region and irradiated by a pulse of YAG laser. The laser energy was varied from 46 to 460 mJ/cm². Photoacoustic waves were detected by optical wave microphone even though the energy was as low as 46 mJ/cm². It was laser induced ultrasonic waves from Si. The frequency of the obtained waveforms ranged from about 100 to 200 kHz that depended on the detector position. Fig.2 shows intensity and velocity of the obtained signals for pulsed laser irradiation of Si as a function of the energy density of the pulsed laser. The intensity and the velocity increased gradually with the laser energy density when it was less than ablation threshold energy. It showed good agreement with surface temperature calculation of Si. The intensity showed drastic increase and

the velocity obviously exceeded sound speed in air due to the influence of the generation of shockwave when the laser energy density increased and ablation occurred.

Surface patterning of an austenitic stainless steel by different low-temperature thermochemical plasma-assisted treatments

T11 Plasma Science and Technology

#PST/SE/TF-3-Or-12

A. Andrieux, G. Marcos, H. Michel, T. Czerwiec.

Institut Jean Lamour - Nancy (France).

Low-temperature thermochemical plasma-assisted treatments are commonly used on austenitic stainless steel to enhance surface properties by forming an enriched surface layer.

During a nitriding treatment a large amount of nitrogen is introduced in the austenite lattice, inducing high compressive residual stresses. As a result, an expansion of the treated layer from the initial position of the substrate in a direction perpendicular to the surface occurs.

We take advantage of this phenomenon, called uplift, to create a pattern on the surface. The idea is to protect locally the surface by covering it with an appropriate masking technique. By doing so, only the uncovered parts will be exposed to the incident plasma. After nitriding the surface presents a controlled topography, due to the difference of height induced by the spatially restricted uplift. We will show that this uplift phenomenon also happens during carburising treatments, with amplitude comparable to that of nitriding.

It is known [1] that a surface pattern enhanced tribological properties in loaded lubricated contact systems by providing a hydrodynamic pressure that helps separating the mating surfaces. Geometry (holes, grooves, dots, etc) and dimensions (from 1 to several hundred micrometres) strongly depend on the working conditions and the configuration of the contact system. The aim of our study is to develop a patterning process of AISI 316L based on thermochemical treatments. Their parameters will be chosen to insure good surface properties (corrosion and tribological behaviour) while achieving the required patterning.

We use a multi-dipolar plasma, based on the Distributed Electron Cyclotron

Resonance concept, to perform thermochemical treatments on austenitic stainless steel samples recovered by different types of masks: copper TEM grids, especially designed nickel stencils and boron-based layers. We will highlight here the difficulties encountered to achieve an efficient masking.

We conduct SEM, XRD and GD-OES analyses to determine surface layer characteristics and tactile profilometry to measure pattern dimensions. The internal compressive stresses were estimated using the basic elastic model described in ref [2].

We will present results concerning pure nitriding and carburising, nitrocarburising and sequential treatments in different conditions. We investigate their influence on the uplift and on the surface layer depth and concentration in nitrogen and/or carbon.

Effects of transverse magnetic field on cathode spot movement in arc ion plating

T11 Plasma Science and Technology

#PST/SE/TF-P1-12

J. Xiao ¹, Y. Zhao ¹, W. Lang ², J. Gong ¹, C. Sun ¹.

**¹Institute of Metal Research Chinese Academy of Sciences - Shenyang (China),
²Wenzhou Vocational & Technical College - Wenzhou (China).**

Macroparticles (MPs) pollutions severally deteriorate the qualities and mechanical properties of the deposited films by arc ion plating. In order to eliminate them, a transverse magnetic field was provided on the basis of increasing the movement rate of arc. The obtained results showed that with the increase of the rotating transverse magnetic field strength in the low-frequency conditions, the arc spot morphology gradually transformed from the congregation of bright blotches into a straight long thin line. And the greater is the magnetic field strength, the longer and finer the arc spot trajectory line is.

Arc spot trajectory line being long describes the proportional acceleration of the speed of movement of the arc spot; arc spot trajectory line being longer and thinner implied that the arc spot trajectory plaques along a certain direction of the linear movement as a result of ampere force. According to action of the ampere force, the inverse of the arc spot in a transverse magnetic field moved "backwards", in which it possibly verified that the rotating magnetic field means is generated in the target surface with a kind of uniform transverse magnetic field. The MPs on the surface of TiN films were significantly reduced, and the reason lied in the increasing linear movement speed and the shorter residence time in one point at the surface of target.

Titanium dioxide films (TiO₂) are attractive for a large range of applications including photocatalysis, high-k materials, optical coatings and waveguides. While most studies deal with TiO₂ films deposited by dip coating or magnetron sputtering, much less studies have been devoted to TiO₂ films prepared by plasma enhanced chemical vapor deposition (PECVD) in O₂/TTIP (titanium tetraisopropoxide) plasmas. Low pressure high density plasmas, such as microwave electron cyclotron resonance plasmas [1] and inductively coupled RF plasma (ICP) [2] have been shown to allow deposition of amorphous or partially crystallized (anatase and/or rutile phases) films at temperature less than 100°C. Nevertheless, plasma deposited TiO₂ films are columnar, which is detrimental for optical and electrical (high-k material) applications. One way to get free from the columnar structure and obtain an homogeneous film is to add silicon in the TiO₂ film, using O₂/TTIP/HMDSO (hexamethyldisiloxane) plasmas in the case of PECVD.

Here, we investigate RF ICP O₂/TTIP/HMDSO plasmas operated at 4 mTorr , 400 W. The pulsed O₂/TTIP/HMDSO plasmas were analysed by time resolved optical emission spectroscopy (TROES). In order to probe the post-discharge, a second pulse was applied to monitor the active species decay in the post-discharge using the method proposed by Bouchoule et al [3] and previously developed in pulsed O₂/HMDSO plasmas [4].

The TROES measurements carried out in pulsed discharges created in oxygen-rich O₂/TTIP and O₂/HMDSO plasmas allow to determine the recombination probabilities of O and H on SiO₂ and TiO₂ walls, respectively. Therefore, the plasma on time was

varied from 10 to 50 ms at a frequency of 5 Hz. O, H, OH species creation (in the discharge) and loss (in the post-discharge) kinetics were investigated. The time variations of the intensities (I) of the Ar (750.4 nm), O (844.6 nm), H α (656 nm) lines and OH emission at 310 nm were recorded. The recombination probabilities of O and H derived from the exponential variations of IO/I_{Ar} and IH/I_{Ar} (using the method detailed in [4]) during the discharge in O₂/HMDSO and O₂/TTIP pulsed plasmas are given hereafter. O and H recombination is shown to be much faster on TiO₂ than on SiO₂ walls.

	O ₂ /HMDSO plasmas (SiO ₂ walls)	O ₂ /TTIP plasmas (TiO ₂ walls)
O atoms	$\gamma_{\text{O}} = 0.03 \pm 0.01$	$\gamma_{\text{O}} = 0.3 \pm 0.1$
H atoms	$\gamma_{\text{H}} = 0.001 \pm 0.0005$	$\gamma_{\text{H}} = 0.014 \pm 0.005$.

Here we will more particularly investigate the decay of O and H density in the post-discharge of O₂/HMDSO and O₂/TTIP pulsed plasmas and compare with the creation kinetics in the discharge period. Then we will investigate the evolution of O, H and OH creation and decay kinetics in O₂/HMDSO/TTIP pulsed plasmas. At last, TROES measurements will be carried out in water vapour and CO₂ plasmas in order to study the effect of H₂O and CO₂ (CO) adsorption on O recombination on TiO₂ based walls.

Samples of lithium, tungsten and stainless steel were exposed to dc Glow Discharges of He, Ar and H₂. Anomalous I-V characteristics for negative biasing (with respect to plasma potential) have been observed in all cases but at different level depending on the kind of surface and the plasma parameters¹. The parameters for which the anomalous effect was maximized correspond to those allowing for the production and propagation of a high-energy tail in the Electron Energy Distribution Function (EEDF). From the I-V characteristics of the exposed samples, the Secondary Electron Emission (SEE) yield vs. the mean energy of the suprathermal electrons for each value of the applied voltage was calculated for Li, SS and W surfaces. While values in good agreement with previous, plasma-free, reports were deduced for W and SS, the SEE yield for lithium is 2.5 times higher than expected. Although the absolute value of the SEE changed with plasma characteristics (gas, pressure, current, voltage), the deduced yield remained the same for a given element. Experiments to address

the effect of oxygen addition to the lithium surfaces were carried as well in the same set up. A clear decrease of both, Sputtering Yield and SEE Yield of lithium with higher oxygen content was observed, thus precluding a simple surface contamination effect as the driving agent. A possible synergetic effect of the target ion bombardment and the SEE for charge-emitting elements, such as lithium, is suggested.

Numerical Simulation of Magnetized Electrostatic Sheath in Presence of Dust Size Distribution

T11 Plasma Science and Technology

#PST-P2-15

S. Chekour, A. Tahraoui, B. Zaham.

Laboratoire d'Electronique Quantique, Faculté de Physique, Université USTHB - Algiers (Algeria).

The sheath formed between plasma and a material boundary has received a lot of attention. The major impetus behind this effort has been an increasing awareness of the importance of the edge plasma in the overall confinement properties of magnetically confined fusion plasmas. Since the sheath represents the outer most layer of the edge plasma, and hence plays an important role in the particle and energy flux to the wall, it is natural that it should attract so much interest. In this work, we have established a three dimensional and stationary theoretical model in presence of oblique magnetic field assuming more realistic plasma where the dust grains are considered with different sizes. For this we have considered a Gaussian law [1]. The positive ions and dust particles are considered as cold fluids. The electron is considered in thermodynamic equilibrium; therefore they obey to Boltzmann's statistic. To describe the dust charge, we have used the orbit motion limited model (OML) [2].

The numerical results show that the presence of magnetic field reduces the sheath thickness but the behavior of the electrostatic potential and the dust grains density is not affected. In addition, the variation the lower value of dust radius has no effect on the sheath structure. However, the increase of the higher value of the dust radius makes the structure of the grain density steeper. The effects of the other parameters are also discussed.

Nano-porous plasma polymers with stable vertical chemical gradients

T11 Plasma Science and Technology

#PST-P2-18

N. Blanchard, B. Hanselmann, D. Hegemann.

Empa - St.gallen (Switzerland).

Using plasma polymerization, we deposit thin nano-porous films exhibiting a vertical chemical gradient. It has been shown that by varying the gas ratio of polymerizable to non-polymerizable gases during the plasma process a broad range of wetting properties can be achieved [1,2]. We are using this result to generate the vertical gradient structure within the coatings. In addition, to ensure that the plasma polymer coatings simultaneously exhibit a certain porosity and a high stability, a precise control of the plasma polymerization processes by variation of the energy input during film growth (ion bombardment) and into the gas phase (determining the chemical processes in the plasma) is established via the control of plasma polymerization conditions such as gas ratio, flow rate, pressure and power input. The functional group content within the nano-porous layer can thus be varied by modifying these plasma polymerization conditions. We generate both, hydrophilic-to-hydrophobic (using HMDSO/O₂) and also hydrophobic-to-hydrophilic (using C₂H₄/CO₂ or C₂H₄/NH₃) gradients and show the stability of these coatings as well as the delayed wetting of the “hidden” layer. The intrinsic vertical gradient will allow adsorbing molecules to “sense” both, hydrophilic and hydrophobic components of the layer provided that the gradient structure is of the same size as the adsorbates, which exhibit typical dimensions of a few nanometers. This requires that the deposition rate of the respective plasma polymer coatings is rather low to ensure controllable and reproducible processes. It is expected that amphiphile (bio-) molecules will adsorb in a preferred and oriented way to these gradient layers and that new adsorption/desorption kinetics will arise, which are subject of further studies.

PST/SE/TF-P1-02

Investigation of a triode sputter source used for the deposition of the inside wall of narrow hollow cylinders

T11 Plasma Science and Technology

#PST/SE/TF-P1-02

J. Laimer ¹, E. Ruppert ¹, H. Störi ¹, W. Gärtner ².

¹TU Wien - Wien (Austria), ²Miba Gleitlager GmbH - Laakirchen (Austria).

Nowadays, it is common practice to deposit coatings by magnetron sputtering with sufficiently high deposition rate. Even inner walls of hollow cylinders may be coated by this technique. However, due to the space required for magnets in the interior of the cylindrical sputter source there is a limit in down sizing the diameter of the source and hence a limit in the minimal diameter of hollow cylinders to be coated.

Triode sputter deposition, which is known since a long time, does not need the incorporation of magnets as the required higher electron density may be achieved by a hot filament supported auxiliary discharge. By omitting magnets from the interior of cylindrical sputter targets the diameter of the targets can be much smaller and hence the deposition of inner walls of narrower hollow cylinders should be possible.

We present a hot filament supported triode sputter system, optimised for high rate deposition inside narrow spaces. In the present study the sputter target made of CuSn₈ had a diameter of 15 mm, whereas the steel sleeve to be coated had an inner diameter of 30 mm in order to prove the principle. This diameters are not the limit of the process, as both diameters could be easily further decreased.

A detailed electrical characterization of the discharge showed a high flexibility and stability of the operation point of the discharge. At filament powers of up to 2600 W and voltages of the auxiliary discharge of up to 65 V discharge currents of up to 20 A were measured. In the present geometry sputter currents of up to 0.75 A for applied sputter voltages of 1000 V were observed leading to deposition rates of up to 1.4 $\mu\text{m}/\text{min}$. The film thickness along the coated sleeve was uniform.

PST-4-Or-7

Deposition of GeTe phase change material by plasma enhanced MOCVD

T11 Plasma Science and Technology

#PST-4-Or-7

M. Aoukar ¹, C. Vallée ¹, A. Pikon ¹, D. Jourde ², P. Michallon ², P. Noe ², S. Maitrejean ².

¹Laboratoire des technologies de la microélectronique (LTM) - CNRS/UJF - Grenoble (France), ²CEA, LETI - Grenoble (France).

The Phase-Change Memory technology is widely recognized as one of the most promising next generation nonvolatile memory solutions, since it offers better scalability, endurance and programming speed compared to standard Flash memories^[1]. However this technology presents two major drawbacks: an archival life for high operating temperatures too short and power consumption too high. The binary compound GeTe seems to be a promising candidate; it shows better retention characteristics at high temperature compared to other chalcogenide alloys. Otherwise, it has been demonstrated that energies can be highly decreased by confinement of the material. To achieve the gap filling of the confined structure, conventional sputtering process cannot be used. Hence, more conformal processes as Chemical Vapour Deposition (CVD) or Atomic Layer Deposition (ALD) are required.

Considering the low deposition rate of ALD, we proposed to study the deposition of GeTe in a shower-head type 200 mm plasma-enhanced pulsed liquid injection CVD reactor. Ge and Te liquid precursors are introduced into the deposition chamber as vapours through a pulsed injection system and an evaporating furnace. Capacitively-coupled RF plasma is applied between the shower head and the substrate heater. The role of the plasma in the process is multiple: optimisation of the substrate before deposition, participation to the precursor decomposition, control of carbon concentration. Moreover, thanks to the plasma assistance, homogeneous deposition of the GeTe material on its amorphous phase is obtained^[2].

In this work we investigate the influence of many plasma parameters such as the injection frequency of the precursors, RF power, pressure and gas rate on the

decomposition of precursors. Precursor decomposition mechanisms are discussed by analysing optical emission spectra of the plasma. Optical Emission Spectroscopy shows that during deposition, peaks with a frequency equal to the injection frequency can be observed for Te, CN, H and Ar species. As shown in figure 1, the emission of CN* (relative to the decomposition of Ge precursor) and Te* are in antiphase although the synchronised injection of precursors and shows thus a different behaviour of the two precursors in the plasma. Fluctuations of the emission intensities are also observed and are correlated to the in situ XPS depth profiling of the deposited material. The etching capacity of the argon-hydrogen plasma and its influence on the conformity of the films is also discussed.

Duplex layer structures produced by low temperature Nitrocarburizing and sequential Nitriding/Carburizing treatments of austenitic stainless steel

T11 Plasma Science and Technology

#PST/SE/TF-3-Or-10

G. Marcos, A. Andrieux, Y. Guo, T. Czerwiec.

Institut Jean Lamour - Nancy (France).

In order to improve tribological properties of austenitic stainless steels, low-temperature diffusion treatments as plasma-assisted nitriding (PAN), plasma-assisted carburizing (PAC) or a combination of these two processes, i.e. plasma-assisted nitrocarburizing (PANC), are developed since the 1980s. PAN is a treatment in which nitrogen atoms diffuse in the metallic material producing, below 693 °K, a specific phase usually called expanded austenite or γN phase. Expanded austenite is a metastable nitrogen supersaturated solid solution with a disordered fcc structure and a distorted lattice. Its nitrogen content can reach 35 at% or more, inducing important compressive residual stresses. Replacing nitrogen by hydrocarbon for conducting a low temperature PAC leads to a carburized layer containing the carbon expanded austenite phase (γC). In this case, the maximum carbon content is of 12 at%. This type of treatment has the double advantage of having a good kinetics and limiting plastic deformation of the material. However, the tribological properties of the carburized layers are not as good as those of the nitriding layers. Finally, it is possible to obtain simultaneously these two phases by combining hydrocarbon and nitrogen in the gas phase through a low temperature PANC.

We perform PAN, PAC and PANC treatments by using a multi-dipolar plasma, based on the Distributed Electron Cyclotron Resonance (DECR) concept [1]. The plasma source is a plane-network of eight microwave antennas placed at the top of a cylindrical diffusion chamber. The substrate-holder can be independently heated and biased. The low-pressure plasma phase is a mixture of Ar, N₂, C₃H₈ and H₂, according to the desired treatment. The studies are realized on substrates in austenitic stainless steel AISI 316L, previously polished like a mirror. The main purpose of this work is to compare PANC treatments with sequential ones:

carburizing followed by nitriding or nitriding followed by carburizing. During PANC, it was found that nitrogen and carbon atoms can simultaneously be dissolved into the austenite lattice, forming a dual layer structure with an extremely hard nitrogen-enriched layer near the substrate surface and above a hard carbon-enriched layer. Our aim is to study the role of the repulsive interaction between nitrogen and carbon on the characteristics of this dual layer structure. X-Ray Diffraction is used to identify the presence and structure of the expanded austenite. The layer thickness is observed by optical microscopy and the composition of the layers is determined by GDOES.

During nitriding followed by carburizing treatments we observe that nitrogen pushes the carbon inside the steel inducing the formation of γ C phase at the interface with the untreated substrate. During carburizing followed by nitriding treatments carbon diffusion through the nitrided layer is observed to be extraordinary fast due to the repulsive interaction of carbon on nitrogen. The amount of carbon incorporated into the material, determined from the integral of the GDOES signal, is found to be must higher from carburizing followed by nitriding sequential treatments than from nitrocarburizing.

PST-P3-04

Plasma modification of functionalized, ceramic membranes in composite gel electrolyte

T11 Plasma Science and Technology

#PST-P3-04

M. Pokora, M. Walkowiak, L. Horla, J. Kunicki.

Institute of Non-Ferrous Metals Branch in Poznan Central Laboratory of Batteries and Cells - Poznan (Poland).

Conventional lithium batteries with liquid electrolytes have achieved a tremendous technological and commercial success over the recent two decades, but they are prone to electrolyte leakages and ignition of volatile solvents. One of the most effective ways to prevent these accidents is to entrap conventional liquid electrolyte in a polymeric matrix, thus forming a stable gel. PVdF/HFP copolymer has proved to be one of the most useful polymeric matrices, which can easily be shaped into thin, elastic membranes. By dispersing in such a membrane certain ceramic powders (fillers) it is possible to improve some crucial characteristics of the gel electrolytes, such as mechanical, chemical, thermal and electrochemical stability. Huge amount of scientific reports have been devoted to identification of the most preferable ceramic filler.

In our work we made attempts to synthesize MCM-41 mesoporous silica functionalized with novel fluorine containing silane coupling agent - tridecafluoro-1,1,2,2-tetrahydrooctyldimethylchlorosilane with different amount. The motivation of this approach was to enhance the effect of mesoporous filler by modifying it with functional groups compatible with the polymer matrix, through the existence of fluorine atoms. What is more, fluorine-based functionalization is expected to give rise to an increased chemical, electrochemical and thermal resistance, which is of particular importance for the viable battery technologies. All membranes were modified by plasma to improve their porosity and increase the electrolyte uptake.

Mesoporous materials and dry membranes have been characterized physicochemically using such techniques as nitrogen adsorption isotherms, XRD, thermal analysis, SEM, TEM and FT-IR. These materials have been examined electrochemically, including the determination of the temperature dependence of specific conductivities (electrochemical impedance spectroscopy), electrochemical

stability window (cyclic voltammetry on platinum electrode) and lithium intercalation ability into graphite. It has been demonstrated that fluorine functionalized mesoporous silica exhibits favorable structural properties, stability and good ionic transport, evidenced by high conductivities.

The work has been financially supported by the European Regional Development Fund in the frameworks of the Innovative Economy Programme 2007-2013, project No. POIG.01.01.02-00-015/09.

Organic memory devices are considered the most promising candidates for a large scale, high density and cost efficient non-volatile memories [1, 2]. The device architecture is very simple, and it is based on an organic layer (which may be evaporated small semiconducting molecules, or a solution processed polymer film), sandwiched between two metal electrodes. The device may include some metal nanoparticles which can be randomly dispersed inside the organic layer or disposed to form an intermediate metal layer.

In this work, the possibility to deposit the organic layer by plasma processing is discussed.

A full polymer memory device based on a polystyrene thin film deposited by plasma polymerization is demonstrated (see J-V curves in *fig. 1*). The system shows good switching properties, high On-Off ratio ($>10^4$), and good On-state retention time. The optimized full cycling scheme (which consists in the memory writing, erasing, and rewriting) is achieved by applying short voltage pulses over a certain voltage threshold. The memory elements were successfully cycled over hundreds of cycles without sensibly affecting the device performances.

The results extend the possibilities for organic memory device processing and present some technologically relevant advantages with respect to conventional deposition methods which will be discussed. In particular, the high control over different hybrid device architectures may be useful in studying the switching effect and so improving the future device performances and lowering the production costs. The switching features will be interpreted in terms of the formation and destruction of metallic filamentary paths inside the polymer layer [3].

Plasma treatment and cell adhesion experiments of porous 3D PCL scaffolds

T11 Plasma Science and Technology

#SE/PST/TF/BI-2-Or-8

R. Morent, N. De Geyter.

Research Unit Plasma Technology - Department of Applied Physics - Ghent University - Ghent (Belgium).

Poly- ϵ -caprolactone (PCL) is an aliphatic biodegradable and biocompatible polymer which has gained attention in the past few years due to its potential use in several biomedical applications. Due to the excellent mechanical and structural properties of PCL it can be used for tissue engineering, drug delivery applications and bone repair [1]. It can be used to create different types of scaffolds due to its ability to form the desired 3D shape [2]. In addition, 3D porous structures can be developed that facilitate ingrowth of blood vessels, ultimately leading to a better integration of the implant [3].

However, PCL has a low surface energy and wettability and these surface properties negatively affect cell attachment and proliferation. Therefore, in most cases a surface modification is required. By using plasma treatment, additional functional groups can be introduced on the polymer surface which alter the surface properties to meet the requirements of biomedical applications. Until now, only little work has been done on the plasma treatment of the biodegradable polymer PCL. In most of these studies, the authors have used vacuum (<0.2 kPa) plasma technologies. In this work, a medium pressure dielectric barrier discharge at 5 kPa will be used to activate the PCL samples.

This presentation will give an overview of some recent results on the surface activation of PCL samples. Spincoated PCL layers on glass substrates, small/flat PCL blocks and porous PCL scaffolds are investigated. The plasma is able to enhance the wettability of all sample types and ageing experiments show that at least part of the treatment effect is permanent. X-Ray photo-electron spectroscopy on the treated PCL surface shows an increased oxygen content for all samples; for the porous structures it is shown that also oxygen is incorporated inside the scaffold.

This proves that the plasma is able to penetrate and alter the surface inside the structure. Cell culture tests are done to study the possible beneficial effect of plasma treatment on cell attachment and proliferation. For flat non-porous PCL samples, the plasma effect on cell adhesion and proliferation is still noticeable after 7 days. For the porous 3D PCL scaffolds, the plasma treatment could also increase the cell numbers compared to untreated scaffolds. The promising results obtained in this work demonstrate the advanced possibilities of plasma technology for surface modification. Especially the improved penetration and adherence of cells inside porous PCL scaffolds can be of great importance for sophisticated applications in the field of tissue engineering.

Bones are complex and hierarchical organs consisting of mineralized organic tissue which are exposed to injuries and illnesses that generate the loss of the bone function with consistent human morbidity. With the aim of overturning bone damage, a bone filling material is required in some clinical applications such as nonunion fractures, osteonecrosis, fragility fractures or bone reconstruction after tumor removal, among others [1]. It is estimated that in Europe bone substitutes are annually used in 1 million surgical procedures. The worldwide market of these materials is estimated to be 5 billion Euros, with an annual growth rate of 8-15%. Hydroxyapatite (HA) and beta tricalcium phosphate (b -TCP) are the most clinically used calcium phosphate (CaP) ceramics for bone regeneration. Their main feature is the compositional similarity with natural bone mineral [2] which makes them bioactive and osteoconductive. To further improve their performance, different drugs such as antibiotics or anti-inflammatories have been added to CaPs with the aim of local controlled release [3].

Atmospheric plasmas are of interest with views on different medical applications and in the design of advanced biomaterials with controlled drug release properties [4]. In this work, the effects of low temperature plasma have been evaluated for the first time with regard to CaP ceramics. In particular, a He atmospheric plasma jet was used to treat sintered b -TCP discs at optimized gas flow rate, power and distance to the material. In the first place the surface effects of the atmospheric plasma treatment at different times between 1 and 20 min were characterized by XPS, SEM and AFM. From the chemical point of view the treatment progressively increased the O/C ratio on the surface of b-TCP with time, while interesting modifications were observed on the topography of the surface leading to increased specific surface area.

Doxycycline hyclate – an antibiotic of the tetracycline family often used in periodontal diseases - was used as model drug for its incorporation to the bioceramics. The drug was incorporated to the β -TCP after the atmospheric jet plasma treatment, and its release was studied according to the European Pharmacopoeia standards. In all conditions evaluated, the plasma jet treatment was effective in slowing down the drug release with respect to the untreated ceramics possibly by increasing the bonding strength between the TCP and the antibiotic studied.

ASS-P1-20

Mass identification of the neutral products generated in the plasma treatment of polluted atmospheres

T11 Plasma Science and Technology

#ASS-P1-20

D. Seymour, A. Rees, S. Davies.

Hidden Analytical - Warrington (United kingdom).

Plasmas produced using Dielectric Barrier Discharge (DBD) devices are very effective in the abatement of air pollution resulting from, for example, the emission of volatile organic compounds (VOCs) by a range of industrial and agricultural processes. The development and monitoring of effective DBD systems can be investigated by advanced mass spectrometric methods specifically configured for analysis at high and atmospheric pressures. The present work involves the operation of a small DBD reactor which uses either a helium or nitrogen carrier gas to sustain the plasma to which may be added reactive gases, such as oxygen, as well as samples of pollutants such as chlorinated hydrocarbons, including trichloroethylene. The mass spectrometric analysis was performed using a specially configured system manufactured by Hidden Analytical Ltd. The DBD source may also be combined with a catalyst for plasma-enhanced catalysis. The neutral products of the reactions proceeding in the plasma at atmospheric pressure are sampled through the Hidden capillary sampling system which also reduces the pressure of the gas mixture delivered to the ionisation source of the quadrupole mass spectrometer. The source is designed to generate production of either positive or negative ions from the sampled gas mixture, and also allows optimisation of the source conditions, which depends primarily on the choice of the energy of the electrons used to generate the positive or negative ions. The ions produced are subsequently mass identified. There are clear advantages, when the pollutants of interest are electronegative, in being able to choose the polarity of the ions generated. We describe typical data and comment on the relative advantages of operating the mass spectrometer in the positive and negative ion modes.

PST-P2-16

Nonlinear dust acoustic waves in a dusty plasma with nonthermal ions featuring Tsallis distribution

T11 Plasma Science and Technology

#PST-P2-16

M. Benzekka, M. Tribeche.

Plasma Physics Group, Theoretical Physics Laboratory, Faculty of Sciences-Physics, University of Bab-Ezzouar, USTHB, B.P. 32, El Alia, Algiers 16111, Algeria (Algeria).

From its beginnings with the initial observations of micron-sized particles in astrophysical and processing plasmas, the study of dusty plasmas has rapidly matured as highlighted in recent books and review. Besides affecting the equilibrium quasi-neutrality condition and modifying the existing plasma wave spectra of an electron-ion plasma, charged dust grains also introduce new types of waves in a dusty plasma and are presumed to play an important role in many astrophysical plasmas. Wave propagation in such complex systems is therefore expected to be substantially different from the ordinary two component plasmas. The dust charge may fluctuate becoming a new dynamical variable, and the electron can be strongly modified by the nonlinear plasma potential by generating a population of fast energetic electrons or trapped ones. However, numerous observations clearly indicated the presence of energetic particles (electrons and ions) as ubiquitous in a variety of astrophysical plasma environments and measurements of their distribution functions revealed them to be highly nonthermal. The aim of the present work is therefore to present a theoretical work to investigate nonlinear DA waves in a plasma comprising electrons, positive ions and mobile negatively charged dust grains. The correct nonthermal ion charging current in the Tsallis thermostatics is based on the orbit motion limited (OML) approach and the variable dust charge is then expressed in terms of the Lambert function. Our results may obtain using a scheme suitable for stiff problems. One can numerically solve Poisson's equation either as a boundary-value problem or as an initial-value problem. The numerical results reveal that the spatial patterns of the variable charge solitary wave are significantly modified by the nonextensive and the nonthermal ions effects.

PST-P2-17

Dust acoustic dressed solitons in a three component dusty plasma

T11 Plasma Science and Technology

#PST-P2-17

R. Amour, M. Tribeche.

Plasma Physics Group (PPG), Theoretical Physics Laboratory (TPL), Faculty of Sciences-Physics, University of Bab-Ezzouar, USTHB, B.P. 32, El Alia, Algiers 16111, Algeria. (Algeria).

Dust acoustic dressed solitons in a three component plasma consisting of a Boltzmann distributed electrons and ions and dust grains are investigated. Using the expansion of the Sagdeev potential to include fourth-order nonlinearities of electric potential and integrating the resulting energy equation, an exact soliton solution is obtained for our model of plasma. This approach gives soliton solution in terms of coefficients of nonlinearities of second order, third order and fourth order of electric potential in the expansion of the Sagdeev potential. Using the Taylor's series development of Mach number in terms of soliton velocity and keeping the terms up to order of, this exact solution reduces to nonsecular dressed soliton solution. It is found that for a given value of the fractional positrons concentration, the ratio of temperature, and the Mach number, the dressed soliton admits two different structures (compressive and rarefactive) due to the presence of the suprathermal electrons.

SE/PST/TF/BI-P1-04

Development of multi-gas DBD plasma jet source and its applications for medical field

T11 Plasma Science and Technology

#SE/PST/TF/BI-P1-04

K. Uehara¹, T. Oshita¹, T. Toshihiro¹, A. Kawate¹, N. Nakashima², H. Miyahara¹, A. Okino¹.

¹Department of Energy Sciences, Tokyo Institute of Technology - Yokohama (Japan), ²Plasma Factory, Co. Ltd. - Yokohama (Japan).

In recent years, non-equilibrium atmospheric plasmas have been attracted much attention in medical field such as sterilization or wound healing. These effects are caused by reactive species such as oxygen radical or nitric monoxide generated in plasmas. Amount and kinds of these reactive species depend on the plasma gas species. Therefore, treatment effect varies depending on the plasma gas. For example, oxygen mixed argon plasma was most effective for sterilization of *E. coli* [1].

For application of plasma directly to living body, not only highly effective treatment but also high safety such as no cytotoxicity is important. For instance, plasma sources using Dielectric Barrier Discharge (DBD) is utilized for plasma irradiation to tissue [2]. This plasma source can generate contamination-free plasma that means absence of electrode particle in plasma. However, standard DBD plasma jet sources have limitation in useable plasma gas species such as argon or helium. So, improvement of treatment effect by varying gas species is not expected too much.

In this study, to treat living body with contamination-free and various gas plasma, we developed multi-gas DBD plasma jet source with a new electrode structure and power waveform. The plasma gas flow rate was 3 L/min, copper electrodes spaced 10 mm apart were provided surrounding a glass tube with 1 mm i.d. and 2 mm o.d.. The electrodes were connected to power supply with a frequently of 16 kHz and high voltage of 9 kV. As shown in Fig. 1, the plasma source can generate stable plasma with argon, helium, oxygen, neon, nitrogen, carbon dioxide, air and their mixture gases. And the plasma does not give thermal damage and discharge damage to the target.

To investigate relation between the treatment effect and the plasma characteristics depending on the gas temperature and the excitation temperature was investigated using spectroscopic method. As a result, the helium excitation temperature was 2,700°C and the gas temperature was 20°C. The excitation temperature was much higher than the gas temperature so the generated plasma was a kind of non-equilibrium plasma. Besides, *E. coli* in agar medium was irradiated with various gas plasmas by varying irradiation distance, irradiation time and gas flow rate. Influence of plasma gas species on sterilization effect was investigated.

Plasma electrochemistry in Ionic liquids

T11 Plasma Science and Technology

#PST-4-Or-9

O. Höfft, N. Spitzcok V. Brisinski, A. Lahiri, F. Endres.

TU Clausthal, Institute of Electrochemistry - Clausthal-Zellerfeld (Germany).

Plasma electrochemistry is a powerful tool to generate free nanoparticles in liquids. Because of the high vapour pressure of aqueous solutions nowadays atmospheric-pressure microplasmas or plasma jets are mostly used to generate colloidal metal nanoparticles [1]. However, this method is more or less restricted to the generation of noble metal particles. Due to their very low vapour pressure ionic liquids can be employed in vacuum experiments as fluid substrates or solvents. Thus, ionic liquids are well suitable electrolytes for plasma electrochemical processes delivering stable and homogeneous plasmas. We have shown that free and isolated copper and germanium nanoparticles can be obtained in ionic liquids (ILs) by applying a plasma as a mechanically contact-free electrode [2,3,4]. In contrast to the classical electrochemistry approach [3], it was not possible with the plasma electrochemistry method to generate silicon nanoparticles in ILs, mainly due to the high vapour pressure of the silicon precursors, like e.g. SiCl_4 . Here we report on our new approach to overcome this problem, by using a new plasma setup. With our modified setup it is possible to use the above mentioned high vapour pressure precursors to make Si nanoparticles. We report about the generation of silicon nanoparticles with an argon plasma from SiCl_4 in 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)amide ([EMIm]Tf₂N), and 1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)amide ([Py_{1,4}]Tf₂N). We will discuss the plasma electrochemical reactions of SiI_4 in the ILs and compare them with our results for the generation of germanium particles from the solid germanium dichloride-1,4-dioxane complex ($\text{GeCl}_2[\text{C}_4\text{H}_8\text{O}_2]$). The analysis of the plasma electrolyte interaction was done with in situ mass spectrometry. The particles were characterized with transmission electron microscopy, dynamic light scattering, UV/VIS spectroscopy and photoluminescence spectroscopy.

PST-2-Or-5

Anisotropic Shear Melting of a 2D Complex (Dusty) Plasma

T11 Plasma Science and Technology

#PST-2-Or-5

V. Nosenko, A. Ivlev, G. Morfill.

Max-Planck-Institut für extraterrestrische Physik - Garching (Germany).

A complex, or dusty plasma is a suspension of fine solid particles in an ionized gas. Particles get charged by collecting electrons and ions from the ambient plasma and interact with each other via a screened Coulomb pair potential. When these interparticle forces are balanced by other forces (gravity, neutral and ion drag, ambipolar electric fields), the particles can form regular structures called plasma crystals. In the presence of gravity, a single-layer (two-dimensional, 2D) plasma crystal can form [1,2]. The shear modulus of such crystals is on the scale of 10^{-13} N/mm [1], and therefore they can be easily manipulated, e.g. by the radiation pressure force of a focused laser beam [2].

Our experimental setup was a modified GEC (Gaseous Electronics Conference) rf reference cell. Plasma was produced using a capacitively coupled rf discharge in argon at 0.66 Pa [1,2]. A single layer of dust particles was suspended in the plasma sheath of the lower rf electrode. The microspheres made of melamine formaldehyde

had a diameter of $9.19 \pm 0.09 \mu\text{m}$, a mass $m = 6.15 \cdot 10^{-13}$ kg, and acquired an electric charge of $Q = -16000 \pm 1600e$. The suspension included around 9000 particles and had a diameter of approximately 60 mm. In our experimental conditions, the particle suspension self-organized in a highly ordered triangular lattice.

The lattice layer was illuminated by a 660 nm diode laser, with its output expanded into a horizontal sheet by a cylindrical lens. A video camera (Photron FASTCAM 1024 PCI) was mounted above the chamber, capturing a top view of the particle

suspension with a size of $42.7 \times 42.7 \text{ mm}^2$, resolution $1024 \times 1024 \text{ pixel}^2$, and recording rate 60 frames per second. The camera lens was equipped with a narrow-band interference filter at the wavelength of the illumination laser. Using Particle Tracking Velocimetry (PTV), we calculated the particle positions and velocities in every frame.

Shear induced melting is a non-equilibrium process where a crystalline lattice is ruptured and eventually melted by an external shearing force. In this work, we

experimentally studied shear induced melting using a 2D plasma crystal as a model system. Shear stress was applied by the radiation pressure force of a focused laser beam that was rastered over a rectangular area in the crystal. A Millennia PRO 15sJ solid-state 532 nm laser with a maximum CW output power of 15 W was used. For the first time, the study was angle-resolved, i.e., the closely packed rows of the crystal were oriented at $\theta=0^\circ$ or 30° (two principal orientations) with respect to the shearing force. Shear melting was found to be strongly anisotropic. The transition of a crystal to flowing liquid with increasing shear stress was rather gradual for $\theta=0^\circ$ and had a distinctly threshold character for 30° . This is explained by the role of dislocations in the crystal plastic deformation. Their nucleation and motion was facilitated for 0° (dislocations gliding in the direction of the laser beam [1]) and retarded for 30° (dislocations gliding at a certain angle with respect to the laser beam).

PST-2-Or-6

DEFECT CLUSTERS IN A TWO-DIMENSIONAL COMPLEX (DUSTY) PLASMA

T11 Plasma Science and Technology

#PST-2-Or-6

S. Zhdanov, M. Thoma, G. Morfill.

Max-Planck-Institut fuer extraterrestrische Physik - D-85741 Garching (Germany).

Complex plasmas, i.e. low-temperature plasmas containing micron-sized solid particles [1], allow investigations of many dynamical and self-organizing processes [2]. In the report we address dynamical processes associated with spontaneous disordering and symmetry breaking accompanying nucleation and clustering of defects in highly ordered complex plasmas — so-called *plasma crystals*. The particles, comprising plasma crystals, acquire large negative charges in the plasma. In the size domain of 1-10 μm (normally used in experimental complex plasmas) these particles can be visualized individually, providing hence an atomistic (kinetic) level of investigations. The interparticle spacing can be of the order of 0.1-1 mm and characteristic time-scales are of the order of 0.01-0.1 s. Plasma crystals are perfectly suited to study order-disorder transitions and symmetry alternations, in particular spontaneous disordering that plays an important role in the physics of highly ordered complex plasmas [3-6]. The results of recent simulations and experiments showing such spontaneous disordering are reviewed and interpreted. The mechanism and physics of defect nucleation are key questions that often remain open irrespective of the suggested melting scenario or the shear instability mechanism. Many important features of the spatial structure of crystals can be modeled with the help of plasma crystals, which are perfectly suited to study the symmetry and multi-scale plasticity of a 2D lattice layer. Complex plasmas can serve as a powerful tool, providing a fundamental insight into the nucleation process generically. Either deformation-induced or thermally initialized nucleation, i.e. the creation of the dislocation pairs, in hexagonal plasma crystals starts with the appearance of compact dislocation clusters having a tetragon in the core. Hence, the competition for the minimal energy configuration between (stable) hexagonal symmetry and (unstable) tetragonal symmetry can be resolved in favour of a (meta-stable) 'mixed symmetry' — a cluster of coupled dislocations in a hexagonal

environment. Nucleation of dislocations and symmetry alternation effects are naturally important in complex plasmas where the *particle–plasma* feedback mechanisms underlying many dynamical processes play an important role. Another option, interesting in many applications, is the clustering of a new phase which is asymmetric with regard to a background symmetry. The nontrivial topology of the dislocation clusters is explored in detail, and the results obtained in simulations and theory agree well with experimental observations.

Multi-scale approach for simulation of deep silicon etching under SF₆/C₄F₈ Bosch process

T11 Plasma Science and Technology

#PST-4-Or-1

A. Pateau ¹, A. Rhallabi ¹, M.C. Peignon-Fernandez ¹, M. Boufnichel ², F. Roqueta ².

¹Institut des Matériaux Jean Rouxel - Nantes (France), ²STMicroelectronics TOURS SAS - Tours (France).

Deep etching of silicon represents a new challenge in the silicon semi-conductor manufacturing. Bosch process, one of the most common processes in microelectronics, is used for silicon deep plasma etching. It is based on a cyclic process consisting in alternating etching and deposition. To better understand the plasma surface interactions for polymer deposition and etching, we have developed a silicon etching simulator under Bosch process using alternating ICP SF₆/O₂ plasma for etching and ICP C₄F₈ plasma for deposition. Such a simulator is composed of three modules permitting to predict the 2D etched silicon morphology versus the operating conditions: plasma kinetic, sheath and etching models. The plasma kinetic model is based on the 0D global approach which allows the calculation of the average densities and fluxes of neutral and ion species as well as the electron density and temperature versus the ICP machine parameters. The sheath model is based on the Monte-Carlo technique. The model allows the calculation of angular and energy ion distribution functions. All these output parameters are introduced as input parameters in the silicon etching model. Cellular Monte-Carlo method is used to describe the plasma surface interactions in a probabilistic way for silicon etching. The reactive species considered are atomic fluorine and C_xF_y radicals produced in the SF₆ and C₄F₈ discharges respectively as well as positive ions. Fig 1 shows the fluorine density (nF) evolution versus the %O₂ for different pressure values. The simulation results show that for a low %O₂, nF increases up to a maximum corresponding to about 40% of oxygen. After this value, it decreases with %O₂.

Fig 2 presents the etch profile evolution through the mask. Scalloping effect is

evidenced.

The aim of this work is to validate the set of simulation and show the influence of some input parameters (Rf power, pressure, gas flow rates and bias voltage) on the etching process.

Superhydrophobicity and self-cleaning by plasma treatments of topographically structured surfaces

T11 Plasma Science and Technology

#PST/SE/TF-P1-03

E. Grimoldi, S. Zanini, C. Riccardi.

Università degli Studi di Milano Bicocca - Milano (Italy).

Superhydrophobicity is a very common phenomenon occurring in nature. The ability of the lotus leaf and other natural materials to promote water repellency and self-cleaning has inspired several research groups. Water drops roll around easily on these surfaces if the substrate is slightly tilted (low roll-off angle). In certain cases, drops rolling off the surface take loosely adherent dirt particles with them, thus giving rise to self-cleaning properties. This effect, called 'Lotus effect', is caused by a combination of chemical (hydrophobic waxes coating) and physical features, i.e. roughness at two or more length scales (hierarchical structures, typically bumps of about 10 μm and submicronic microfibers).

Superhydrophobicity and self cleaning can be achieved onto artificial materials, using appropriate methods of micro/nanostructuring or employing surfaces which possess particular roughness themselves (for example leather or velvet paper).

In this work, hydrophobic and self cleaning surfaces were prepared by means of different plasma treatments. In particular, leather and velvet paper surfaces were modified by low pressure plasma discharges in sulphur hexafluoride (SF_6) and hexamethyldisiloxane (HMDSO) or by atmospheric plasma graft-polymerization of 3,3,4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-Heptadecafluorodecyl acrylate.

Hydrophobic properties were evaluated by means of static and roll-off contact angles measurements, while the morphological characteristics of the surfaces were studied using Scanning Electron Microscopy (SEM) and the surface chemical composition of the treated samples was analyzed with X-rays Photoelectron Spectroscopy (XPS).

Fig. 1. Water drops on untreated (left) and HMDSO plasma treated (right) velvet paper

H atom surface loss kinetics in pulsed inductively coupled plasma

T11 Plasma Science and Technology

#PST-2-Or-1

C. Cardinaud, S. Jacq, L. Le Brizoual, A. Granier.

Institut des matériaux de Nantes - CNRS - Nantes (France).

In microelectronics and microtechnology, as the semiconductor feature size decreases and pattern density increases, the industry is facing the challenge of finding new plasma processes to meet the requirement of the next devices generation. Within this scheme pulsed RF plasmas are increasingly being employed for plasma etching or deposition. Besides the interest for potential applications, pulsed plasmas combined to time resolved measurements are known to be powerful tools to study species kinetics.

This study is focused on H atom kinetics in low pressure high density inductively coupled CH₄-H₂ pulsed plasmas. The H density is investigated by time resolved optical emission spectroscopy. Since electron temperature collapses at the end of the ON time, no emission occurs during the OFF time. Hence, plasma induced fluorescence is used to probe the time variation of the H atom density in the afterglow. Ion flux density measurements are done with a planar probe in order to correlate the H atom surface loss probability (β) to the ion flux reaching the wall.

We explore pure H₂, H₂-N₂, CH₄-H₂ and CH₄-N₂ mixtures. These gas mixtures offer very different wall conditions, namely stainless steel for the first two and hydrocarbonated walls for the other two. Results show that β is strongly sensitive to wall conditions. Compared to values of 0.073 (β -on) and 0.065 (β -off) in H₂, β -on increases steadily with the percentage of CH₄ in CH₄-H₂, reaching 0.15 in pure CH₄, while β -off attains 0.4. Adding N₂ to CH₄ leads to β -on values even higher: 0.25 at 75%N₂. Results will be discussed considering various surface loss mechanisms. Effect of pressure in stainless steel wall conditions is also investigated. β behaviour shows significant differences between pure H₂ and the H₂-N₂ mixture. E.g. in the latter β -on increases in the whole range of pressure (fig.1), whereas in pure H₂ the evolution of Beta-on with pressure is not monotonic (fig.2).

Study and conception of a DBD (Dielectric Barrier Discharge) process and equipment for the industrial deposition of silica like coatings on continuously running strips

T11 Plasma Science and Technology

#PST/SE/TF-1-Or-2

V. Leclercq.

AC&CS - CRM Group - Liège (Belgium).

As a preliminary work, we studied and tested silica like coatings to improve some of the in use properties of steel (adhesion, corrosion, surface energy, end so on), and we identified the required coating characteristics.

Industrially, these silica layers have to be deposited through a continuous process, on commodity products, which are webs of steel, characterised by their high throughput (thousands of tons per year), their large width (> 1.5m) and their high speed (> 100 m/min).

After considering different technologies, we chose to further look into the DBD (Dielectric Barrier Discharge) technology, especially because of its potential in terms of limited capital expenditures and operating costs.

However, when used in this context, the DBD technology has serious weaknesses, which are:

- too short a distance from substrate to electrode, which prevents the continuous running of many metallic substrates,
- too fast a fouling of the coating equipment, which leads to excessive maintenance and operating costs.

The developments presented permitted the elimination of these weaknesses, via the conception of a maverick process.

Finally, we designed an industrial modular coating equipment, that can be installed on existing conventional production lines, and which takes into account the targeted in use properties, the required product characteristics and the necessary process parameters.

¹University of Applied Sciences and Arts - Göttingen (Germany), ²Institut d'Optique Graduate School - Palaiseau (France), ³Clausthal University of Technology - Clausthal-Zellerfeld (Germany).

In this contribution, we present an atmospheric pressure argon plasma aided laser ablation technique for cutting and drilling applications. Here, a cone-shape rotation-symmetric plasma source with an inner hollow-core high-voltage electrode was used. Based on a dielectric barrier discharge, this source provides a slight plasma beam with a diameter of approx. 200 μm . The dielectric separation of the inner high-voltage and outer ground electrode was accomplished by the sample and an additional dielectric, respectively, as the case may be for conductive sample materials such as aluminium. As laser source, a 3rd harmonic Nd:YAG laser with pulse durations in the nanosecond range was applied. As shown in figure 1, both the applied plasma and the laser beam propagate coaxially.

Experiments were performed on barite crown and heavy flint glass, aluminium oxide ceramic and aluminium. In the case of ablation of glasses, an increase in the ablation depth by a factor of 2.1 was achieved by the presented plasma aided technique in comparison to pure laser ablation. Further, the ablated volume was increased by a factor of 1.5 for barite crown glass and 3.7 for heavy flint glass [1]. Regarding aluminium oxide ceramic, it was shown that the presented technique affects a reduction of the laser ablation threshold. The ablation process was additionally enhanced in terms of an increased contour accuracy and ablation rate [2]. Such enhancements were also observed for aluminium, where the ablation rate was significantly increased in comparison to pure laser ablation [3]. The presented plasma aided ablation technique thus allows enhancing laser material processing results and reducing the required laser energy due to energetic synergies that result from de-excitation processes of generated argon metastable species.

Laboratory of Plasma and Gases Physics, CNRS (UMR8578) University Paris-Sud - Orsay (France).

Over the last two decades atmospheric pressure non-thermal plasmas coupled to traditional catalysis have received a growing interest as a promising tool for a more efficient VOC removal [1]. The post-plasma catalysis, in particular, can complete the oxidation process started in the plasma phase reducing, at the same time, the reaction temperature at the catalyst surface. In this field the catalytic ozonation of VOCs is particularly advantageous: catalysts based on transition metal oxides are able to decompose the O_3 produced into the discharge thus providing highly active oxygen species which can contribute to oxidation of VOCs at low temperatures [2]. In this work the plasma-catalytic abatement of two target molecules, ethanol and acetone, has been investigated. Air Dielectric Barrier Discharges were carried out in a symmetric pin-to-pin DBD reactor. Due to the high activity of Mn oxides in O_3 decomposition, Al_2O_3 supported MnO_2 (5%) pellets were placed downstream the DBD reactor. The air flow rate was kept constant at 2 l/min, whereas ethanol and acetone concentrations were fixed at 300 ppm. Catalyst temperature was maintained at 60 °C. In line by-products detection and quantification was allowed by a gas chromatograph equipped with a thermal conductivity detector (MicroGC-TCD), a Fourier transform infrared spectrometer (FT-IR), an O_3 UV-absorption based detector and a CO_2 - H_2O infrared gas analyzer placed in the exhaust gas line. A first result, in term of removal efficiency and by-products distribution, for the plasma conversion of the starting pollutants, both alone and in mixture, has already been given [3]. In this work a complete characterization is provided. When singularly considered, the abatement of both pollutants is enhanced by the post-catalytic treatment. As shown in Fig. 1 acetone plasma-catalytic process is quite efficient, as the concentration of all partially oxidized products issued from the plasma phase fall down to zero: both the primary and secondary molecules are converted to CO_2 and CO. Differently, ethanol catalytic conversion, in addition to the CO_2 enhancement,

mainly promotes the acetaldehyde and carboxylic acid production; other species produced in the discharges, as formaldehyde and formic acid, are instead reduced. When 1:1 ethanol-to-acetone mixtures are investigated, competition between the primary VOCs prevents the catalytic acetone abatement.

Metal/plasma polymer nanocomposite coatings have been studied for many decades due to an extraordinary potential in tuning their mechanical, electrical and optical properties in various different directions according to the special requirements of any particular application [1,2]. Several plasma-based vacuum deposition techniques have been utilized in order to incorporate metal nanoparticles into a plasma polymer matrix, e.g. simultaneous magnetron sputtering from metal and polymer targets or metal evaporation during PECVD [3,4,5]. Plasma technology offers a controlled film growth at high surface diffusion and low temperatures.

Filling factor (or volume fraction ratio) is the principal parameter describing structure of a metal/plasma polymer nanocomposite coating. It is defined as the volume of metal inclusions in the total volume of the composite material. Structure of such a nanocomposite film determines also its properties. The filling factor at which the structure of a nanocomposite film switches from an insulating to a conductive nature is called percolation threshold.

For any practical application, a long-term stability and limited aging of such coatings are required for their reliable and repeatable performance. In this contribution, we present a study of structure and properties of Ag/a-C:H:O nanocomposite coatings and their changes upon aging in air and influence of an aqueous environment. The characterization of the film microstructure by TEM, optical properties by UV-vis spectroscopy (Figure 1) and electrical properties showed that changes in film properties are much more pronounced upon aging in water than in air.

The Atmospheric Pressure Plasma Jet is a unique technique which operates at standard temperature and pressure conditions therefore enables us to explore possibilities of material treatment which cannot be introduced to vacuum system or treated at elevated temperatures. This is especially important for biological systems such as cells and living tissues.

The research conducted on cancer cells irradiated by the APPJ is very new starting just in 2010 [1], where it was hypothesized that the APPJ could initiate the cascade of biochemical processes leading to the death of the cells. It has been also shown that the APPJ offers a complex gas environment consists of reactive oxygen species and reactive nitrogen species, photons, charged particles, which may all contribute to biological effects like cell death [2]. This shows that APPJ treatment can activate cell apoptosis (events which lead to specific changes in morphology of the cell and then death, in contrast to necrosis which happens immediately upon some events).

However, a little has been done on understanding of the physical, chemical and biological processes underlying the interaction of APPJ and biological systems. Any data collected on the role of plasma during interaction with the cell or its components is a great concern and helpful in progressing plasma medical technology.

In these studies SCC-25 oral cancer cells were exposed to plasma radiation and cell damage, i.e., DNA double strand breaks in nuclei was analyzed by immunofluorescence microscopy. It has been observed the increase in both effective areas and a number of damaged cells with plasma irradiation time. Such an effect can be due to the fact that the reactive species have been continually accumulating on a surface at the plasma-liquid interface. Optical emission spectra were taken to characterize these reactive species produced in APPJ.

Synthesis of Pt based catalyst for PEM fuel cell by a novel plasma deposition method

T11 Plasma Science and Technology

#PST/SE/TF-2-Or-3

M. Laurent-Brocq ¹, N. Job ², J.J. Pireaux ¹.

¹LISE - Namur university - Namur (Belgium), ²LGC - Liège university - Liège (Belgium).

Polymer exchange membrane (PEM) fuel cells are promising energy conversion devices [1]. One major challenge for their commercial spreading is to reduce the cost, for example by decreasing Pt loading in the catalytic layers composing the electrodes. To do so while keeping the same catalytic properties, the dispersion of Pt nanoparticles onto the carbon support need to be fine and dense [2].

We propose to apply a novel low temperature plasma method using organometallic precursors [3] to graft Pt nanoparticles on carbon black and to study the influence of synthesis conditions on nanoparticles characteristics. So, catalysts were synthesized under various plasma treatment conditions (gas and power) and then characterized by X-ray diffraction, transmission electron microscopy and X-ray photoelectron spectroscopy. It was deduced that the formation of Pt nanoparticles depends on two phenomena: (i) the functionalization of the carbon black surface which is influenced by the plasma gas nature and (ii) the decomposition of the organometallic precursor which results from a thermal effect and is influenced by the plasma power. Finally, catalysts were annealed and the stability of the nanoparticles was studied.

Acetaldehyde decomposition in atmospheric gases by spatially homogeneous and DBD filamentary plasmas: a comparative study

T11 Plasma Science and Technology

#PST-P3-05

S. Pasquiers¹, W. Faider¹, O. Koeta², N. Blin-Simiand¹, P. Jeanney¹, L. Magne¹.

¹LPGP-CNRS - Orsay (France), ²LACARE - Ouagadougou (Burkina faso).

Acetaldehyde has long been recognized as a toxic Volatile Organic Compound. This pollutant is found both in indoor air, coming from building materials, and in exhaust gases of ethanol combustion, or coming from incinerators. The reduction of the emissions of dangerous substances like this VOC passes by the development of effective and economically successful processes of clean-up. For this purpose, the use of non-thermal plasma, eventually coupled to catalysis, is under study for many years but works regarding acetaldehyde are rather scarce [1-3].

An important subject to be addressed is the energy needed for a given discharge type in order to convert CH₃CHO in other compounds which could be efficiently oxidized by a catalyst placed after the plasma, at low temperature (i.e. as close as possible to the ambient). The specific energy (energy consumed per unit volume of gas processed) should be as low as possible in order to make the process economically attractive. Thus the type of discharge used appears as an important parameter.

In the present work, the conversion of 500 ppm of CH₃CHO diluted in N₂/O₂ mixtures (oxygen up to 20 %) at a total pressure of 0.46 bar (photo-triggered discharge) or 1 bar (dielectric barrier discharges, DBD) are compared. The photo-triggering technique allows one to achieve homogeneous transient high-pressure plasmas in various types of gas mixtures [4]; a detailed description of the UV-preionized reactor used has been previously published [2, 4, 5]. Two kinds of DBD were used also, the first one with a plane-to-plane geometry (a copper plate for HV electrode), and others with a cylindrical geometry (tungsten rods for HV electrode). All DBD reactors were energized using positive pulsed high voltages so that the

generated plasmas were either strongly non-homogeneous (cylindrical reactors) or much less filamentary (flat reactor).

It was found that, at a low percentage of oxygen (less than 2 %), the energetic efficiency of filamentary DBD-plasmas for removing the acetaldehyde is lower than the efficiency for the more homogeneous one. For same gas mixtures, the efficiency for the photo-triggered reactor is even higher than the efficiency for all DBD-reactors. However, the three types of reactors have almost the same energetic performance for an oxygen concentration higher than a few percent. As a result, it seems that the spatial distribution of the deposited electrical energy in the discharge has a strong effect on the energetic efficiency of the plasma reactor when the degradation of acetaldehyde through oxidation reactions by O and by OH (important kinetic for the removal of CH₃CHO in a gas mixture with a high oxygen concentration) are counterbalanced by the dissociation of the pollutant molecule through quenching process of the excited (essentially metastable) states of the nitrogen molecule [5] (dominant kinetic in the binary N₂/CH₃CHO mixture). This will be discussed with the help of a kinetic modeling.

Magnetic field penetration and ion separation in a multi-ion plasma

T11 Plasma Science and Technology

#PST-2-Or-7

A. Fruchtman¹, R. Doron², Y. Maron².

¹H.I.T. - Holon Institute of Technology - Holon (Israel), ²Weizmann Institute of Science - Rehovot (Israel).

A theory is presented that deciphers the puzzle of magnetic field penetration into a multi-ion plasma of an initially uniform electron density observed in recent pulsed plasma experiments.

The Hall electric field has been shown to play a crucial role in the interaction of magnetic field and a plasma, in processes that govern the behavior of plasmas spanning space and laboratory.¹ In all these processes, the role of the Hall electric field becomes dominant only when a relevant characteristic spatial length is smaller than the ion skin depth. For example, the Hall field enhances dramatically the rate of magnetic reconnection when the current layer is narrower than the ion skin depth. An important process in which the Hall electric field has a dramatic effect is the fast magnetic field penetration into a low collisionality plasma. Such a penetration has been measured in detail²⁻⁵ and was found to be much faster than expected due to the plasma resistivity. It has been shown theoretically that this fast penetration is induced by the Hall electric field and the characteristic spatial scale that has to be smaller than the ion skin depth was identified in this case to be that of the electron density nonuniformity.⁶⁻⁸ In recent experiments, however, fast magnetic field penetration into multi-ion plasmas was observed even when the initial electron density was approximately uniform.⁵ In addition, the magnetic field penetration into the plasma was found to occur simultaneously with ion separation, in which a light-ion plasma is pushed ahead of, while a heavy-ion plasma lags behind the magnetic piston.⁴

In the talk we will present a model that explains these two processes, the fast magnetic field penetration into a plasma of initially uniform density and the ion separation. We will show that if the plasma ion composition is nonuniform, then, even if the total electron density is initially uniform, the different pushing of the different ion

species by the magnetic field generates an electron density nonuniformity which, in turn, induces the field penetration, that increases further the ion separation. Thus, the two processes, magnetic field penetration and ion separation, are closely linked, and occur simultaneously. Since very often plasmas are multi-ions with ion-composition nonuniformity, our analysis shows that magnetic field penetration is a much more general process that has been previously believed and that ion separation is likely to occur in many cases in which a pulsed current is driven through a multi-ion plasma. The mechanism explained here plays a major role in plasma opening switches, plasma pinches, and other plasma devices. This mechanism is likely to have an important effect also in space and astrophysical plasmas.

Sheath Potential Measurements in SF₆/Xe Plasma

T11 Plasma Science and Technology

#PST-P2-06

Y. Kawai ¹, J. Zhang ², R. Ichiki ³.

¹Kyushu University - Kasuga (Japan), ²Dalian University - Dalian (China), ³Oita University - Oita (Japan).

As well known, there are negative ions in reactive plasmas for such as CVD. Negative ions are confined in plasma without diffusing to discharge electrodes, leading to high negative ion density. Therefore, negative ions may play an important role especially in plasma CVD. However, there are almost no reports on the behaviour of negative ions in plasma CVD because of the difficulty of negative ion measurements in reactive plasma. The simplest method to estimate the negative ion density is to use the Langmuir probe, that is, the negative ion density normalized to the ion density n_-/n_+ is easily estimated from the reduction of the electron saturation current [1]: $n_-/n_+ = 1 - I_{es}/I_{es0}$. Here I_{es} and I_{es0} is the electron saturation current with negative ions and without negative ions, respectively. Furthermore, when there are negative ions in plasma, the sheath potential decreases and Bohm sheath is modified [2]. Thus, the sheath potential that is defined as the difference between the plasma potential and the floating potential provides interesting information about negative ions. In this experiment, we measured the sheath potential in SF₆/Xe DP plasma with the Langmuir probe and compared with the theory [3].

The experiments were performed using a double plasma device. The diameter and length of the stainless vacuum chamber were 500 mm and 1000 mm, respectively. Xe and SF₆ gases were introduced into the chamber with the mass flow controllers separately. The flow rate of Xe gas was kept at 6 sccm (8×10^{-4} Torr) and that of SF₆ gas was regulated from 0 to 0.1 sccm. A 0.6-cm-diam planar Langmuir probe was used to measure the plasma parameters. Mass spectra of positive and negative ion species were analyzed with the QMS.

When SF₆/(Xe+SF₆) was increased, the negative ion concentration increased. Then, we measured the sheath potential as a function of SF₆/(Xe+SF₆) and plotted the sheath potential as a function of negative ion concentration n_-/n_+ . The sheath potential is very sensitive to the temperature of ions (T_+) and negative ions (T_-). In this calculation, $T_+ (=T_-) = 0.025$ eV and 0.03 eV was assumed. Fig.1 shows the results agree with the theoretical sheath potentials at $T_+ = 0.03$ eV except for high

negative concentrations. This deviation is not understood because the sheath potentials in SF₆/Ar plasma agreed with the theoretical ones [1]. In addition, Fig.1 indicates that there are three solutions of the sheath potential at T₊=0.025 eV.

E. Hong, S. Ryu, S. Yoo, J. Park, T. Lho.

NFRI - Deajeon (Korea, republic of).

Recently, the various treatments processed for removal of non-biodegradable organics have been studied.

High-voltage electrical discharges directly in water are an emerging techniques in environmental pollutant degradation. It can produce hydrogen peroxide, molecular oxygen and hydrogen and hydroxyl, hydroperoxyl, hydrogen, oxygen, ozone and micro bubbles at the high voltage electrode.

The traditional flotation processes have no anti biotic ability. Besides, Dissolved air floatation process(DAF) requires the circulation of compressed water by air, expensive installation and operation cost.

Plasma air flotation can utilize OH radical and micro bubbles generated by plasma. These bubbles and oxidants enhance degradation, separation and inactivation of suspended solids and microorganisms in salt water.

In this study, It is tried to find optimum discharge conditions to remove the non-biodegradable organics. The Fig. 1 is the reactor is divided to 4 regions by 4 walls. 1st region was rapidly mixed for coagulation. 2nd to 4th regions were slowly mixed for flocculation and flotation continuously.

The target material is humic-acids. The selected concentration of humic acid is 100 mg/L. Alum dose for flocculation is 10mL of 1% alum solution in 1L humic salty water (3.5% NaCl).

The flow rate conditions are increased from 1lpm to 3lpm.

The plasma discharge time are 5, 10, 20 seconds. And the plasma discharge cycles are 1,2,4 minutes.

The experimental results, optimal conditions are 4min of discharge cycle, 2lpm of flow rate, 20sec of discharge time.

Electrical discharges in water produce lots of oxidants like hydrogen peroxide, hydroxyl radical and hydrogen. In addition, shock waves, UV light and bubbles can be formed. In this experiment, feasibility test of plasma aided bubble flotation for humic acid was conducted compared with sedimentation, heated sedimentation, electrolytic flotation and dissolved air flotation. The humic substance of Aldrich, Inc. was selected as the representative of contaminants. The artificial sea water containing 3.5% concentration of NaCl was used for testing separation efficiency of humic acid. The selected concentration of humic acid is 100 mg/L and UV 254nm absorbance is 2.0~2.3 cm⁻¹. Aluminum sulfate concentration for flocculation is about 100 mg/L. After coagulation and flocculation of salin humic water for 1 and 30 minutes, treated water was moved into batch reactor for separation of humic flocs by sedimentation, heated sedimentation, electrolytic flotation dissolved air flotation and plasma aided flotation. As a results, plasma aided flotation is faster process to remove flocs than others. Therefore PAF process can be an alternative of pretreatment of reverse osmosis

Volatile organic compound (VOC) removal is becoming more attractive owing to rigorous environmental issues. Moreover, VOCs removal in ppb level is more challenging because of high energy demand. In this regards, Non Thermal Plasma (NTP) coupled with inorganic sorbent (catalyst) system has been widely reported for continuous effluent treatment. This process would be energetically in efficient for ppb level VOC treatment. Therefore, we have suggested that two step process likely Adsorption followed by Plasma treatments would be better method for low level VOC treatment. Hence, this work aims at investigating the energy efficiencies between continuous effluent treatment and Adsorption/Plasma treatment process. MnO₂ coated packed bed reactor has been designed and tested for two step adsorptive removal of VOCs at indoor level (ppb) concentration. Organic products during adsorption and plasma treatment have been monitored by Selective Ion Flow Tube Mass Spectrometry (SIFT-MS); whereas online FT-IR spectroscopy has been used to quantify the CO_x produced by NTP assisted regeneration step. The system efficiency has been studied by using IPA as a model VOC. In addition to that, IPA removal efficiency have been investigated for two different experimental conditions, (i), *Continuous plasma treatment*: 300 ppb of IPA were sent to MnO₂ coated reactor, once IPA breakthrough is reached, NTP has been ignited with the fixed power of 0.82 W.

(ii), *IPA adsorption followed by plasma treatment*: After reaching the IPA breakthrough the reactor has been swept with dry air, thereby the reversibly and irreversibly adsorbed IPA has been quantified. Thereafter plasma was ignited under dry air (absence of IPA) with the power of 0.82 W. The removal efficiency of two different conditions has been reported in table 1.

As shown in table 1, Adsorption/Plasma treatment has shown 2 times higher IPA removal efficiency than continuous plasma treatment with same injected power. In addition to that, Adsorption/Plasma treatment has shown 50% less CO selectivity. Moreover, Adsorption/Plasma treatments have been studied for 4 consecutive cycles, and we have found that MnO₂ coated reactor has shown no change in adsorption capacity and product selectivity. In conclusion, Adsorption/Plasma treatment has shown better performance in regards of energy efficiency and product selectivity in comparison with continuous plasma treatment.

Table 1- IPA removal efficiency and product selectivity: comparison between continuous and Adsorption/Plasma treatment.

Pulsed plasma polymerization of propanethiol: correlation between plasma and film chemistries

T11 Plasma Science and Technology

#PST-3-Or-2

R. Snyders ¹, R. Francq ², M. Guillaume ¹, J. Cornil ¹, D. Thiry ¹.

¹University of Mons - Mons (Belgium), ²Materia Nova - Mons (Belgium).

Plasma polymerization of sulfur-based molecules such as propanethiol is a promising approach to grow thiol (-SH) supporting surfaces that can serve as nucleation centers for gold nanoparticles or for the immobilization of DNA molecules. However, despite the potential of such a kind of thin films, it is still necessary to get a deeper understanding of the fundamental mechanism occurring during the plasma polymerization of sulfur-based precursors.

In this work, propanethiol plasma polymers (Pr-PPF) were synthesized using a pulsed ICP plasma varying the mean power dissipated in the discharge ($\langle P \rangle$) in the range of 14-100 W. $\langle P \rangle$ was adjusted by varying t_{off} (0-3.6 ms) while keeping constant t_{on} and the peak power to 0.5 ms and 100 W, respectively. XPS measurements were performed in order to evaluate the chemical composition of the coatings. These data were correlated with the evolution of the plasma chemistry probed by mass spectrometry measurements in Residual Gas Analysis (RGA) mode and understood with the help of DFT calculations.

As a general trend, the sulfur-to-carbon ratio (S/C), measured by XPS, decreases as a function of $\langle P \rangle$ (From 1 to 0.38). An unexpected observation concerns the Pr-PPF synthesized at low $\langle P \rangle$ for which the S/C ratio (~ 1) is much higher than in the precursor (0.33). This behavior is explained by the trapping, in the Pr-PFF, of sulfur-based molecules presenting a high S/C ratio. RGA measurements support this explanation by revealing, at low $\langle P \rangle$, a strong production of H₂S in the plasma. On the other hand, ageing of these films leads to the "loss" of sulfur which again is consistent with the trapping of stable S-based molecules. For high $\langle P \rangle$ the plasma is dominated by CS₂ molecules illustrating the strong fragmentation degree of the precursor. The modification of the plasma chemistry and the higher interface temperature explain the lower S/C in these conditions.

Tailoring of the Degradation Processes at Photocatalytically Active Titania Thin Films

T11 Plasma Science and Technology

#PST/SE/TF-3-Or-7

E. Moser ¹, K. Ambord ¹, S. Chappuis ¹, V. Vishnyakov ².

¹University of Applied Sciences - Geneva (Switzerland), ²Dalton Research Institute - Manchester (United kingdom).

The photo induced benefits of titania thin films have been attracting increasing attention during the past years. In particular, the modification of the titania networks has intensely been investigated since it enables to shift the optical energy bandgap to the visible part of the light spectrum.

Recently, the deposition of photocatalytically active titania layers at ambient temperature has been developed using the reactive dc sputtering process and the metal organic chemical vapour deposition (MOCVD) method by increasing the working pressure up to atmospheric pressure for the latter method. [1]

In this work, the wettability and the chemical composition of the titania layers will be modified by adapting the deposition parameters and doping the titania layers using non-metallic elements. The produced titania thin films will be analyzed using AFM, XPS, FTIR, XRD, and Raman spectroscopy. The chemical reactivity and topography of the various titania surfaces will be investigated in detail. Insight into the incorporation of the doping elements and its consequences onto the photo induced properties will be highlighted.

Preliminary results regarding the mineralization of methylene blue dye and stearic acid by the titania thin films, irradiated under UV light at 365 nm and visible light at 428 nm, will be presented and correlated with the specific functional features of the different surfaces. In this way, the manufacturing of photo active titania layers may be directed towards specific anti-fingerprint and anti-microbial properties.

High entropy alloys deposited by magnetron sputtering

T11 Plasma Science and Technology

#PST/SE/TF-2-Or-6

P. Dutheil ¹, A.L. Thomann ¹, H. Hidalgo ¹, D. Depla ², F. Boydens ², M. Jullien ³.

¹GREMI - Orleans (France), ²Research Group DRAFT - Gent (Belgium), ³Institut Jean Lamour - Nancy (France).

In the 90s Yeh and al. proposed a novel alloy system called “high entropy alloy” (HEA) which contain 5 to 13 major elements (or multi principal elements), with concentrations ranging from 5 at. % to 35 at. %. HEAs exhibit very interesting properties, for examples: hydrophobicity, good temperature stability, high hardness, wear resistance and superplasticity and high corrosion and oxidation resistance. These properties are similar to those of Metallic glasses (MG) but kept at higher temperature. HEA mixing entropy is high, leading to the formation of random solid solutions (FCC or BCC) during solidification, rather than intermetallic compounds or other complex ordered phases [1].

Since 15 years many papers were published on the synthesis of HEA thin films, mainly dealing with the study of the features and properties modification when one of the element concentration is varied. Considering thin films, the challenge is not to stabilize low ordered forms, which is quite easy by working at low temperature, but rather to control the film features. All the reported works point out the complex relationship existing between chemical composition, structure and morphology of the films.

In this work, different studies on HEAs thin films grown by magnetron sputter deposition using powder targets will be presented. In fact, in order to scan a wide range of different compositions of thin films, elements powders were mixed in different quantities to obtain several target compositions. The complex relationships between crystalline structure, thin film composition and experimental parameters will be tackled as well as their influence on the hardness and hydrophobicity properties of HEA thin films.

DEVELOPMENT OF AN ICP-RF PLASMA SOURCE FOR THE STUDY OF HELIUM INSERTION IN TUNGSTEN

T11 Plasma Science and Technology

#PST-5-Or-3

L. Pentecoste ¹, A. Melhem ¹, A.L. Thomann ¹, P. Desgardin ², T. Belhabib ¹, M.F. Barthe ².

¹Groupe de Recherches sur l'Energétique des Milieux Ionisés, CNRS-Polytech'Orléans, 14 rue d'Issoudun, B.P. 6744, F-45067 Orléans cedex 2, France - Orleans (France), ²Conditions Extrêmes et Matériaux sous Haute Température et sous Irradiation, CNRS, 3A rue de la Férollerie, F-45071 Orléans, cedex2, France - Orleans (France).

Tungsten has been selected as a potential Plasma Facing Material in the future nuclear fusion reactor such as ITER. It is supposed to become the shield material for the Divertor and will be exposed to the most severe plasma conditions i.e. a bombardment of particles like neutrons, deuterium, tritium and helium. Helium ion flux interaction with a tungsten surface leads to a generation of vacancy defects and eventually larger defects like helium bubbles or vacancy clusters [1]. These defects affect the tungsten mechanical properties and can have an impact on yield and safety of the experimental reactor. The objective of this study is to study the first steps of the implantation process, i.e. at low ion flux and kinetic energy to avoid damaging of the material.

In this study, an ICP-RF plasma source has been built and developed at the GREMI laboratory of Orleans. Both Langmuir probe and Heat Flux Microsensor [2] techniques were used respectively to determine the Helium plasma parameters and to measure the global energy transfer from the plasma to the substrate surface. After helium plasma characterization, the tungsten samples were immersed in the plasma under $^3\text{He}^+$ flux with incident ion energy of the order of 320 eV. The helium behavior in tungsten was studied by using nuclear reaction analysis technique.

The ion flux accessible with the ICP source varies between 10^{11} to 10^{16} at.cm⁻².s⁻¹. From plasma characterization optimized implantation conditions were defined for

which ions do not encounter collisions during their acceleration in the sheath (comparing the Debye length to the mean free path of the He⁺). The kinetic energy of the ions is thus determined by the substrate bias voltage and can typically be varied between 50 eV to 500 eV. Measurement of the global energy transfer allowed isolating the specific contribution of the incident He⁺ ions. At substrate bias voltages lower than -50 V, it seems to be the main part of the global energy flux delivered to the surface. The first surface characterizations with NRA technique showed low He retention rates (below 10²¹ at/m²) similar to the ones presented by P-E. Lhuillier [3] in a previous study. Positron Annihilation Spectroscopy and Scanning Electronic Microscopy will be used to characterize respectively the vacancy defects induced in the tungsten surface and eventually helium bubbles formation.

Plasma mixtures containing chemically active species are used in many technologies. When studying processes in such plasmas, a macroscopic kinetic approach is often used. This technique is based on the system of chemical reactions between plasma species, from which the continuity equations for concentrations of individual species can be derived [1]. If the number of species in the model is moderate, the standard numerical methods can be used. However, due to high complexity of processes in many chemically active plasmas, the set of input chemical reactions has to be reduced before the model preparation and solving. In the literature, various techniques of model simplification, e.g. approaches based on the sensitivities of individual reactions, on the corresponding reaction rates or on methods of time-scale separation, can be found. In the present contribution we monitored the speed of every reaction during the kinetic calculation, resulting in weight factors of reactions describing the relative importance of individual reactions in the kinetic scheme. The goal was to preserve only the reactions influencing profoundly the resulting concentrations of main products.

The developed reduction technique was applied to the analysis of two different types of chemically active plasmas. The first system was obtained by the mixing of methane to the nitrogen flowing afterglow discharge [1]. The original kinetic scheme consisted from more than 250 chemical reactions. After the reduction only about 50-60 reactions found to be important. The second studied system was the active discharge in oxygen and argon-oxygen mixtures [2]. The input data for modelling were obtained from the measurements in a DC glow discharge in oxygen containing gas mixtures. The original kinetic scheme was reduced from about 160 reactions to less than 50 chemical reactions between the most important species. After the reduction of model complexity without significant loss of its preciseness, the residual

kinetic schemes of both of methane and oxygen containing mixtures can be solved by standard algorithms for solving stiff sets of differential equations.

In the main part of contribution the role of the most important chemical reactions in the dependence on various plasma parameters was discussed. The obtained results, i.e. the steady-state concentrations of individual species, were used as input data for 2D particle model [3] describing the sheath structure near substrates immersed into chemically active plasma in selected plasma-assisted technologies. Here the main studied question was the determination of the spatial distribution of fluxes of individual charged species to uneven substrates of complicated forms [4].

¹Institut des Matériaux Jean Rouxel - Nantes (France), ²CEA/LETI-DOPT - Nantes (France).

Etching mechanism of mercury cadmium telluride (MCT) has been investigated in hydro-carbonated based mixtures inductively coupled plasma (ICP). According to literature it can be described by the etching of HgTe and CdTe compounds [1][2]. Hg desorbs spontaneously from the surface. Te is etched by the formation of volatile TeH₂. Cd is assumed to form volatile metal organic species with methyl; this latter step limits the etching of MCT.

Methane-based plasma is compared to another methyl precursor gas (labelled B). The plasma phase is characterized thanks to electrostatic probes, optical emission spectroscopy and mass spectrometry. Etched samples are characterized by profilometry, SEM and XPS. Process parameters investigated are source power, pressure and sample bias.

In the same conditions of flow, pressure and source power, the positive ion flow toward the surface and the surface composition are very similar for the two gas precursors (Fig 1), the VI/II ratio is slightly lower in B-based plasma. In this mixture, methyl concentration is typically five times smaller than in the methane-based plasma. However the etch rate does not present such a difference.

On going work concerns quantitative evaluation of the ion and methyl fluxes for a better description of the plasma and the understanding of the etching mechanism. Our experimental results have been compared in the frame of the Mayer and Barker, ion assisted chemical etching mechanism model [3][4] (Eq 1) with a good qualitative agreement (Fig 2).

$$V_{\text{eff}} = \frac{V_{\text{ion}} \cdot \Gamma_{\text{M}}}{1 + \frac{V_{\text{ion}}}{V_{\text{M}}}}$$

Probe Diagnostics of RF Plasmas for Material Processing

T11 Plasma Science and Technology

#PST-1-Or-8

V. Godyak.

RF Plasma Consulting - Brookline, Ma (United states).

During the last decades, plasma processing of materials became a significant component of contemporary industries. Plasma chemistry, manufacturing of semiconductor chips, nanotechnology, and plasma treatment of organic and live tissues are well known examples of plasma processing. To control plasma interaction with materials, the knowledge of plasma parameters and their spatial distribution are vitally important. Typically, processing of low temperature plasma is characterized by a high degree of different kinds of non-equilibrium conditions. The electron temperature in such plasmas exceeds by far the temperatures of ions and neutral species. The electron energy distribution function is non-Maxwellian. The plasma parameters are not in temporal, nor spatial equilibrium with the electromagnetic field that maintains the plasma [1]. Today, numerical modeling is the main method of studying highly non-equilibrium plasma in plasma processing reactors. The validity of those codes for reactive plasmas has never been proved in experiments. The cross section data of some plasma-chemical reactions imbedded in these codes are frequently ambiguous. Moreover, many of these codes are missing effects of non-local electron kinetics and non-local electrodynamics, which both play important roles in rf plasmas at low gas pressure [2]. Most universal and informative diagnostics for low temperature non-Maxwellian plasma at low gas pressure is the Langmuir probe in its Druyvesteyn modification. Contemporary probe diagnostics requires probe measurement of the electron energy distribution function, EEDF, from which the plasma parameters and the rates of plasma-chemical reactions are found as appropriate integral of the measured EEDF [3]. This approach has been successfully implemented for laboratory plasma experiments with noble gases at moderate rf power. However, attempts to implement the same probe diagnostics routine in plasma reactors with chemically active molecular gases have failed due to various kinds of distortions in probe measurement. There are three major problems in implementing meaningful probe diagnostics in rf plasma reactors. They are: 1) a wide frequency spectrum with significant amplitudes of the plasma rf potential corresponding to the rf power and rf bias fundamental frequencies and their

harmonics; 2) contamination of the probe surface with a low conductive layer of the reaction products; and 3) high impedance between the plasma and grounded chamber due to chamber contamination or/and to artificial protective chamber coating. In this presentation, we consider the ways to resolve those issues and illustrate their effectiveness in obtaining undistorted EEDFs with high energy resolution and large dynamic range, in different kinds of rf plasma reactors.

Ion Temperature Measurement in the Plasma of an ECR Ion Source by Means of Precision X-Ray Spectroscopy

T11 Plasma Science and Technology

#PST-1-Or-9

C. Szabo-Foster ¹, P. Amaro ², M. Guerra ³, A. Gumberidze ⁴, P. Indelicato ¹.

¹Laboratoire Kastler Brossel - Paris (France), ²Physikalisches Institut, Heidelberg University - Heidelberg (Germany), ³Centro de Física Atómica, Departamento de Física, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa - Lisboa (Portugal), ⁴ExtreMe Matter Institute - Darmstadt (Germany).

In our laboratory we are performing precision x-ray spectroscopy of highly charged ions (HCI) to prove quantum electrodynamics calculations. (QED tests). For these precision measurements down to the ppm level we have developed a double crystal spectrometer (DCS) to allow absolute measurements (without the use of an external reference) and we attached the DCS to an Electron Cyclotron Resonance Ion Source (ECRIS) to directly observe the HCI of the ECR plasma.

Measuring the broadening of transitions in highly charged ions (HCI) in the plasma of an Electron Cyclotron Resonance (ECR) ion source can provide an experimental method for the determination of the natural line widths of these transitions in the x-ray energy range. The energy of the $1s2s\ 3S1 \rightarrow 1s2\ 1S0$ “relativistic” M1 line in He-like Ar has been recently measured by our group in the “Source d’Ions Multichargés de Paris” (SIMPA) ECR ion source, at the Laboratoire Kastler Brossel (Ecole Normale Supérieure, Université Pierre and Marie Curie and CNRS), to a 2.5 ppm precision without the use of an external reference [1]. This measurement has been performed directly on the plasma of an ECR ion source with a vacuum double crystal spectrometer [2]. The M1 transition in He-like Ar has a very small (calculated) natural width ($\sim 10^{-7}$ eV), which can be considered negligible for the purposes of our investigations. By defining the response function of our double crystal spectrometer with the help of a Monte Carlo Simulation code we have obtained ion temperatures inside the ECR plasma from the determined Doppler broadening of the M1 line.

Within our robust analysis, simulations are run for various Doppler and Lorentzian input distributions. An average value of 81 ± 12 meV was found for the Gaussian width of the M1 line in the ECRIS plasma during our measurements, which provides a lower than expected ion temperature for He-like Ar ions inside an ECR ion source. This method can be extended to lines with non-negligible natural line widths and provide experimental values for these widths.

Langmuir-probe analysis of photoemission-assisted Ar plasma for planarization process

T11 Plasma Science and Technology

#PST-2-Or-9

S. Ajia, Y. Ohtomo, S. Ogawa, Y. Takakuwa.

Tohoku University - Sendai (Japan).

A photoemission-assisted (PA) Ar plasma, which is DC discharge plasma triggered by the photoelectrons emitting from the substrate irradiated with UV light as shown in Fig.1, has been developed to make the substrate surface morphology flattened in an atomic scale for applications of surface activated bonding and DNA chips. Hereafter this is called “ a dry planarization process”. In the previous reports [1], it was demonstrated that the surface roughness is considerably improved for the Al and Cu substrates by this dry process. In this study, we measured the plasma potential distribution of the PA Ar plasma by using a Langmuir probe to estimate the kinetic energy E_k of Ar^+ ions impinging on the substrate.

In the PA Ar plasma apparatus, a Xe excimer lamp with UV light ($\lambda = 172$ nm) was employed, leading to the order of 10^{12} photoelectrons/cm²/s, which enabled us to generate uniformly a glow discharge on a 2-inch Si wafer at bias voltage V_B of 120 V and Ar pressure of 100 Pa, and to increase a discharge current up to 10^{-6} - 10^{-4} A at smaller V_B than 120V, which is referred to as Townsend plasma. A Langmuir probe was made of W with 0.8 mm in diameter. Its position was precisely adjusted with a X-Y-Z manipulator between the Si wafer and the Cu electrode with 29 mm in distance. As shown in Fig. 2, the plasma potential distribution is almost flat for the glow discharge at V_B of 150 V, suggesting that an ion sheath is thinner than 1 mm. On the other hand, a plasma potential gradient of the Townsend discharge at V_B of 60 V is almost the same as the calculated electric potential distribution, implying that there is no ion sheath effectively. Taking the energy loss due to elastic collisions between Ar^+ ion and Ar atom into account, we estimate the E_k of Ar ion upon the impingement with the substrate to be 0.23 and 8.9 eV for Townsend and glow discharge, respectively, and a surface flattening model of the dry planarization process is discussed.

From an industrial point of view, there is an increasing interest to control the surface functionalities and the surface properties of all kind of materials. In particular, an increasing demand is registered to develop high-function textile products. The new generation of manufacturing processing that includes plasma treatment ensures flexibility of the technology and possibility of easy adaptation for application of different finishing methods to meet variable consumers' requirements [1].

Recent development in the field of atmospheric plasma technology is creating new perspectives for surface treatment of materials [2]. By controlling the atmospheric gas and electrical conditions, one can significantly increase the efficiency of the plasma surface treatment. Besides, by adding reactive chemical precursors to the plasma discharge, the surface chemistry can be controlled and thin functional coatings can be deposited. A wide number of monomers can be used as precursors to incorporate functional groups on various surfaces.

In this study, plasma polymers of allylamine were deposited by using an atmospheric pressure plasma jet. Firstly, we have investigated the influence of different external plasma parameters (like deposition time, precursor flow rate, substrate-plasma distance, power frequency...) on the final thin film properties. Physical and chemical properties of the deposited thin films were characterized by several characterization techniques such as ellipsometry, infra-red spectroscopy, SEM or XPS.

Then, examples of potential applications of this amine-containing atmospheric plasma functional coating will be given. First, polyamide microcapsules are immobilized onto plasma treated cotton surfaces via amide linkages which guarantee high durability and accessibility. Secondly, dyeing properties of cotton textile could be enhanced and the dyeing process mainly occurs through the plasma treated regions.

These results show that atmospheric plasma is a promising process for the fabrication of functional coatings on textile substrates and has immense potential for future industrial applications.

³Chimie des Interactions Plasma Surface (ChIPS), CIRMAP, Université de Mons, 23 Place du Parc, B-7000 Mons, Belgium / Materia Nova Research Center, Parc Initialis, B-7000 Mons, Belgium - Mons (Belgium).

Keywords: microwave discharge, CO₂ conversion, exhaust gases, optical diagnostics

The recent results on the time-resolved optical diagnostics of CO₂ containing pulsed surface wave-sustained microwave discharges working at 2.45 GHz and operating at moderate pressure (~ 5 Torr) are presented. The plasma was sustained in the flowing CO₂ and CO₂+N₂ gas mixtures in a quartz tube crossing a waveguide [1]. The characteristic plasma temperatures, namely the gas temperature (via the N₂ and CO rotational temperatures), and N₂ vibrational temperature are determined as a function of time at different axial positions along the discharge tube. Besides this, the space-resolved measurements of CO₂ conversion rate through the discharge volume, as well as the measurements of energetic coefficient of plasma efficiency for such a conversion are performed using optical actinometry. For the last purpose, assuming low decomposition rate of molecular nitrogen during the plasma pulse, N₂ molecule is utilized as an actinometer [2,3] to determine the CO density, as one of the products of CO₂ decomposition [4]. The validity of this method has been analysed for the described experimental conditions based on the assumption of a steady state of actinometric signal achieved during the discharge pulse. The results show a non-uniform dissociation rate of CO₂ that grows from the upper to the bottom part of the discharge tube, where it saturates. The dissociation degree is substantially modified by the variations of the power balance and the composition of the gas mixture.

The results are compared to those obtained by means of the gas chromatography in a 0.9 GHz microwave discharge, showing a good agreement between these two microwave plasma discharges in terms of CO₂ conversion.

Plasma-assisted deposition of polymethyl methacrylate on titanium substrates

T11 Plasma Science and Technology

#SE/PST/TF/BI-2-Or-9

N. De Geyter, P. Cools, E. Vanderleyden, P. Dubruel, R. Morent.

Ghent University - Ghent (Belgium).

Plasma polymerization is a unique technique to fabricate thin polymer films from a wide variety of organic and organometallic precursors [1]. Plasma polymerized films are pinhole-free and highly cross-linked and therefore insoluble, thermally stable, chemically inert and mechanically tough. Furthermore, such films are often highly adherent to a variety of substrates including conventional polymer, glass and metal surfaces [2]. Due to these excellent characteristics, plasma-polymerized films have been used in a wide variety of applications including barrier coatings, protective coatings, selective permeation membranes and dielectric layers in microelectronics [3]. Besides these well-known examples, state-of-the-art applications are continuously being developed, especially in the biomedical domain. Generally, a large part of research related to plasma-assisted thin film deposition has involved low pressure non-thermal plasma technologies. Although vacuum treatment processes afford good control over gas chemistry and provide the possibility of using high energetic species (in the range of several eV to hundreds of eV) in the deposition process, atmospheric pressure processing techniques are offering specific advantages, such as the elimination of expensive vacuum equipment, easier handling of the samples and scalability for industrial on-line processing [4,5]. Therefore, in recent years, a lot of effort has been put into the development of non-thermal plasma reactors for thin film deposition working at or near atmospheric pressure.

This paper will focus on the formation of coatings in an atmospheric pressure dielectric barrier discharge (DBD) using methyl methacrylate (MMA) as gaseous precursor. Plasma polymerized films will be deposited onto Ti samples, which is a common material used for artificial hips. Depositing a polymethyl methacrylate (PMMA)-like coating onto Ti can improve the fixation of artificial hips, since the bone cement used to fixate the hip into the human body normally consists of MMA or PMMA. In this work, the chemical and physical properties of the obtained PMMA-like

coatings will be discussed in detail using Fourier transform infrared spectroscopy (FTIR), X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM).

PST-P3-08

Characterization of Surface Dielectric Barrier Devices for Aerodynamic and Acoustic Applications

T11 Plasma Science and Technology

#PST-P3-08

I. Biganzoli, R. Barni, C. Riccardi.

Dipartimento di Fisica Occhialini, University of Milano-Bicocca - Milan (Italy).

Atmospheric pressure dielectric barrier discharges (DBDs) are widely employed as cold plasma sources for plasma processing and applications [1]. In a Surface Dielectric Barrier Discharge (SDBD) device two electrodes are placed at the opposite sides of an insulating material and a plasma is created by the ionization of a thin air layer just above the dielectric surface.

The non-thermal plasma state allows these devices to be used in presence of thermodegradable materials or living tissues, rendering them suitable for many applications such as surface treatment and sterilization. However, at present SDBDs are mainly known in the field of cold plasma aerodynamic applications, being these discharges particularly suitable in energizing the boundary layer of airflows surrounding a body, and thus in the active flow control field [2]. As a matter of fact, many experimental studies have proved that SDBDs can generate an induced airflow of several m/s. This induced airflow can favourably interact with an external wind and provide, for instance, stall prevention, lift enhancement or drag reduction. It is evident that the aeronautical sector can take many benefits from the application of the so called plasma actuators. However, the growing interest for these devices is also due to the environmental benefits they can deal to. As a matter of fact, apart from the fact that drag reduction can result in fuel and thus pollution reduction, it is known that the problem of acoustic pollution affecting an airport neighbourhood is mainly due to the the airflow detachment occurring in correspondence of an aircraft bluff body (such as a landing gear).

For these kinds of applications, plasma is generally created in correspondence of just one side of the insulating barrier, so one electrode is buried into a dielectric frame whereas the other one is exposed to air. When the device is fed with a sinusoidal high voltage supply some differences in the plasma properties result from this asymmetric configuration. The discharge has been characterized by electrical diagnostics, in particular Rogowski coils have been adopted for measuring the

electrical current flowing into the circuit, which is the superimposition of a low frequency capacitive current, almost independent of the plasma presence, and of a discharge current appearing as a series of fast pulses [3]. A high temporal resolution has been achieved and a statistical analysis has been implemented to evaluate some properties of these current peaks, as well as their distribution in the course of the voltage signal. This allows to evaluate the entity of the asymmetry between the two discharge semi-cycles, which depends on the electric field configuration inside the gap. A change in the dielectric properties and in the electrode configuration influences some plasma properties (such as the intensity of the current pulses or their frequency of appearance) as well as the discharge asymmetry. This electrical characterization is useful not only because the physics of these devices is not completely understood, but also because it allows a better understanding of how aerodynamic effects are correlated to the discharge properties.

There has been much interest in gliding arc discharge plasma due to its potential for pollution control of exhaust gas decomposition, material processing, surface treatment and biological application such as sanitization, the sterilization. [1,2] It is well known that the gliding arc discharge starts from breakdown of atmospheric gas at the shortest gap between two divergent electrodes under DC or AC power supply and it glides along the same direction as the gas flow. However, our study on simultaneous observation of the dynamic behavior of the plasma path via a high speed camera and the corresponding electrical properties revealed that the plasma path was very complicated due to gas turbulence and reconnections were repeated especially in high gas flow to maintain plasma. Moreover, the plasma impedance was not as low as that of normal arc discharge because plasma length increased with gliding.[3,4] Therefore, we call this plasma as serpentine plasma. A serpentine plasma discharge was nonequilibrium, a kind of the non-steady discharge, and a large number of applied research works has been performed as a gliding arc discharge. Many studies relate to decomposed chemical species, and there are a few papers about the discharge mechanism. We carried out the observation using a high-speed camera (Max frame rate of 1300000 fps) about the discharge mechanism of the serpentine plasma discharge without any kind of pre-ignition system. It was confirmed by using the high speed camera where paths of discharge between electrodes existed temporally. This measurement had been performed in the serpentine plasma discharge system of 2, 3 and 6 electrodes type. However,

discharge voltage rose when a pre-ignition did not exist in comparison with the system which equipped pre-ignition system. In this study, it was proposed a new pre-ignite process which was not based on an electric discharge, and the discharge mechanism with multi electrode (3 and 6) type was confirmed by a high speed camera and I-V characteristics simultaneously.

PST-P3-16

Template-free elaboration of polyaniline nanofibers by cold plasma

T11 Plasma Science and Technology

#PST-P3-16

A. Zaitsev ¹, A. Lacoste ², F. Poncin-Epaillard ¹, D. Debarnot ¹.

¹LUNAM Université, UMR Université du Maine, CNRS 6283, Institut des Molécules et Matériaux du Mans (IMMM), Département Polymères, Colloïdes et Interfaces (PCI), Avenue Olivier Messiaen - Le Mans (France), ²Laboratoire de Physique Subatomique et de Cosmologie, Université Joseph Fourier Grenoble 1, CNRS/IN2P3, Institut Polytechnique de Grenoble, 53, Avenue des Martyrs - Grenoble (France).

The interest of one-dimensional materials has been demonstrated in a great number of applications due to their high shape factor and sometimes, new properties.

The objective of this work is to synthesize polyaniline nanofibers thanks to the plasma technique without using any template. To get such architecture, a metallic catalyst (Pd) is used. Two ways of catalyst deposition are considered: by the means of chemical deposition from a colloidal solution and by physical vapor deposition (PEPVD). The catalyst forms a discontinuous layer on the surface of the substrate, in the form of nods with controlled size. This can be done by controlling the size of the colloidal particles and deposition time in the case of chemical deposition and by controlling the plasma conditions (such as target biasing, power supply), and deposition time in the case of sputtering.

The polymerization of polyaniline is conducted by chemical vapor deposition (PECVD) thanks to a reactor that provides the possibility of PEPVD and PECVD. It uses the multi-dipolar microwave-assisted excitation source that offers uniform plasma at low precursor pressures (0.01 Torr) and low energy supply (60W). Also the advantage of this method is that the substrate is situated out of the plasma phase that prevents the polymer from the degradation. The control of the polymer growth consists in the control of process parameters such as the discharge power, the monomer flow, the substrate bias and the deposition time.

The morphology of the catalyst and the polymer is studied by the means of scanning electron microscopy (SEM) and atomic force microscopy (AFM). The chemical

structure of the fibers is studied by Fourier transform infrared spectroscopy (FTIR), X-ray photoelectron spectroscopy and UV-Vis spectroscopy.

Plasmid DNA degradation induced by atmospheric pressure microplasma jets

T11 Plasma Science and Technology

#SE/PST/TF/BI-1-Or-5

C. Douat ¹, J. Santos Sousa ¹, L. Tessier ², G. Bauville ¹, M. Fleury ¹, P.M. Girard ², V. Puech ¹.

¹LPGP, CNRS & Univ. Paris-Sud - Orsay (France), ²Institut Curie - Orsay (France).

In the last few years, atmospheric pressure microplasma jets have sparked considerable interest because of the possibility of propagating non-thermal plasmas in open air. As so, reactive plasma species (viz. radicals, positive or negative ions, electrons, UV radiation), and not only long-lived afterglow species, can be delivered, at ambient pressure and temperature, to targets located some centimeters away from the main discharge zone. This property opens up a host of new and fascinating possibilities including, among others, localized surface treatment in 2D and 3D (for cleaning and thin film deposition), production of nanomaterials, decontamination, and biomedical applications (odontology, dermatology, cancer research,...). To get a better insight into the biomedical effects of plasma jets, fundamental studies on the interaction of the microplasmas with biological structures are essential. In this context, we have exposed plasmid DNA to a plasma jet.

The studied plasma is created by a dielectric barrier discharge (DBD) with an axial symmetry. Indeed, our microjet device consists of concentric tubular electrodes separated by a dielectric cylindrical structure. The dielectric tube is made of quartz, and has inner and outer diameters of 2 and 4 mm, respectively. A grounded electrode is wrapped around the external side of the dielectric, while a high voltage electrode is glued inside the tube. Pure helium is flowing through the inner electrode at a flow rate in the range 100–1000 cm³/min. High voltage pulses (3–6 kV) are applied between the electrodes at a repetition rate frequency of 20 kHz. The created plasma propagates in surrounding air. Experiments have also been performed with low O₂ admixture (<3%).

The plasma jet is set up vertically with the gas flowing downwards for interaction with plasmid DNA solutions (200 μL of buffer solution with a plasmid DNA concentration

of 20 mg/L) placed inside micro-wells or Eppendorf tubes. The damages to the DNA (oxidized bases, strand breaks, abasic sites) have been analyzed through specific enzymes (Fpg, Nth and Ape1) by agarose gel electrophoresis. Different buffer solutions have been used in order to identify their influence on the DNA degradation. It has been found that most of the damages were direct single and double strand breaks, while the oxidation of the amino-acid bases was of minor importance. The nature of the buffer solution does not change the nature of the DNA damages. However, in order to get a given amount of DNA damages, different exposure times have been required for the several buffer solutions used. It will also be shown that the observed DNA damages result from direct interaction of the plasmid DNA with the plasma jet, e.g., without the participation of by-products from the buffer solution.

PST/SE/TF-3-Or-2 PREPARATION OF DIFFERENT ANTIBACTERIAL POLYETHYLENE TEREPHTHALATE BY PLASMA TECHNOLOGY

T11 Plasma Science and Technology

#PST/SE/TF-3-Or-2

**F. Poncin-Epaillard¹, D. Debarnot¹, M.J. Perez-Roldan¹, J. Tarrade²,
E. Guittard², F. Guittard², T. Darmanin².**

The bacterial adhesion and the formation of biofilm are natural and spontaneous processes. These phenomena happen whatever the nature of bacteria, surrounding fluids and receiving substrates (plastics, metals, glasses, ...). The mechanism of biofilm formation proceeds in four steps: transport, adhesion, strengthening and colonization. Bacterial adhesion depends on physico-chemical interactions between the bacteria and the receiving substrate. The nature of the substrate and its surface characteristics, such as superhydrophobic or superhydrophilic character, can affect the development of a biofilm. In both cases, the wetting is reduced and associated with the chemical functionality of the coating and its roughness adapted to the size of the bacteria, which is less than 1 micrometer. Therefore, polyethylene terephthalate (PET) foils surfaces were modified by plasma treatment in order to increase or to decrease the surface wettability and to tailor the surface roughness. Nanostructured and hydrophilic surfaces were obtained with both He and O₂ plasma treatments showing features around 45 and 85 nm. A posterior step was carried out by grafting the treated surfaces with polymer solutions in order to modify the surface free energy values. Treated surfaces were grafted with pluronic F108 and F68, polymers well known by their protein repulsive properties and by mixed solutions of pluronic and surfactants. Three different surfactants were selected, nonaethylene glycol monodecyl ether (C12E9), sodium taurodeoxycholate (STDC) and hexadecyltrimethyl ammonium bromide (CTAB) in order to characterize the effect on the surface free energy values of nonionic (C12E9), anionic (STDC) and cationic (CTAB) surfactants on the grafting with pluronic-surfactant mixed solutions. The grafting homogeneity was studied by pico-contact angle mapping and the ageing

of grafted surfaces was also studied, showing a good adherence of grafted polymers on the hydrophilic surfaces. Besides, remarked variations on the surface free energy parameters were obtained, specially with surfaces grafted with pluronic-CTAB solutions. Besides, the bioadhesive properties of grafted surfaces will be characterized.

Among the methods allowing to structure and functionalize surfaces in order to make them superhydrophobic, plasma is a simple, inexpensive and perfectly manageable method. In order to create the roughness, oxygen plasma is first performed on a PET substrate. Then, the surface is composed of microfibrillars involving a nanostructuration. After, the modified surface is hydrophobized by pyrrole plasma deposition so as to obtain superhydrophobic PET. Each surface-modification was characterized by wettability measurement, AFM and XPS showing the characteristics of superhydrophobic surface whose antibacterial behaviour was tested.

PST/SE/TF-2-Or-5

Study of polymers surfaces metallization by plasma processes

T11 Plasma Science and Technology

#PST/SE/TF-2-Or-5

C. Lambaré ¹, P.Y. Tessier ¹, F. Poncin-Epaillard ², D. Debarnot ².

Today, the metallization of plastics materials deals with a lot of industrial applications in the field of automotive, optic, electronic, etc. Nowadays, for industrial applications, the metallization of non conductive substrates (such as polymers) is generally performed by a chemical and/or electrochemical process. These chemical pathways imply the use of hexavalent chromium (CrVI), a molecule which is carcinogenic, mutagenic and toxic for the reproduction, during the surface etching before film deposition.

The aim of this project is to develop one or more innovative processes allowing free of CrVI. To address this problematic the plasma technology considered. The study is focused on: ABS (acrylonitrile butadiene styrene), ABS/PC (acrylonitrile butadiene styrene / poly carbonate) and PEEK (poly ether ether ketone) polymers used by industrial partners of this project. The first metallic layer is a copper layer. Two pathways are studied to carry out the deposition of the first thin conductive metal layer (so-called primary adhesive layer). This layer is elaborated either by plasma activation of the surface followed by metallic deposition by magnetron sputtering or by plasma enhanced chemical vapor deposition using an organometallic precursor.

The first way consists on a plasma activation of the surface followed by a metallic deposition by magnetron sputtering of a copper target. First of all, surfaces are treated by a radio frequency (13.56 MHz) plasma treatment under argon in order to improve the adhesion of the metallic layer. The characterization by wettability measurements (performed at different scale) highlights that the dependence of the hydrophilic properties of the plasma-treated surface on discharge power, gas flow, gas nature and duration. Plasma parameters were optimized during this study in

order to increase the surface energy. A roughness study has also been done before and after the treatment. Then, after the plasma treatment, polymers are coated with a thin copper layer by magnetron sputtering. The copper layer deposition parameters are also studied. The adhesion of the metallic layer is then evaluated with different tests as: pull off test, immersion in industrial partners' chemical baths used for the thick deposition of metallic layers. This study shows an improvement of the adhesion of the metallic layer with plasma-activated polymers.

The other way consists of a radiofrequency plasma-enhanced chemical vapor deposition of a copper layer using an organometallic precursor. The organometallic precursor used is copper acetylacetonate and depending on plasma parameters, the plasma-deposited metallic layer is characterized by XPS, adhesion tests, SEM, etc.

This work was supported by Région Pays de la Loire within the framework program COMPLIMA.

Optical and electrical study of RF plasma for nanotubes film growth and correlation with resulting nanostructures properties

T11 Plasma Science and Technology

#PST-P3-17

M. Gaillard, T. Labbaye, E. Kovacevic, N. Semmar, A. Petit, C. Boulmer-Leborgne.

GREMI - Orleans (France).

The heat transfer study is of prime importance in the microelectronic field because of continuous components size decrease. The heat generated by the active zones reduces systems performance and increases energy consumption. The carbon nanotubes (CNTs) are potential candidates to improve current technology as they behave simultaneously as current and heat conducting material. They are studied in order to be integrated into microelectronics circuits as interconnects between components and support.

Their electrical and thermal properties are function of their microstructure as outer and inner diameter, of their morphology, also function of their surfacic density. The microstructure of CNTs is due to the choice of substrate and catalyst materials [1] and of process parameters chosen.

A low-pressure RF plasma is used to grow densely packed vertically aligned CNTs by plasma enhanced chemical vapor deposition. This study is focused on the influence of the plasma parameters on the morphology of nanotubes and the properties of films. Sets of substrates (TiN, Si₃N₄, TiNi and TiNiCu) and catalysts (Fe and Ni) systems are chosen in agreement with our partner STMicroelectronics, and remain fixed for the study. The catalyst is deposited by pulsed laser deposition technique with fixed parameters. Then the RF power (from 15 W to 200 W), the polarization of substrate (from 1 W to 100 W), the gas flow (from 15 sccm to 100 sccm), H₂/C₂H₄ gas ratio (from 1 to 4) and finally the pressure (from 0.5 mbar to 10 mbar) are varied.

The CNTs films morphology and microstructure are characterized by SEM and TEM. The electrical properties are checked with the four-probe technique and the thermal

properties are identified with nanosecond pulsed photothermal pyrometry experiments in the IR range [2].

Nowadays, the use of bio-based materials is of great interest and the finding of environmentally-friendly techniques for their processing is of major importance. Plasma polymerization arises as a good alternative for the development of ultra-thin films as this is a non-toxic, solventless and low energy-demanding process. Maleic anhydride (MA) is one of the most studied precursors in plasma polymerization, due to its high reactivity and versatility under pulsed plasma excitation [1-3]. Cellulose nanowhiskers (CNWs) are excellent materials for the development of bio-based nanocomposites. Besides of the intrinsic characteristics of low density and biodegradability of cellulose, CNWs characteristics of high crystallinity and high aspect ratio result in outstanding properties like very high tensile strength and Young's modulus, which are highly demanded in nano-reinforcing fillers for materials [4,5]. In this work, we propose the synthesis of CNWs/plasma polymerized nanocomposite films. The morphology of the obtained ultra-thin film is organized in thermo- and water-sensitive superstructures showing different patterns such as fibrillar superstructures, fractal "trees", and ring structures depending on process parameters and exposure to heat and water. In addition, some fundamental studies were performed in order to investigate the driving forces behind the formation of such structures.

Plasma copolymerization is nowadays considered as a promising and versatile technique for the deposition of thin films because of its possibility to prepare tailored films with pre-defined surface characteristics. The plasma copolymerization of monomers with different physico-chemical characteristics (eg polar and non-polar) has recently received a lot of attention due to the possibility to combine the properties of each of the monomers which provide a defined surface functionalized and structured.

The present work aims to elaborate thin films of amphiphilic copolymer with chemical and morphological structuration. In this frame, plasma polymerization and copolymerization of 2-(N,N-dimethylamino) ethyl methacrylate (DMAEMA) as polar monomer and heptadecafluoro-1-decene (HDFD) as apolar monomer, under low pressure RF reactor using pulsed mode have been realized. The characterizations of thin layers were done through contact angle goniometry, profilometry, Fourier transform infrared spectroscopy (FTIR), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM) and scanning electron microscopy (SEM). The plasma polymerization study of this couple of monomers showed the catalytic role of fluorine groups leading a more consequent deposition rate for pp-HDFD than for pp-DMAEMA. Even if the growth is significant during the time of discharge, the deposition rate is not negligible during the post-discharge time. The chemical structure of plasma polymers is highly dependent on the plasma parameters and mainly the power and time of discharge. The FTIR spectroscopy has revealed as a powerful tool for evaluating the chemical structure retention of the monomer entity in the plasma polymer. These polymers present a homogenous morphology without roughness.

The plasma copolymerization of these comonomers (p-DMAEMA-co-HDFD) at different ratio showed a kinetic of deposition and surface properties between the two polymers. The different chemical analyses taken at different plasma parameters present a chemical structuration and the formation of a mixture of polymers or a block copolymer but not alternating or random copolymers. The AFM results showed a morphologic structuration and a phase microseparation in the amphiphilic copolymer coating due to the chemical incompatibility between the hydrophilic component (pp-DMAEMA) and the hydrophobic one (pp-HDFD). Some results on plasma copolymerization using other monomers than DMAEMA and HDFD will also be presented.

#PST/SE/TF-1-Or-5

D. Ben Salem, J. Pulpytel, F. Arefi-Khonsari.

3492 - Paris (France).

Polyamide 6 (PA6) substrates were treated using an atmospheric pressure pulsed-arc plasma jet working with air (fig.1). The samples were treated with a pulse frequency between 21 and 25 kHz for different jet speed ranging from 3 to 30 m/min, enabling very short treatment times around 100 ms. Polyamide 6 has two major crystalline forms, i.e. α and γ which are highly dependent on the cooling speed and thermal treatment [1]. With this fast and innovative process, it was shown that the plasma treatment increased the oxygen concentration of the polymer surface through the formation of carbonyl and carboxylic groups, involving a higher surface energy but also modified the topology of the surface. The latter was mainly due to the thermal component of the plasma jet. [2]. Polymorphism modifications were investigated and linked, along with the other surface properties, to the self-adhesion properties of PA6. Depending on the surface treatments, the relative contents of α and γ PA6 were evaluated using XRD. The results shows that a low jet speed, i.e. long treatment time, corresponding to a more intense heating of the surface, favors the form α . Surface chemistry of the plasma treated polyamide 6 was also studied by XPS and FTIR measurements showing an increase of the hydrophilic groups on the surface. A Gaussian curve fitting method of the infrared spectra has also been investigated to estimate the α/γ crystalline phase ratio. The obtained results were in agreement with the polymorphism modification observed by XRD. Moreover, the surface morphology was also studied by SEM and AFM, and the results showed that low speed and high frequency treatment induced an important increase of the surface roughness, due to the etching of PA6 by the reactive species produced in the plasma.

The self-adhesion properties of the surface were finally linked to the treatment conditions. As expected, adhesion increased with the introduction of chemical polar groups at the surface and with a higher roughness. Moreover, one can suggest that the plasma treatment induces some chain rotation and reorganization of the

hydrogen bonds which can affect the adhesion properties.

Atmospheric pressure plasma treatment of flat surfaces emerged in the last years as a promising technique for surface modification of organic [1] and inorganic [2] materials, in order to improve their properties and further processability. Nevertheless, the use of cold plasma sources operating at atmospheric pressure for powder functionalization was less investigated. In this context, the present contribution focuses on the modification of micrometric size commercial tungsten powder by using an atmospheric pressure plasma jet working in argon or in admixture with reactive gases.

A fluidized bed reactor was implemented for the tungsten particles treatment. The system consists in a vertically placed cylindrical quartz recipient, used as fluidization chamber, a plasma source based on a radiofrequency discharge with bare electrodes for plasma jet generation [3], an adapting device between them and a separate particle trap on the gas exhaust path. The adaptor was provided with two ports, one for the admission of reactive gases in the chamber, and the other one for the gas exhaust. The vertically plasma jet is directed toward the reactor bottom where the powder is placed, thus providing a drag force adequate to circulate the particles in the jet and expose their surface to plasma species. In order to induce various chemical modifications of the particles surface, discharges were generated in several gases and mixtures, namely argon, argon/nitrogen, and argon/oxygen. Additionally, acetylene was admitted in the fluidization chamber during plasma working in argon and argon/nitrogen, in order to assess the possible carbon deposition process on the particles surface, while preventing the carbon formation inside of plasma source.

The results showed that the fluidization process lead to the transport of small tungsten particles outside the fluidization chamber. Two sets of particles were obtained: one remained in the fluidization chamber and another transported to and collected from the trap. Concluding, the fluidization can be used to separate the particles according to their size. The as received and plasma treated tungsten powders were investigated with respect to the morphology, composition and chemical bonding by means of SEM, EDX and XPS measurements. The compositional characterization evidenced the reduction of oxygen content on the tungsten surface upon argon plasma treatment and respectively their enhanced oxidation when argon/oxygen admixture is used. When acetylene is injected in the fluidization chamber during plasma treatment in argon and argon/nitrogen admixture, the particles are covered with carbon layers.

Motivation

For the last two decades, atmospheric plasma processes have demonstrated their good efficiency for the removal of a single pollutant [1]. However studies on simultaneous removal of several pollutants by this type of discharge are still scarce. This work proposes to study experimentally and by modeling the degradation of acetaldehyde and acetylene, two representative molecules of volatile organic compounds [2], using an atmospheric pressure pulsed plasma at room temperature.

Experimental and modeling conditions

Generated by a Marx generator, the nano-pulsed atmospheric plasma discharge is occurring in a N_2 gas flow with oxygen (5%) and 1000 ppmC of an equimolar pollutants mixture. The process efficiency is evaluated by measuring pollutants residual concentrations and the end products selectivities as a function of the input energy (expressed in J/L). To improve the description of the chemical phenomena occurring in the plasma, a quasi-homogeneous 0D model taking into account 90 species involved in 460 reactions has been developed [3-5].

Results

As a main result, we observed that the measured residual level, at the reactor exit, of each pollutant individually injected is very close to the rate measured when both pollutants are injected together. Moreover, we did observe a good agreement between computed and experimental results for pollutants removal as a function of the specific input energy (see figure 1).

Thus, a analysis of the consumption flows of the two pollutants and production of by-products, computed by the model, will be proposed and discussed. One of the main conclusions is that acetaldehyde is mainly decomposed during the pulse period by short life species like N_2 metastable states or electrons, whereas acetylene is mainly consumed during the post discharge phase by long life oxygenated species as O and OH.

Dust particles are produced by PECVD in a RF capacitive discharge (13.56 MHz) under a pressure of 120 Pa in pure CH₄ injected with a constant total flow rate of 5.6 sccm (9.45×10^{-3} Pa. m³.s⁻¹). Throughout our experiments, the 13.56 MHz RF power is 80 W. The study is based on the discharge duration (2 - 15 min) in order to show the electrode surface effect on the particle formation.

The CH₄ dissociation in the discharge leads to the formation of both particles in the plasma and coating on the powered electrode [1,2]. The surface of the RF electrode modifies the discharge parameters and the particle formation. The time evolution of the electrical characteristics of the discharge is investigated. The plasma is analysed by Optical Emission Spectroscopy (OES). Spectroscopic parameters (such as electron number density and excitation temperature) are determined during discharge processing. Mass Spectrometry of neutral species and ions is used to understand the generation and growth of particles within the plasma [3].

At the end of each experiment, particles and coating are collected. Scanning Electron Microscopy (SEM) analyses are realized on dust particles depending on time. The particles present a spherical shape and a smooth surface, with a diameter range of 0.3 to 2.0 μm (fig. 1). Electrode coating is also observed and shows an unexpected appearance of its surface (fig. 2).

Deposition of thin TiO₂ films by atmospheric pressure plasma enhanced chemical vapour deposition (APPECVD) using an Injection Axial Torch

T11 Plasma Science and Technology

#PST/SE/TF-P1-04

Y. Gazal, C. Dublanche-Tixier, A. Roemer, C. Chazelas, P. Tristant, C. Jaoul, C. Le Niniven.

SPCTS (UMR CNRS 7315) - Université de Limoges - Limoges (France).

Plasma enhanced chemical vapour deposition (PECVD) processes are widely used to deposit thin films and particularly thin ceramic films for different applications. Traditionally, PECVD systems operate under controlled pressure (usually from 0.1 Pa to 1 kPa). However, because these processes require expensive vacuum systems and pumps, there has been a growing interest in the last decades to replace them by atmospheric plasma systems [1].

Crystallized titanium oxide films are of great interest both for the photocatalytic activity of this semiconductor and its remarkable electrical and optical properties. Catalytic properties led to interesting industrial applications in water purification, decomposition of organic pollutants, self-cleaning surfaces, hydrogen production, solar cells...

In this context, a deposition system using atmospheric pressure axial injection microwave excited plasma torch (TIA, Torche à Injection Axiale), has been developed to deposit thin films of TiO₂ on silicon (100) substrates. The plasma was ignited with Ar gas. A further quantity of Ar carrier gas saturated with titanium isopropoxide (TTIP, Ti(OC₃H₇)₄) by passing through a bubbler, was mixed in the plasma gas before its entrance in the torch. The plasma treatment was carried out in an open-air reactor (fig. 1).

In a previous work, it has been shown that for SiO_x thin films deposition the increase of substrate temperature during the process generates powder formation.

Consequently, a substrate temperature controller was installed to keep the substrate

in a suitable domain of temperature [2,3].

For a given deposition time, a parametric study was carried out varying the microwave excitation power, the torch to substrate distance and the precursor mass flow, in order to optimize the film quality by minimising the homogeneous reactions in the plasma phase. These films were characterised in terms of composition and microstructure by X-ray Photoelectron Spectroscopy (XPS), X-ray Diffraction (XRD), Fourier Transformed Infrared Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM). The effects of each parameter were investigated and correlated to the characteristics of the film. Finally, conditions for obtaining crystallized TiO₂ films have been discussed.

PST-P2-09

Characterization of a soft atmospheric DBD plasma jet for surface analysis

T11 Plasma Science and Technology

#PST-P2-09

L. Chauvet, C. Muja, B. Caillier, L. Therese, P. Guillot.

Université Jean François Champollion - Albi.

In direct sample analysis domain, atmospheric pressure sources are widely investigated for ambient surface analysis by mass spectrometry [1-3]. In this domain, many plasma sources have been developed from DC to RF excitations. Generated by alternative signals, Dielectric barrier discharge (DBD) can be used as plasma source to generate low temperature plasmas at atmospheric pressure and create soft ionization [4]. The desorption/ionization jet coming out of the discharge cell can be then directed to the contaminated surface to be analyzed. Coupled to mass spectrometry detection, high selectivity and sensitivity can be obtained as a function of the source efficiency and the detector capability. In this work, a dielectric barrier discharge source has been developed. This source is composed of a large cylindrical dielectric chamber with a capillary termination. One electrode is covering the cylindrical chamber and the second one covering the capillary tube. The source is operating in a flow of rare gases and is powered by a square alternative voltage (tens of kHz). When the plasma is created, a plasma jet is created out of the capillary tube. Then the plasma jet can be directed towards the surface to be characterized during desorption/ionization. This experimental work is based on electrical and optical diagnostics. Electrical measurements are made using a Tektronix TDS7104, 1GHz, 4 channels, 10 GS/s digital phosphor oscilloscope. Optical measurements are achieved using an Ocean Optics spectrometer (USB4000) by an optical fiber. The spatial and temporal characterizations are obtained by a gated ICCD instrument (Princeton PIMAX-1K-RB, 1024x1024 pixels) allowing the observation of the plasma distribution during variation of the power supply signal. The parameters of the study are the maximum voltage, the power and the frequency for the electrical excitation and the flow rate for the operating gas which can be neon, helium or argon. The spatial and temporal distributions and the emission spectra will be presented and discussed according to the previous parameters. The future step will be to couple the dielectric barrier discharge source with Time Of Flight Mass Spectrometer (TOS-MS) and to optimize the plasma conditions for sample surface characterization.

Gallium Nitride (GaN) is a III-V semiconductor with a large and direct bandgap (3,4 eV). Furthermore GaN has a high electron mobility and strong chemical bonds. These physical properties make GaN very interesting and open new prospects for microelectronics power devices. Indeed, GaN-based devices, compared to silicon devices, can operate under high temperature, high power and high frequency.

For GaN-based power devices, an etched depth as high as 6 to 10 μm is typically required. This is considered as a deep etching, since for light emitter devices the typical etch depth is a few hundred nanometers. It was shown that wet etching of GaN c-plan (plan where etching is generally needed) is limited due to its chemical inertness [1]. Therefore, GaN deep etching is achieved by plasma etching. Generally, chlorine based chemistries are used because GaCl_3 is the most volatile Ga etching product.

We studied the etch of GaN (7 μm thick epilayer grown on Si) in Cl_2/Ar plasma using two industrial Inductively Coupled Plasma (ICP) reactors (Corial 200-IL and Alcatel A601-E) and with Ar plasma using Ion Beam Etching (IBE) (Plassys MU450). After etching, three types of defects can be observed : columns, pits and "white GaN". It was shown that both first defects are linked to nanopipes and dislocations created during epitaxial growth of GaN [2]. For industrial applications both surface defects and roughness must be limited. Cl_2/Ar plasma investigations using mass spectrometry, optical spectroscopy and Langmuir probe have shown that defects formation closely depends on plasma parameters (RF bias, ICP power,...). Impact of coverplate (silicon or quartz) during etching was also particularly important. Indeed, during etching, coverplate produces oxygen based species which are responsible of columnar defects formation. In ICP reactors, defects have almost been eliminated by adding SiCl_4 to the Cl_2/Ar

chemistry. In the case of IBE, optimisation can also be performed to reduce surface defects.

Finally, impact of adding gas, like SiCl_4 , BCl_3 or CHF_3 , on both the etch rate and selectivity with SiO_2 mask were studied. An etch rate as high as $1\mu\text{m}\cdot\text{min}^{-1}$ and a selectivity of 6 can be obtained.

Micro-plasma sources research and development have known a growing interest over the last years due to their potential applications in various fields. For example they can be used as a powerful UV laser source for waste water decontamination or skin illness treatment [1,2]. Another promising prospect is the use of these plasmas as a source of chemically active species [1], for instance in the field of plasma-medicine or gases treatment, especially when plasma is produced under microfluidics flows conditions.

All the aforementioned potential applications require a compact plasma source. For this purpose a continuous wave electrodeless plasma device was developed at the laboratory using two different microwave applicators: surfatron [3] (surface wave launcher) and microstrip (split ring resonator) [4]. It generates plasmas in a broad range of gas pressure, from mbar up to several bar. Plasmas are initiated in the presence of a gas flow in small capillary tubes with diameters ranging between 180 and 690 microns. Up to now, the elementary processes governing this kind of micrometric scale plasma still remain unknown. Nevertheless, it is of fundamental interest since at this small scale, the sheaths surrounding the bulk plasma represent a significant part of the whole discharge. It could thus significantly modify the energy transfer path to the plasma.

The present work focuses on the plasma properties for various discharge tube diameters, gas mixtures (argon and air), gas flows, and pressures and their

correlations with the production of various chemical species. Several diagnostic tools were employed. Laser based absorption techniques were used to probe key plasma species (e.g. argon metastable, nitric oxide). Spatially resolved optical emission spectroscopy was employed for measurements of species densities, discharge gas temperature and electron density (from Stark broadening). A home-made technique based upon phase measurements of the wave (local wavelength determination) in the case of the surface-wave sustained discharge (surfatron) is also used to provide the electron density. The last diagnostic allows also to assess the electron-neutral collision frequency. This is a key parameter to determine if the behaviour of the microwave discharges in capillary tube is similar to the well-known regime observed for larger tube diameters.

This present characterization of the capillary microwave plasma offers a novel opportunity to understand the mechanisms involved in the chemical species production. The obtained results are useful to design and optimize chemical species sources and are suitable for an extension to other molecular gases.

PST/SE/TF-1-Or-4

Etching mechanisms of polyethylene and fluoropolymer surfaces treated by an atmospheric He-O₂ post-discharge: the role of VUV radiation and O radicals

T11 Plasma Science and Technology

#PST/SE/TF-1-Or-4

T. Dufour, J. Hubert, N. Vandencastele, F. Reniers.

ULB - Bruxelles (Belgium).

Polyethylene and various fluoropolymer surfaces (PVF, PVDF, PTFE, FEP and PFA) have been exposed to a He and a He-O₂ post-discharge at atmospheric pressure. The plasma source is a radiofrequenced plasma torch from SurfX Technologies, supplied in helium and oxygen gases with powers ranging between 60 and 160 W. Optical emission spectroscopy shows that O radicals and He metastable atoms are produced within the He post-discharge (15 L/min). We also show that the production of excimers (located between the electrodes) is accompanied with the emission of a VUV radiation corresponding to the first He excimer continuum (around 60 nm). When mixing helium gas (15 L/min) with oxygen (200 mL/min), the He metastable species and excimers are consumed while the O radicals (with the O₂^M species) are mostly produced through dissociation reactions. Those two very different post-discharges were therefore investigated on the previously mentioned polymer surfaces. Those ones were characterized by mass losses measurements, dynamic water contact angles, X-ray Photo-electron Spectroscopy (XPS) and Atomic Force Microscopy (AFM). We hence obtain a lot of information on the plasma-treated surfaces in terms of hydrophobicity/hydrophilicity, roughening/smoothing, chemical composition, chemical bonds and the nature of polymeric fragments ejected from the surface during the treatments. For instance, we show that an increase in the O₂ flow rate induced a superhydrophobic state for PTFE, while a dramatic decrease in the water contact angles is obtained in the case of HDPE. We also evidence that an increase in the O₂ flow rate induces a strong mass loss of the sample after its treatment while a tiny mass loss is measured in the case of PTFE. The ejection of carbonated fragments is also evidenced in some cases, depending on the plasma treatment and on the polymer. By correlating all these information with a characterization of the plasma phase, we highlight several etching mechanisms

occurring at the post-discharge/surface interface. We propose a discussion of those mechanisms on the basis of geometrical considerations and on C-C, C-O and C-F bond dissociation energies. We will present how competitive and synergistic effects can result from the oxidation and/or the roughening of the surface but also from the excimer VUV radiation, the He metastable species and the O radicals reaching the polymer surface.

This work was part of the IAP/7 program "PSI - Physical Chemistry of Plasma Surface Interactions" financially supported by the Belgian Federal Office for Science Policy (BELSPO). This work was also financially supported by the FNRS (Belgian National Fund for Scientific Research).

Key-words: etching mechanisms of fluoropolymers, polymer roughening, polymer oxidation, VUV radiation on polymer.

PST-3-Or-4

Impact of the chemical structure of the precursor on the plasma polymer's free radical generation and stabilization

T11 Plasma Science and Technology

Plasma polymerized films (PPF) synthesized by plasma enhanced chemical vapor deposition (PECVD) find increasing applications in biomedicine and microelectronic devices and differ in many ways from conventional polymers. One of the most specific properties of the PPF is the high reactivity of its surface rich in free radicals arising from deposition mechanism. So although generally considered as a disadvantage leading to the ageing of the PPF, reactivity of the plasma treated polymers and PPF surfaces can be beneficially employed, for example, for grafting of a specific chemical functionality. The quantitative evaluation of the surface radical density of the PPF and the mechanisms responsible for their stabilization are thus considered to be the mandatory knowledge for any further grafting reaction.

The aim of this work is to compare the free radicals density in PPF synthesized from a linear precursor and its resonant counterpart in order to evaluate the impact of resonance on the radical's stabilization. In the present study the surface radical density of isopropanol- and benzyl alcohol-based PPF have been quantitatively determined by a combination of NO chemical derivatization and X-ray Photoelectron Spectroscopy (XPS). Once derivatization conditions were optimized, the radical density, derived from at.% N determined by XPS, was evaluated as a function of deposition power.

As an example, for isopropanol it has been found out that the surface density of free radicals presents a maximum for the deposition power of 200 W ($\sim 1.6 \cdot 10^{14}$ spin/cm²) and it stabilizes ($\sim 1.45 \cdot 10^{14}$ spin/cm²) with further power increase. XPS findings were supported by in situ Fourier Transform Infrared Spectroscopy (FTIR) measurements that provided extra information about the degree of plasma

fragmentation yielding fragmentation saturation for a deposition power of 200 W (Figure 1). Finally, some preliminary subsequent chemical grafting experiments with 2-ethylhexyl acrylate (EHA) allowed to cross-check the relevance of derivatization results.

Figure 1. In situ FTIR spectrum of the isopropanol plasma with PRF = 65 W (a) and the surface density of free radicals and the intensity of a C-H stretching band as a function of deposition power (b)

Titanium is a biocompatible material which is of great interest in the biomedical field, especially for bioMEMS. Their fabrication is based on micromachining techniques derived from microelectronics technologies. Most of the processes reported in the literature are performed with a Cl₂/Ar chemistry with typical etch rates close to 1 μm/min and provide rather smooth surfaces. A patterned TiO₂, Ni or even thick (40 μm) SU8 layer is often used as a mask.

We report here the performances of deep titanium etching with SF₆ and Cl₂ based chemistries in an Alcatel 601E ICP etching tool. Samples are pieces of a patterned titanium wafer glued on a silicon carrier wafer. The titanium wafer is 300 μm thick and the mask is a 5 μm thick nickel layer. Its backside is coated with a 15 μm thick thermal TiO₂ layer.

Our preliminary results have shown that either a SF₆ plasma or a Cl₂/Ar plasma can be used separately to etch titanium. A SF₆ plasma with a pressure of several Pa helps to reach etch rates as high as 4 μm/min but profiles are isotropic. A Cl₂/Ar chemistry at lower pressure (~1 Pa) is preferred to get vertical sidewalls but the etch rate is reduced. This is why we proposed to mix these two chemistries to obtain anisotropic profiles with an etch rate of almost 1 μm/min. However, these performances were not reproducible since in most cases this process lead to a high roughness, which is not acceptable.

This non-reproducibility may be due to the presence of the silicon carrier wafer: SiCl_x species, coming from the etch by-products of the silicon wafer may redeposit on the surface as well as the chamber walls. It was shown by our group that a SF₆ plasma helps to remove this layer, leading to the formation of SiF₄ and Cl containing volatile species.

Such a result suggests that adding SF₆ in the plasma should make the process more reproducible. But this is not sufficient because non-reproducibility issues can still happen. Process parameters have been further tuned so that the balance between etching and redeposition remains favorable to etching from one process to another.

The resulting profile on one ring is displayed in Figure 1. Titanium has been completely etched down to the backside TiO_2 layer within nearly 3h 30, with an average etch rate of $1.4 \mu\text{m}/\text{min}$. The profile is not perfectly anisotropic due to the presence of SF_6 : the slope is slightly negative on the first half of the ring and tends to be more isotropic on the second half. A significant undercut can also be observed (several 10s of μm). The estimated selectivity to the nickel mask is 35. The process has been repeated many times and the profiles were always reproducible, which is a significant improvement.

A new microfluidic device with a metal-organic catalytic coating was developed using metal-organic plasma enhanced chemical vapor (MO-PECVD) deposition technique. Hot embossing techniques were used to create a microchannel in a COC (Cyclic Olefin Copolymer) surface. The design of the microchannel is a simple 500µm large, 40µm height and 2cm long microchannel. Cobalt oxide-based (CoO and Co₃O₄) catalysts were chosen for their efficiency during mineralisation of organic pollutants achieved by an Advanced Oxidation Process (AOP) such as catalytic ozonation. Moreover, the antibacterial properties of these oxides are not negligible. Cobalt thin films were deposited using a parallel electrodes RF low-pressure plasma reactor (13.56 MHz, 100 Pa, 200W). Starting from a cobalt carbonyl (Co(CO)₈) organo-metallic precursor mixed to argon and oxygen gas carrier, the catalytic coating was directly deposited on the inner surface of the microchannel. Hexamethyldisiloxane (HMDSO) was used to improve the adhesion between the cobalt film and COC substrate. First results showed that the contact angle (CA) of the coated COC decreased from 95° close to 0°. The obtained films were characterized by XPS, XRD, SEM and TEM. SEM micrographs showed that a homogenous 6µm thin cauliflower-shaped layer of cobalt oxides was obtained and XRD proved that nano-clusters of 40nm of cobalt oxides were formed within the film but it wasn't possible to distinguish neither the oxidation degree nor the observed cobalt oxide structure. High resolution XPS analysis allowed excluding the presence of CoO in the deposited layer. The catalytic microsystem was then obtained by sealing the surface with a thin layer of COC under heating and pressure (1 bar, 140°C). Catalytic properties of the

microreactor will be further tested in ozonation of various acids and followed by HPLC as a technique of wastewater treatment.

From low to atmospheric pressure plasma diagnostics based on quantum cascade laser absorption spectroscopy

T11 Plasma Science and Technology

#PST-1-Or-4

S. Iseni ¹, K.D. Weltmann ², S. Reuter ¹.

¹Centre for Innovation Competence plasmatis, Leibniz Institute for Plasma Science and Technology (INP) - Greifswald (Germany), ²Leibniz Institute for Plasma Science and Technology (INP) - Greifswald (Germany).

The interest in plasma jets operating at atmospheric pressure have considerably grown during the last decade. The non-equilibrium properties of the discharge enhances specific and interesting chemistry especially that of reactive nitric-oxide species (RNOS) such as O₃, NO. It is already known that reactive species such as O₃ have biological effects and have been used for sterilization of non-living objects[1]. In the field of plasma medicine, O₃ is investigated as an antibacterial agent to support wound healing. Therefore, we investigate the O₃ and NO_x productions of an argon MHz radiofrequency plasma jet operating at atmospheric pressure in order to control the chemistry in the effluent region[2-3]. Moreover, for biomedicine applications, *absolute densities* have to be known in order to identify the biological effects.

For the purpose of our studies, we required a diagnostic technique, which allows a non-disturbing method with a *very high molecular selectivity*. It has to provide accurate and reliable detection and measurements of the selected species. Moreover, it must be able to reach absolute concentration in a sub-ppm range. Such requirement has already been reached at low pressure by using absorption spectroscopy in the mid-infrared (IR) range performed with pulsed quantum cascade laser (QCLAS)[4]. By adapting this diagnostics for the first time from low pressure plasma diagnostic to atmospheric pressure, we were able to reach our goal. The spectral range is restricted to the so-called fingerprint area (500-1500cm⁻¹) which allows a total identification of the species. The mid-IR beam goes through a multipass White type cell in which the plasma jet is operated. Due to an additional air inlet, the inner atmosphere is adjusted to be similar to the application conditions in ambient air. Furthermore, in order to produce species specific detection, the recorded spectra are compared on-line with a spectrum simulation which provides a very good

quality of the measurement. By this technique, a detection limit of 30ppb is reached with an accuracy of 40ppb. Thus, it allows us to measure the *chemical dynamics* of the species production according to the gas admixture such as O₂, N₂ or H₂O. This talk aims to show the growing interest in this diagnostic technique which evolved from low pressure plasma diagnostics to atmospheric plasma diagnostics. A specific care on O₃ and NO_x production will be presented and the generation dynamics of reactive species regarding different admixtures is discussed.

¹Laboratoire de Génie des Procédés Plasma et Traitements de Surface, ENSCP - Paris (France), ²Institut d'Electronique Fondamentale, Uni. Paris Sud - Orsay (France).

Microplasma reactors are very attractive for the decomposition of Volatile Organic Compounds (VOCs) decomposition for indoor air control. By using a dielectric barrier discharge (DBD), a cold microplasma could be generated at ambient temperature and atmospheric pressure leading to the generation of numerous active species such as radicals, electrons, ions, excited species, ... Here, we have developed a miniaturized device combining an atmospheric pressure plasma with a cobalt based catalytic coating for the purpose of VOC decomposition at ppm concentration. The micrometric feature size microchannel (Figure 1) was elaborated by the mean of hot embossing of a Cyclic Olefin Copolymer (COC) substrate. The metallic electrodes were easily patterned on the COC substrate by a combination of photolithography and metallization techniques. Cobalt thin films were deposited using a parallel electrodes RF low-pressure plasma reactor. Starting from a cobalt carbonyl (Co(CO)₈) organo-metallic precursor mixed to argon and oxygen gas carrier, the catalytic coating was directly deposited onto the inner surface of the microchannel [1]. Figure 2 exposes an argon discharge under continuous flow performed inside the catalyst coated microreactor. Since the device is fully operational, the challenge will consist in monitoring the mechanisms governing catalytic processes with plasma interactions by using in-situ characterization techniques (OES, ultra-rapid camera, FTIR analysis). Moreover, the electrical performances of the barrier discharge will be

accessed by using the Lissajous method [2]. Finally, VOCs decomposition in the microreactor will be further tested with several model gases and followed by GC-MS.

Effect of Plasma Exposure on Unvulcanized Polybutadiene Surfaces

T11 Plasma Science and Technology

#PST/SE/TF-3-Or-4

A. Henry.

IS2M-CNRS-UMR7361 - Mulhouse (France).

Rubbers are polymeric materials with high elasticity and their properties are generally improved by using fillers. Most of the rubbers used are vulcanized and their processing includes also the addition of plasticizers, antioxidants, vulcanizing agent and activator [1].

Adhesive bonding of rubbers presents an especially important problem in diverse branches of industry. [2] The strength and quality of such adhesive-bonded joints depend on important parameters such as compatibility, reactivity and co-crosslinking. In some cases, surface treatment is necessary in order to increase reactivity. Among them, plasma treatments have become a powerful candidate as it combines high chemical reactivity with low operational costs, in environmental friendly processes. Plasma treatment has been extensively studied for surface modification of vulcanized rubbers. [3] The plasma process results in physical or chemical modification of the first few molecular layers of the surface while retaining bulk properties. During plasma exposition, the surface is driven away from its thermodynamic equilibrium and after plasma treatment the modified surface reconstructs (e.g. chain reorganization and migration of additives) in order to return to an equilibrium state. [4] These dynamics are strongly dependent on the nature and number of additives in the formulations and the role of each additive during plasma treatments are poorly understood.

To get better understanding the plasma-surface mechanism and to limit the complexity of the study, attention has been paid to unvulcanized filler-free polybutadiene rubber (BR) which can be used as a model rubber. Low pressure radio-frequencies air plasma was used to modify the surface of unvulcanized BR samples. Plasma processing was carried out in a home-built R.F. plasma reactor. The plasma chamber consists of a glass tube (680 cm³ in volume) coupled with an externally wound copper coil and surmounting with a 20 cm round cylinder glass hall. This design allows to modify the distance between the sample

and the electrodes in a large range. An L-C matching network was used to match the output impedance of a 13,56 MHz R.F. power supply to the partially ionized gas load by minimizing the standing wave ratio of the transmitted power. The effect of three main parameters which directly influence the amount of energy and the nature of the excited species in the plasma were analyzed: the RF source power, the exposition time, the distance between the rubber samples and the electrodes

Surface modifications were investigated by wettability measurements. The surface ageing was investigated at different temperatures by comparing the hydrophobic recovery in air and under inert atmosphere at different temperatures. The nature of the surface modifications were characterized by X-Ray Photoelectron Spectroscopy and Electron Spin Resonance. Autohesion properties of assemblies were investigated with tack measurements.

This work puts in light interesting properties of plasma treated unvulcanized rubber surfaces leading to interesting autohesion properties.

Only with the recent development of non-thermal atmospheric pressure plasma sources plasmas are broadly studied for application in therapeutic medicine. These plasma sources generate highly reactive plasma components in ambient conditions and their gas temperature is below the destruction threshold of extremely sensitive surfaces such as biomaterials [1]. For an understanding of fundamental processes in plasma surface interaction, a control and detailed diagnostic of the reactive plasma components is vital. To control plasma, three different approaches can be made and will be discussed in the presentation: Control by plasma source design, control of operation parameters, and control of environmental conditions. In this work we present optical diagnostics on atmospheric pressure plasma jets combined with modeling yielding an understanding of fundamental processes such as air species diffusion into the jet effluent. To gain control over the reactive components, their generation processes need to be controlled [2]. The plasma jet is characterized by laser induced fluorescence spectroscopy, by absorption and emission spectroscopy and by flow simulations [3]. The reactive oxygen and nitrogen output especially O, O₃, O₂(a¹Δ_g) [4], H₂O₂, NO₂, and OH are investigated. With the gained knowledge, we show that it is possible to tailor the reactive components and to influence plasma jet-liquid interaction. We show that reactive species generation within plasma treated liquids can be controlled and apply the findings to cells and lipids to investigate the effect of reactive oxygen and nitrogen species (RONS) [5].

Inorganic lead compounds generate liquid wastewaters charged on Pb²⁺ ions. The latter are generally eliminated by precipitation in a basic medium [1]. However, when they are in the organic form, the precipitation technique becomes inappropriate for its elimination such is the case of lead acetate (PbAC). According to Noyes and Withcomb [2], though this molecule is relatively very soluble in water, it slightly ionises there. The small degree of ionisation appears to be connected with the spontaneous formation of complex anion in aqueous solution.

The Gliding Arc Discharge (GAD) is an efficient non-thermal plasma technique able to degrade organic compounds dispersed in water at atmospheric pressure.

The degradation of the organometallic lead acetate (PbAC) in aqueous solution was realised by two plasmageneous processes GAD and GAD/TiO₂. This degradation was simultaneously followed by the Total Organic Carbon (TOC) and by the Chemical Oxygen Demand (COD). The Pb²⁺ ions released during the degradation process were analysed by Atomic Absorption Spectroscopy (AAS). For 2 hours of GAD/TiO₂ treatment, the degradation rate of PbAC (10 mM) reached 93% with a constant rate of 0.023 min⁻¹ in presence of 1 g L⁻¹ of TiO₂. For the same duration of treatment and without photo-catalyst (GAD), the degradation reached 83% with a constant rate of 0.014 min⁻¹. The release of Lead II in the solution was of 57% with a constant rate of 6.1 mg L⁻¹ min⁻¹ for the GAD treatment and was of 95% with a constant rate of 10.2 mg L⁻¹ min⁻¹ for the GAD/TiO₂ treatment.

The Pb^{2+} release was studied under basic control which was operated at different pH. The results showed that there was a total precipitation of this element at pH = 11.1. Reactional mechanisms were proposed to explain the degradation of PbAC molecule and the Pb^{2+} elimination modes by precipitation.

A novel method to control silver doping in TiO₂ using TiO₂/AgO bi-layer thin film stacks

T11 Plasma Science and Technology

#PST/SE/TF-P1-05

A. Jaiswal.

Ph.D. Student, UPMC - Paris (France).

Multi-layer thin films of TiO₂ and AgO were deposited by RF reactive magnetron sputtering, and their structural, optical, and compositional properties were studied. The total thickness of each film was kept constant. Firstly, the overall composition of the films (AgO to TiO₂ ratio) was kept constant and the number of layers and thickness of each layer was controlled to create bi-layer thin films which were composed of: 2 up to 45 bi-layers. Secondly, different nominal AgO/TiO₂ ratios were attempted within the bilayers. To investigate the benefit of the bilayer coating, we prepared Ag doped TiO₂ by co-sputtering with different percentages of Ag (0 to 10 %, at.) for comparison. The effect of post annealing was investigated on the photocatalytic activity and the photo-electrochemical properties of the different coatings. In addition, bi-layer stacking significantly affected the films optical properties by lowering the band gap into the visible light region, and also showed improvement in the photo activity under UV and visible irradiations due to the formation of Schottky barriers at the interfaces between TiO₂ and AgO layers. Overall, bi-layer stacking of TiO₂/AgO films has shown a unique and highly desirable control over several important physical characteristics which can be beneficial for many optoelectronic and photocatalytic applications due to the good controlled charge separation within the doped TiO₂. Furthermore doping with silver offers bactericidal properties to the TiO₂ coatings.

Key words: TiO₂ thin film, silver doping, photocurrent, bi-layer, RF sputtering, photo catalyze, AgO.

Titanium dioxide is an attractive material for electrical (high-k) and optical (high optical index, up to 2.5) applications. However, TiO₂ films deposited by plasma processes exhibit a columnar structure [1](figure 1) which is a drawback for MIS (Metal Insulator Semiconductor) and MIM (Metal Insulator Metal) capacitor integration or optical waveguide applications. One way to get more homogeneous films is to incorporate SiO₂ phase in the TiO₂ network[2].

We study here the deposition of mixed layers of TiO₂/SiO₂ by low pressure ICP plasma enhanced chemical vapour deposition (PECVD) using titanium tetraisopropoxide (TTIP) and hexamethyldisiloxane (HMDSO) mixed with O₂. Plasma is generated by an RF source working at 400 W and 13,56MHz and the working pressure is fixed at 3mTorr.

The resulting composition of the layer depending on the fraction of each precursor injected inside the plasma is determined by X-Ray Photoelectron Spectroscopy and Wavelength-Dispersive X-ray Spectroscopy analyses whereas the distribution of Ti and Si related bonds in the film network is investigated by Fourier Transformed InfraRed spectroscopy.

The impact of silicon oxide concentration on the layer morphology, roughness, optical refractive index and dielectric permittivity (at 1MHz) are studied by Scanning Electron Microscopy, Atomic Force Microscopy, spectroscopic ellipsometry and C(V) measurements, respectively. In addition the optical gap and leakage currents are also determined.

Preliminary results have already proven the possibility to get rid of the columnar structure of the layers (figure 2) while keeping a rather high optical index (around 1.7 at 1.96 eV).

Different structures of N-doped TiO₂ (TiO_xN_y) have been prepared by RF reactive magnetron sputtering with two methods. First, we used dual reactive gas, oxygen and nitrogen, simultaneously in the deposition chamber in order to get homogeneous N-doped TiO₂ with different doping levels. Secondly, we deposited multi-layers of TiO₂ and TiN having different percentages of TiN in the coatings. The multilayers were separated by 1 to 3 nm of Ti in order to get a good Schottky barrier at the interface between TiO₂ and TiN layers (figure 1). The crystalline, optical, and composition properties were analyzed. The behavior of the resulted films was studied by measuring the generated photo-electrochemical current and the photocatalytic activity under both UV and visible light.

The competitive effects of the structure, the chemical composition and nitrogen states on the efficiency of the photo activity of the coatings were investigated. Samples prepared at high pressure gave the best photocatalytic activity due to the high specific surface area, the optimal presence of TiO_xN_y crystals in the lattice and the good charge separation thanks to the interstitial nitrogen sites. However, deposition at low pressure leads to N-doped film with the best photo-electrochemical properties. Under such conditions and in particularly at high nitrogen doping levels (> 6% at.), the formation of TiN crystals became most probable acting as recombination centers between the photo-generated charge carriers. The bilayer morphology gave a good alternative, especially when the films were deposited at lower pressure and higher percentage of nitrogen doping. A good understanding of the complex processes involved in the deposition of the thin coatings by sputtering was achieved. In particularly, the effect of deposition parameters on the photo-activity of the N doped titania, as well as the preferential presence of interstitial and/or substitutional nitrogen sites in the lattice were pointed out.

Figure 1: Electronic band structure of: (a) TiO₂ thin film and (b) two bi-layers of TiO₂/TiN showing the formation of two Schottky barriers.

Formation and transport of nanoparticles in magnetically confined acetylene plasmas produced at very low pressure

T11 Plasma Science and Technology

#PST-2-Or-8

G. Al Makdessi ¹, J. Margot ¹, R. Clergereaux ².

¹Université de Montréal - Montréal (Canada), ²Université Paul Sabatier - Toulouse (France).

Dusty plasmas are plasmas containing charged nano-sized or even charged micro-sized particles. Known for decades, dusty plasmas have attracted the interest of the scientific community in the early 80s, especially in astrophysics when dusty particles were discovered in the rings of Saturn [1]. Comets, planetary rings, interstellar dust and interstellar clouds are some examples of natural objects formed by dusty plasmas [2]. Far from being limited to distant objects, dusty particles are also found in laboratories, in plasmas used for deposition and etching of thin films. In addition, dusty particles are present in different systems such as radio frequency capacitive discharges, inductively coupled discharges and DC discharges when the plasma gas is chemically reactive such as methane or acetylene. Dusty plasmas may behave as weakly coupled environment (such as gases) or strongly coupled environment (like liquids or solids). Therefore, they can form coulomb crystals also called plasma crystals in which aggregates of dust have spontaneously well-organized structure [3,4]. This property can be used to create monolayer crystals and to deposit it on the surface of materials to change their surface properties.

In this presentation, we investigate magnetically confined low pressure dusty plasmas in acetylene. The plasma is created by an electromagnetic surface wave at a frequency of 200 MHz. Our goal is to examine how the use of magnetic confinement allows circumventing the low pressure by enabling the formation of nanoparticles in the plasma volume. By performing a parametric study of the influence of the magnetic field on the formation of these particles, we expect to achieve a good understanding of their creation mechanisms, and, ultimately to control their characteristics.

Our results show that there exist specific conditions in which nanoparticles are

generated. We will present the dependence of characteristics of the deposits as a function of the plasma parameters. In particular, we will examine the influence of the magnetic field intensity (from 0 Gauss to a few hundreds of Gauss) and its spatial distribution on the properties (structure and size) of the nano and micro particles generated in the plasma volume. This will be achieved using various materials characterization techniques, including scanning electron microscopy, X-ray diffraction and Raman scattering. The impact of other parameters on the structure and size of the synthesized particles will also be analysed. These include the degree of dilution of acetylene by a rare gas, the power injected in the plasma and the operating pressure.

PST-P2-10

Production of neutral oxygen atoms in low pressure gaseous discharges

T11 Plasma Science and Technology

#PST-P2-10

M. Mozetic.

Jozef Stefan Institute - Ljubljana (Slovenia).

Methods for production of large quantities of neutral oxygen atoms by passing molecular oxygen through a discharge region are presented. Although atmospheric pressure discharges are increasingly popular they do not represent suitable sources of neutral atoms in the ground state due a high probability for gas phase recombination of atoms to parent molecules. Low pressure discharges perform much better for this particular application. A variety of low pressure discharges can be used as sources of neutral atoms and the choice depends on particularity of the required conditions. An important one is optimization of the discharge in order to minimize energy consumption. This requirement dictates application of sources with minimal loss of created atoms. The loss will occur either in the gas phase or on the surfaces. Gas phase loss is effectively reduced if discharges run at low enough pressure to avoid recombination at three body collisions. In many practical cases the maximal allowable pressure is close to 10 mbar. The surface loss is effectively minimized by construction of the system from materials with negligible coefficients for heterogeneous surface recombination of O atoms. The choice of appropriate materials includes many glasses and ceramics as well as some metals which form very stable oxides, such as aluminum. The loss rate depends also on surface morphology so it is recommended to use materials of very small roughness. Since glasses meet these requirements the best discharge chambers are made from these materials. Glasses are electrical insulators so the choice of appropriate electrical discharges is limited to electrode-less high-frequency discharges. Both radiofrequency and microwave discharges are popular for creation of large concentration of neutral oxygen atoms. The microwave discharges often operate with surface waves and are suitable for creation of highly dissociated plasma in rather narrow tubes while radiofrequency discharges are applied in larger volumes. Methods for rather precise determination of the density of O atoms in gasses which have been allowed to pass through a discharge region include the NO titration, optical absorption techniques, actinometry and catalytic probes. These methods were applied to measure the production of O atoms in above mentioned discharges

created at different powers up to 5 kW and in different discharge chambers. The best results in terms of power efficiency are obtained for radiofrequency discharges operating at the pressure of the order of 0.1 mbar. In such systems the efficiency is better than 10%. Atoms are lead to a processing chamber where they are allowed to interact chemically with surfaces of solid materials. The transmission efficiency, i.e. ratio between the atom density in the processing and discharge chambers, depends on the surface finishing of the connection tube as well as vacuum parameters, the main being the conductance of the connecting tube. Several examples will be presented.

PST-P2-11

Spatial distribution of electronic temperature, density and plasma emission in argon inductively coupled plasma for surface treatment

T11 Plasma Science and Technology

#PST-P2-11

C. Laurent, J. Lo, B. Caillier, L. Therese, P. Belenguer, P. Guillot.

DPHE Laboratory, CUFR J.F. Champollion, University of Toulouse - Albi (France).

Inductively coupled plasma (ICP) is currently used in analytical chemistry (e.g. mass and optical spectrometry) and industrial applications. In microelectronic industries, ICP sources associated with a downstream reactor are utilized for layer depositions, surface etching, photoresist stripping and wafer cleaning [1-3]. The advantages of ICP sources are their wide pressure range and high charged species densities obtained even at low pressure [4]. In this work, supported by the French public funding agency OSEO, the aim is to develop and characterize a plasma reactor for surface treatment. Prior to any treatment study, physical and optical diagnostics of the source have been investigated to acquire a better understanding of the plasma properties.

In our experimental setup, the gas is introduced through a cylindrical quartz tube which is connected to a separate process chamber. The discharge is generated within the tube by a 13.56 MHz radiofrequency ICP source including a matching box. Different operating conditions are obtained by regulating independently three parameters: the gas flow (from 10 up to 500 sccm), the chamber pressure (from $5 \cdot 10^{-3}$ up to 1 mbar) and the injected power (from 10 up to 1000 W).

A parametric study is conducted on these variables by optical emission spectroscopy and double Langmuir probe diagnostics with respectively a Fully Automated Imaging Spectrometer (iHR320 Horiba Jobin Yvon) with a groove density of 1200 gr/mm (resolution < 0.15 nm) and a linearly driven probe (Impedans ALP Sytem by Impedans Ltd, Ireland). Simultaneous measurements are done through several reactor openings for spatial distribution characterization as a function of the three

mentioned parameters. These measurements will provide us basic plasma characteristics (i.e. plasma optical emission, electron temperature, charged species densities, EEDF and plasma potential) in the entire chamber. They will also supply experimental data necessary for comparison purpose with numerical modelling results.

The potential applications for microdischarges are numerous and span a wide variety of areas such as lighting, detection, local treatments, sensors, lab on a chip, micro-machine processing, instrumentation etc. One of the most important technological and scientific issues of this new research area is the elaboration of the microreactors: They have to be robust enough to sustain power densities as high as a few hundreds of kilowatts per cubic centimeter.

Arrays of microreactors built from silicon wafers in clean room facilities have been recently developed [1, 2]. They consist of Micro Hollow Cathode Discharges (MHCD) operating in parallel in DC. One of the remarkable properties of these MHCDs is that stable DC plasmas can operate at atmospheric pressure without arcing [3]. AC operation is also possible and offers some advantages in terms of homogeneity and life time [4, 5].

We will present recent results obtained in both DC and AC operation. Discharges were formed in both helium and argon gases. While using DC power to ignite large arrays of microdischarges (1024 holes, 100 μm diameter) we observed spiking in the current waveform. This indicates that the microplasmas still have instability. V-I curves were systematically acquired during the experiments. Simultaneous optical characterization was also carried out (both imaging and spectroscopy). The device life time can vary from a few minutes to a few hours in DC operation depending on the injected power level. The failure mechanisms, investigated using different characterization techniques, will also be presented.

Microplasmas were made in DC regime using sandwich type micro-hollow cathode devices.

Plasmas through Ar and He with small admixture of N₂ were examined by simultaneously measuring plasma RF impedance and OES of N₂ bands as a function of the DC potential between the electrodes and current intensity through the plasma. Since the RF fields are concentrated between the anode and the cathode, these two diagnostics allow us to have an estimate of the electron density inside the hole[1] as a function of DC Current, DC Power, Pressure and Gas Composition.

In addition, time resolved impedance measurements become possible since the RF impedance can be effectively measured during the course of a single RF cycle.

As expected, we found that the plasma resistivity of the Microplasmas decreases monotonically with increasing DC current.

The RF technique will be explained and data from Argon, Helium and Nitrogen containing plasmas will be presented.

Atomic processes in laser produced plasmas studied by cavity-ring down spectroscopy

T11 Plasma Science and Technology

#PST-1-Or-10

S. Milosevic, M. Biscan, N. Krstulovic.

Institute of Physics - Zagreb (Croatia).

Plasmas produced by means of small lasers with typically of nanosecond pulse duration (4 ns – 20 ns) and energy up to 300 mJ offers a versatile medium for applications relevant in advanced materials research. The progress in that field depends on a deeper understanding of details of plasma processes by improving plasma diagnostics and theoretical modelling. Cavity ring-down spectroscopy is a versatile absorption method which provides data on the plume and its surroundings, with spatial and temporal resolution [1]. This method offers advantages compared to classical absorption techniques and can easily reach ppb sensitivity. Recently we have shown that regions around and below the visible plasma plume can be studied, in addition to the plume itself [2]. This opens possibility to study atomic processes important for the small particles formation when pulsed laser deposition technique is employed [3]. We have measured densities of various atomic states within the plume emerging from the target or created in the surrounding gas, and followed their decay [4]. Several examples will be presented discussing advantages and limitations of the CRDS technique applied to laser produced plasma diagnostics.

Energy flux measurements at the substrate position during reactive and non reactive magnetron sputter deposition processes

T11 Plasma Science and Technology

#PST-2-Or-2

P.A. Cormier¹, A. Balhamri¹, A.L. Thomann², R. Dussart², T. Lecas², N. Semmar², R. Snyders¹, S. Konstantinidis¹.

¹ChIPS, UMONS - Mons (Belgium), ²GREMI, Université Orléans - Orléans (France).

During thin film deposition processes, energetic conditions at the substrate surface influence the thin film characteristics such as density, crystalline structure or roughness. Determining the energy flux at the substrate is therefore of particular relevance for the understanding of thin film growth mechanisms [1]. In this contribution, we have quantified the total energy flux at the substrate position by using heat flux sensor designed for working in PVD processes [2]. The increased sensitivity of the probe allowed differentiating fast energy transfer originating from the bombardment of the plasma species (e.g. ions and electrons) from radiation flux emanating from the heated target surface.

DC magnetron sputtering (DCMS), Pulsed dc magnetron sputtering (pDCMS) and high power impulse magnetron sputtering (HiPIMS) discharges were analyzed. The sputter power delivered to the Ti target, the magnetic field configuration (unbalanced or balanced), the total pressure, and the gas mixture (O₂ in Ar) were systematically varied.

The use of an unbalanced magnetic field is found to significantly increase the energy transferred to the film, whatever the discharge type. Moreover, in situation where the plasma is confined to the target vicinity (balanced field), the target surface heating is enhanced during pulsed processes and large radiative IR fluxes are measured. This contribution is found to be the most significant energy transfer process during the HiPIMS process run with the balanced magnetron target. Finally, when oxygen is added to the gas mixture, the energy flux decreases as the discharge enters the

oxidized regime and it exhibits a hysteresis. Energy flux values are correlated to TiO₂ thin film properties in some particular cases.

Synthesis of electrodes and proton exchange membranes by atmospheric plasma for fuel cells applications

T11 Plasma Science and Technology

#PST-5-Or-9

D. Merche ¹, M. Vernailen ¹, M. Laurent-Brocq ², M. Raes ³, H. Terryn ³, J.J. Pireaux ², N. Job ⁴, F. Reniers ¹.

¹ULB - Brussels (Belgium), ²FUNDP - Namur (Belgium), ³VUB - Brussels (Belgium), ⁴ULg - Liège (Belgium).

Plasma technologies are widely used for a large panel of applications (etching, grafting, thin films deposition, pollutants removal, etc.). They are very advantageous because they are environmental friendly (no release of toxic solvents, process at room temperature), and they present a low energy cost. In this study, (sub)-atmospheric plasmas were used to develop electrodes and proton exchange membranes (on C and on Si substrates) for fuel cells using hydrogen or methanol [1,2]. Plasma processes for the synthesis of electrodes and membranes could be a major asset for the production of the fuel cell elements at lower cost.

An easy-procedure to synthesize half-membrane-electrode assemblies is reported in figure 1:

-Firstly, the catalyst nanoparticles are grafted on carbon powder with high specific surface area (carbon black) by spraying a Pt colloidal solution or by treating a carbon black/Pt acetyl- acetonate mixture in the argon post-discharge of an RF atmospheric plasma torch. The influence of the grafting conditions on the size, dispersion, amount, chemical state of platinum grafted and on the nature of the carbon-metal interface are investigated for both processes by SEM, TEM, XPS and SIMS.

-Secondly, the platinum-loaded carbon is covered in one single-step by plasma synthesized polymeric membrane. The sulfonated polystyrene membranes are synthesized in a DBD by injecting simultaneously styrene and trifluoromethanesulfonic acid monomers, in the presence of a carrier gas (Ar). The trifluoromethane sulfonic acid monomer brings sulfonic acid groups (necessary for the proton conductivity) in the polystyrene matrix. The plasma-membranes are

chemically characterized by XPS, SIMS (static and dynamic), and FTIR (IRRAS). The thickness and the morphology are investigated by SEM. Therefore, it is possible to produce plasma membrane with a good in-depth homogeneity and with a high content of sulfonic acid groups.

Infrared characterization of SiH₄ decomposition in a glow dielectric barrier discharge: comparison of continuous and modulated excitation

T11 Plasma Science and Technology

#PST-1-Or-6

J. Vallade ¹, F. Massines ².

¹CNRS PROMES ADEME - Perpignan (France), ²CNRS PROMES - Perpignan (France).

The aim of this work is to make in-line SiN_x:H thin films by atmospheric pressure PEVCD. SiN:H is an antireflective and passivating coating for silicon solar cells. The discharge is an Ar/NH₃/SiH₄ glow dielectric barrier discharge obtained with a 50kHz excitation. The reactor has plane/plane configuration with a 2mm gas gap. Gas is injected on one side of the plasma area, parallel to the substrate displacement. Evolution of gas chemical composition as a function of gas residence time in the plasma induces a gradient of the chemical composition of the thin film which causes problems for the application. Thus, the aim of this work is to reduce this gradient by a better control of SiH₄ decomposition. To reach that goal, FTIR (Fourier Transformed InfraRed) absorption measurements of silane concentration in the gas are made as a function of the gas residence time in the plasma. Continuous and modulated excitations are compared because modulation has proven to reduce the chemical gradient¹. The infrared beam is a square of 2x2mm². A double pass system allows a total absorption length of 100mm. Space resolution in the direction of the gas flow is 2mm². Gas flow of 3l/min is guided in the plasma zone. Thus, position, d, is related to the mean gas residence time, t, through the relation: $t(\text{ms}) = \frac{\text{gap} \times d \times \text{plasma length}}{\text{gas flow}} = \frac{2d(\text{mm})}{\text{flow}}$. Figure 1 presents measurements made as a function of the position, the power and the ratio T_{on}/T_{off} of the plasma. These different parameters can be converted in plasma energy a SiH₄ molecule has interacted with $E = \text{power} \times (T_{\text{on}}/T_{\text{off}}) \times t$. Figure 1 shows silane concentration as a function of energy. All the points are aligned and can be fitted by the exponential law: $[\text{SiH}_4] = 67 e^{(-524 E)}$. That means that SiH₄ dissociation depends only on the plasma energy which is defined by T_{on}. Chemistry occurring during the T_{off} is negligible. This result is explained by the nature

of the discharge. GDBD is a pulsed discharge having duration of $2\mu\text{s}$. For 50kHz excitation it is on 10% of the time. The fact that the modulation of the excitation at a time scale of ms has no influence shows that SiH_4 dissociation is controlled by mechanisms having a shorter life time. This is in agreement with Ar^* excited state life time: 120ns at atmospheric pressure. Modulation allows to maintain the same chemistry for larger t or longer d. SiH_4 decrease is related to the thin film chemical composition and growth rate characterized by IRTF and ellipsometry.

This paper presents an electric and kinetic approach to study homogeneous DBD in Kr–Xe plasma. The context of this study, based on a spatially homogenous model including the plasma chemistry module, the circuit module and the Boltzmann equation module is the controlling of the UV emission in Kr–Xe lamp. The model predicts the optimal operating conditions and investigates the electrical and chemical characteristics of high-pressure dielectric barrier discharges. The temporal variations of discharge voltage, dielectric voltage, discharge current, electric field and species concentrations are calculated and the plasma kinetic processes are discussed.

Zirconium containing thin films for optical applications (anti-reflecting systems, high optical index, etc...) are deposited at low temperature with the use of Zirconium Tetra tert-Butoxide (ZTB) as precursor. To understand the reaction mechanisms that lead to the formation of thin films knowledge of the precursor dissociation in the plasma phase is required. Here we monitor a ZTB low pressure (around 0,4 Pa) RF coil plasma at powers ranging from 10 W to 125 W with the help of Fourier Transform Infrared Spectroscopy (FTIR) and Mass Spectrometry (MS).

As we can see on figure 1 and figure 2 the increase in power first decreases specific chemical bond vibrations and then causes the apparition of new bonds. The MS permits the determination of the compounds likely found in the plasma phase. The MS peak attribution is greatly simplified due to the presence of Zirconium and Carbon as there relatively abundant isotopes yield significant signatures. As a result a fragmentation mechanism can be presented, this is strongly supported by the use of Density Functional Theory (DFT) calculations giving the energies of the reactions taking place.

New sterilization process by non thermal plasma discharge inside disposable bag

T11 Plasma Science and Technology

#SE/PST/TF/BI-P1-05

Z. Ben Belgacem¹, F. Velard¹, D. Laurent-Maquin¹, J.M. Popot², B. Cawe², M. Boudifa², S. Gangloff¹, M.P. Gellé¹.

¹EA 4691 - Reims (France), ²CRITT-MDTS - Charleville-Mézières (France).

Steam sterilization (autoclave), ionizing radiation and ethylene oxide are the most commonly methods for medical devices sterilization. However, the sterilization of some new devices presents some difficulties linked to their vulnerability to physical or chemical sterilizing agents. Therefore, new sterilization processes by non thermal plasma have been studied for over 10 years. The idea is to expose a sample to plasma, created in chamber, at atmospheric pressure or in vacuum condition. Many studies have demonstrated the efficacy of plasma on microorganisms inactivation [1, 2, 3]. However, these studies cannot be considered entirely satisfying without generating directly plasma inside the sealed bag containing the medical device and maintaining its sterile state. This is a real challenge which had not been reached up to now. Packaging and storage methods of sterile equipment are an important part of the process leading to obtain sterile conditions [EN ISO 11607, EN 868]. CRITT-MDTS (Charleville-Mézières, France) and EA 4691 "BIOS" (URCA, Reims, France) have developed a process which allows the conservation of the state's sterilization by a direct plasma treatment inside a sterilization bag. The plasma prototype reactor was manufactured by Sominex (Bayeux, France). The process vacuum was provided by 2 pumps (primary and molecular turbo Agilent Pumps) to obtain a high vacuum ($9 \cdot 10^{-5}$ mbar). The vessel was equipped in the upper center with a magnetic field coupled with a radio-frequency polarization plate in the lower center to generate hybrid plasma. Samples were packed in a sealed bag that was placed in a chamber and then subjected to vacuum. Different gases were injected into the pouch through a filter and the plasma was raised only in the sterilization bag and not in the chamber. We evaluated the efficiency of this plasma-sterilization process against *Pseudomonas aeruginosa* CIP A22 and *Staphylococcus aureus* CIP 53.154 (Pasteur

Institute, Paris, France). These strains were chosen as they serve as reference in the assays of biocidal activity according to European norms. Bacterial suspensions (10^6 cells/mL) were inoculated on glass slides which were placed in a specific sterilization bag and put on the radio-frequency polarization plate in the plasma vessel. The glass slides were exposed to O₂, N₂ or Ar - plasma treatment for various time periods (5, 15 or 30 min). Then bacteria were collected from the slides and the colonies enumeration (CFU) was completed with the standard method agar plate medium. Samples that had not been exposed to plasma were used as controls. The bacterial effect was determined by $\log N_0 - \log N_t$, where N_0 and N_t are the number of CFUs in control and sterilized respectively. The first microbiological tests with strains of *Pseudomonas aeruginosa* and *Staphylococcus aureus* seem promising.

We thank, F. Szydal, D.Boitel and F.Polidor for technical skills.

INERTIZATION OF CHROMIUM PRESENT IN GALVANIC SLUDGE BY DIRECT CURRENT THERMAL PLASMA

T11 Plasma Science and Technology

#PST-P3-09

A. Cubas.

UNISUL - Florianópolis (Brazil).

Galvanic sludge results from the treatment of effluents generated by the industrial surface treatment of parts. It is considered to be rich in heavy metals, a material requiring special treatment. The treatment proposed herein is exposure of the galvanic sludge to the high temperatures provided by thermal plasma, a process which aims to vitrify the chromium in the sludge and render this metal inert. Two different reactors were assembled in order to carry out the experiments as follows: with a transferred arc and with a non-transferred arc. In this way it was possible to verify which reactor was more efficient in the inertization of the metals and also to investigate whether the addition of quartzite sand to the sludge influences the vitrification of the material. The chemical composition and the form of the pyrolyzed and vitrified sludge were analyzed by scanning electron microscopy, and the inertization of the sludge was verified in leaching tests, where the leachate was analyzed by flame AAS. The efficiency of the sludge inertization was 100% for chromium. The results also showed that the most efficient reactor was that with the transferred arc and quartzite sand positively influenced the vitrification during the pyrolysis of the galvanic sludge. .

Plasma processes allow the synthesis of thin ion-exchange membranes in one single step, contrary to the conventional methods such as the “liquid-phase based” methods requiring multiple steps, reactants, solvents and long reaction times. Plasma polymerized-sulfonated polystyrene membranes deposited by PECVD at (sub)-atmospheric pressure could present interesting properties for applications in fuel cells using polymeric membranes (PEMFC). The membranes were synthesized from a mixture of styrene and trifluoromethane sulfonic acid (triflic acid) monomers in the discharge of a DBD (cf figure 1). The triflic acid allows the grafting of the proton exchange groups on the polystyrene backbone [1,2]. However, coatings deposited by plasma under atmospheric pressure may suffer from poor mechanical and chemical properties because of a low degree of cross-linking, contrary to their analogous synthesized under low pressure. Divinylbenzene (DVB) used as a cross-linking agent was added to the liquid styrene vessel to enhance the mechanical and the chemical properties of the membranes. The effect of the amount of DVB (decreasing the solubility to organic solvents) on the chemical properties and on the elemental composition was studied by XPS, SIMS, and FTIR. XPS measurements confirmed that the elemental composition was not changed in the presence of DVB and all the sulfur was present under the sulfonic acid form. According to the dynamic SIMS results, these groups, necessary for the proton conductivity, were homogeneously grafted on the whole thickness of the

membranes. The influence of the quantity of DVB on the cross-linking was highlighted by solubility tests in methanol. The signal of the substrate was followed by XPS. The cross-linking was also indirectly observed by studying the morphology of the surfaces by SEM.

In addition to the deposition of the membranes on Si for chemical characterizations, the membranes were also deposited on commercial electrodes (gas diffusion layers covered by a catalytic layer) to constitute membranes-electrodes assembly for applications in fuel cells. The various interfaces were characterized by dynamic SIMS and by SEM.

Use of cold plasma treatment to modify the surface of activated carbon as an adsorbent of organochlorinated compounds

T11 Plasma Science and Technology

#PST-P3-10

J. Levalois-Grützmacher, V.K. Rana.

ETH-Zürich - Zürich (Switzerland).

The specific physical characteristics (surface area, pore volume/diameter) and chemical characteristics (pH, ash content, surface functional groups, conductivity) of activated carbon (AC) determine its performance and specific application mode.

Because of its high adsorptive porosity, it has been widely used as adsorbent for organochlorinated insecticides and in catalysis or separation processes.

Two organochlorinated insecticides such as chlordane (CLD) and β -hexachlorocyclohexane (β -HCH) had been intensively used in Guadeloupe and Martinique to control the banana weevil *Cosmopolites sordidus* from 1972 to 1993.

Due to their strong persistence in natural environments, high resistance to chemical reactions and microbiological degradation, the intensive use of these compounds resulted to a generalized pollution of the banana producing area. In order to limit the impregnation by this pesticide, in the polluted areas of Guadeloupe and Martinique, drinking water production plants were equipped with commercial activated carbon (AC) filters.

Cold plasma is well known for being used as a surface modifier and surface cleaning technique of various materials, polymers, powders, nanoparticles and so on for the past decade or more. Here in, several Ammonia-, Argon-, Nitrogen-, Carbon dioxide- and their mixture- cold plasma have been used to modify the surface of activated carbon in order to study the influence of new chemical species at its surface for adsorption of organic compound. The textural properties of these samples were probed by adsorption-desorption isotherm of nitrogen at 77K. Fourier Transform Infrared (FT-IR) and X-ray photoelectron spectroscopy (XPS) were further used to investigate the surface chemistry plasma treated activated carbon.

When a solid is immersed in plasma, two different types of energy transfer occurs: by radiation and by collision of particles. In the first case the heat is transferred uniformly and parallel to the surface. In the second case, it is transferred to the vicinity of micro regions where the thermal spikes are generated. To investigate these two effects, samples of AISI M35, whose hardness values are strongly temperature sensitive tempering were used as micro thermal sensors. By correlating the hardness values with temperature, it was possible to obtain the thermal profile of the samples of AISI M35 treated by plasma. It was found that plasma treated samples exhibited a surface layer and a lower layer in contact with sample port, which is not present in the samples tempered resistive furnace. Furthermore, it was found that samples with a higher thermal gradient in the lower region, were treated in the hollow cathode planar configuration with a pressure of 2 mbar.

Carbon nanotubes (CNTs) have generated a growing interest in various multifunctional applications due to their wide-ranging properties such as high electrical and thermal conductivity, good mechanical properties and electron emission properties. More especially, vertically-aligned CNTs are very attractive as they can be readily incorporated into micro- and nanoelectronic devices. The growth of these forests requires a nanoscale transition-metal catalyst (such as cobalt, iron or nickel) homogeneously dispersed on the surface.

It has already been shown that atmospheric plasma is suitable for the deposition of Au, Pt and Rh nanoparticles. A colloidal solution containing metal nanoparticles is nebulized in the afterglow of a RF torch. The present study shows the deposition of monometallic and bimetallic nanoparticles of Fe and Co. Afterwards, the deposited nanoparticles are characterized by XPS and FEG-SEM combined with EDX to determine the sample composition and the nanoparticles dispersion. As seen on the SEM pictures presented in Figure 1, the nanoparticles dispersion strongly depends on the plasma parameters and the injection geometry. The XPS observations show nanoparticles constituted of iron and cobalt. It is seen on Figure 2 that high resolution cobalt spectra can be fitted in four components due to the presence of metallic and oxidized cobalt. The various oxidation states depend on the deposition conditions such as the discharge temperature and the injection geometry. After heating the sample, the oxidation decreases from 32 to 12%. Gases in the discharge and in the post-discharge are analysed by OES to explain the different oxidation percentages of the samples.

In conclusion, transition-metal nanoparticles of iron and cobalt are deposited by an

atmospheric plasma RF torch. The oxidation of these nanomaterials varies with the process conditions and can be controlled to some extent.

Electron Ionization of RTV Adhesive Outgases in Vacuum

T11 Plasma Science and Technology

#PST-P3-11

W. Feng.

Beijing Institute of Spacecraft Environment Engineering - Beijing (China).

RTV adhesive is widely used in spacecraft such as solar array. It is considered main contamination sources in spacecraft due to outgases of RTV adhesive in orbit. The outgas molecules in orbit might be ionized under space electron environment. Due to spacecraft charging effects in orbit, these contaminant ions will be re-attracted to spacecraft sensitive surfaces and cause severe contamination. In this paper, RTV S691 is used as a contaminant source with heating temperature about 120°C in vacuum. The outgases are ionized by low energy electrons impact which simulate space electron environment. 500eV of electron energy is found to be optimal for ionization. Ionization properties of outgases are researched experimentally. Magnetic deflection method is used for measuring Q/M of outgassing ions. Q/M of RTV –S691 outgassing ions is about 3×10^7 C/kg. The results can be used for simulation of charging effect on spacecraft.

We have recently extended the range of applications of dielectric barrier discharges (DBD) at atmospheric-pressure to the functionalization of wood with the objective of improving its durability following natural weathering [1]. The physics driving the treatment of such materials is however much more challenging than for conventional substrates. This can be attributed not only to the highly anisotropic nature of this polymer, but also to its highly porous microstructure which can release impurities. The influence of wood outgassing on the plasma characteristics was explored using a combination of optical emission spectroscopy (OES) and plasma modeling. In addition to the expected strong He emission lines between 500 and 750 nm, noticeable emission from N₂ and N₂⁺ was observed due to outgassing of air entrapped in wood. OH and O emissions at 309 nm and 777 nm were also present. While the O emission also results from air outgassing, the OH emission is ascribed to etching of the weak boundary layer and humidity desorption from the wood samples and chamber walls. To further analyze the OES spectra and extract the time-evolution of basic plasma parameters we have developed a collisional-radiative (CR) model in which the number density of the emitting n=3 He I states are assumed to be populated according the diagram presented in Fig. 1. Based on this framework, the steady-state rate balance equations for such levels can be written as in Fig. 1, where [He_i] denotes the population of ith state and where 'm' and 'g' refers to metastable and ground state, respectively. A_{ij} is the Einstein coefficient for spontaneous emission. k₁ and k₂ represents the rate coefficients for direct and stepwise electron impact excitation [3]. k₃, k₄ and k₅ are the rate coefficients for energy transfer reactions between the n=3 levels following their interaction with ground state He atoms [4]. Given the low electron temperature (T_e<1 eV) and the low [He_m]/[He_g] ratio (~10⁻⁹ [5]), stepwise excitation dominates over excitation from ground state. In such

conditions, the intensity ratios between the various He I lines are only function of T_e . The measured OES spectra were fitted to the prediction of our model using T_e as the only adjustable parameter. T_e was found to decrease from right after ignition of the first discharge when substrate outgassing are important to longer treatment times when “pumping” of the wood samples is nearly complete.

The evaluation of aerosol (solid and liquid particles suspended in gas) dry deposition rate in rural areas is necessary to evaluate impact of pollutants released in the environment. A method based on eddy covariance measurements has recently been developed for this purpose; this method requires aerosol size distribution and wind velocity with a real time measurement (10 Hz)¹. A device for measuring the aerosol concentration with a response time of 100 ms is to be developed. For such short time measurements, electrical methods based on aerosol charging are promising. Corona discharge is used to produce unipolar ions required for aerosol charging². To limit aerosol losses, charging is carried in the post-discharge zone where the electric field value is lower than 10^5 V.m^{-1} .

For short time charging (<100 ms) a mean ion concentration N_i of 10^{13} m^{-3} is required. Due to electrostatic repulsions, the initial ion concentration is about 10^{16} m^{-3} ^{2,3}.

Two strategies can be used to increase the ion density extracted from the discharge (i) optimisation of the discharge in order to confine ions produced to the extraction hole and/or (ii) optimisation of the extraction by increasing the proportion of ions extracted. Experimental investigations on different discharge geometries are studied and compared to increase the post discharge ion current and density. This work focuses on the ionic current and density extracted from the discharge. The distribution of ions in the charging zone is the next step.

The transport of ions depends on an electro-hydrodynamic competition. A negative point to plane Corona discharge is first studied in various conditions. Ions are
