extracted from the discharge through a hole located in the plane on the axis of the point. The electrical and geometrical parameters are dimensioned to ensure the temporal stability of the ion source. Two methods of ion confinement are then used, convective confinement using a gas flow and electrostatic confinement using an electric field. The effect of the gas flow on the distribution of ionic density of current on the plane for flow range of 5 to 30 L.min⁻¹ and for the hole diameter of 2 mm is studied. The gas flow allows a confinement of the ions to the hole. In fact, the empirical Warburg profile $J(r)=J_0\cos^{4.65}\theta$ given without gas flow⁴ is modified to $J(r)=J_0\cos^6\theta$ ($J(r)$ current density with radial variation, J_0 current density at $r=0$, and $\tan(\theta)=d/r$; d is the inter-electrode distance). The second method of ion confinement is based on electrostatics, the plane is composed of three layers: a thin metallic layer (<50 μm) on the discharge side superposed with an insulator layer and a metallic layer in the post-discharge side. The electric field generated by the polarization of the sandwich increases ions velocity in the hole. An electric field of 10^5 V.m^{-1} increases by three times the ionic current extracted. Two other arrangements, developed to limit the ion electrostatic losses, are investigated to define the optimal one.

Abstract :

Cold Atmospheric Pressure Plasma Enhanced Chemical Vapour Deposition (AP-PECVD) has already demonstrated its potential for homogeneous thin film deposition. A new challenge is the deposition of nanocomposite thin films in AP discharges in order to obtain multifunctional properties.

This contribution is focused on the study of the growth of nanocomposite coatings

based on titanium oxide (TiO₂) nanoparticles embedded in a silica-like (SiO₂) matrix, using a parallel plate dielectric barrier discharge (DBD) at atmospheric pressure. The gas mixture is made of nitrogen (N₂) as the main gas, a mixture of hexamethyldisiloxane (HMDSO) and nitrous oxide (N₂O) for the deposition of the SiO₂ matrix, and nanoparticles of TiO₂, which are introduced in the gas mixture by nebulizing different stable colloidal solutions.

The discharge works in the homogeneous regime, namely the Atmospheric Pressure Townsend Discharge. The gas mixture is injected longitudinally to the dielectric plates, allowing gas phase and surface analyses as a function of the mean residence time, which gives additional information on the thin film deposition mechanisms. The DBD is characterized through electrical and optical diagnostics and the characterization of the coatings is performed using Fourier transform infrared spectroscopy, X-ray photoelectron spectroscopy, Raman spectroscopy and scanning electron microscopy.

Preliminary results show that TiO₂ nanoparticles can be incorporated in the thin film through this process. Moreover, similarly to low-pressure dusty plasmas, the electrostatic forces play a dominant role on the transport of the nanoparticles in the discharge. As a result, an appropriate tuning of the applied voltage waveform (shape, amplitude and frequency) has a direct impact on the distribution of the nanoparticles in the thin film, allowing to elaborate coatings with several potential applications for instance due to the oxygen barrier properties of the SiO₂ matrix and the UV-protection properties of TiO₂.

The cleaning processes of metallic surfaces are often expensive and produces high amounts of waste. Plasma cleaning is a alternative process but it's mechanisms are not completely understood [1,2]. The goal of the present work is to understand how plasma process generates degradation of stearic acid. This material is used as a organic molecule model containing a linear carbonaceous chain and a acid function. The experimental study was made using an inductively coupled RF discharge at 13,56 MHz, with the sample immerse in the discharge. The use of pure Nitrogen as carrier gas is compared with atmospheric air. The mass variation analysis shows that even in long process times it is possible to attain a negative mass variation rate. Atmospheric air plasma showed more efficient cleaning rates than pure N₂ as can be seen in Fig. 1. In other hand, a resin like appearance was observed when the air plasma is used. Infrared spectra (FTIR) were performed on both treated and non treated samples, as shown in Fig. 2. New peaks are observed in the air plasma treated sample: the 3400 cm⁻¹ region shows a small and large peak resulting from the O-H stretching from alcohol function. The peak at 1700 cm⁻¹ becomes more intense and large to higher values of wavenumber, meaning that more C=O are formed in new oxygenated functions with the presence of esters between 1735-1750 cm⁻¹. The region 1100-1300 cm⁻¹ become more intense, probably due to the presence of C-O stretching in some of those new oxygenated functions. In pure N₂ plasma, none of those modifications were observed, meaning that the SA was degraded, seen by the mass loss, but not functionalized as none N-C, N-H or N-O peaks were found in FTIR spectrum.

In the field of plasma bactericidal effects, role of active species produced by plasma is still discussed. Escherichia coli, a well-known GRAM negative bacterium, is chosen as a model to evaluate biological inactivation induced by Atmospheric Pressure Guided Streamers “APGS”, more often called Plasma Jets [1-2].

In a first part, the description of the reactive gaseous medium used for this study is given. Supplied by a pulsed High Voltage power and based on the formation of Dielectric Barrier Discharges (DBD), the plasma jet reactor is electrically analyzed. Optical emission spectroscopy is used in order to qualify the excited species created. Helium and Argon being used as carrying plasma gas, the air environment around the jet lead to the production of numerous Reactive Oxygen and Nitrogen Species (ROS, RNS, RONS) known for their potential actions on biologic cells [3].

In a second part, bacterial inactivation mechanisms are investigated by two ways. First approach is to realize desiccation of bacteria samples on microscopic glass slides. Under these non-physiological conditions, the bactericidal effect of APGS is estimated by traditional counting: survivor bacteria are incubated, and after an overnight, colonies are numerated on Petri dishes. The second approach is to keep the bacteria in physiological liquid medium and to expose directly the solutions to the APGS. Numeration of survivors allows once again to determine the impact of the plasmas by varying several parameters (gas composition, distance between jet and sample, and exposure times).

Finally and in order to try a better understanding of the interaction mechanisms between APGS and the bacteria, chemical analyses of the liquids exposed using

APOLLO 4000 a free radical analyzer will allow to determine the different Reactive Oxygen and Nitrogen Species in solutions, produced or induced by the excited active gases formed by the "APGS".

Abstract

Low-temperature plasma carburizing [1] was performed in order to study the effect of treatment temperature and time on the microstructure characteristics of the carburized layer obtained in AISI 420 martensitic stainless steel samples. Plasma carburizing experiments were carried out in DC-pulsed power supply glow discharge, at 700 V voltage, in 99.5% (80% H₂+20% Ar) + 0.5% CH₄ gas mixture, 1.66×10^{-6} Nm³ s⁻¹ gas flow rate, and 400 Pa pressure, for temperatures of 623, 673, 723 and 773 K, and times of 8, 12, and 16 h. The carburized layers were characterized by SEM, optical microscopy, XRD analysis for two different geometries, Bragg-Brentano and Glancing Angle, and microhardness measurements. The microstructure of the treated samples was revealed by using different etchants, id. est Nital 2%, Marble, and Acqua Regia. Results are discussed aiming to determine the phase constitution of the carburized layers and the eventual occurrence of precipitation-free diffusion layers obtained for the different studied conditions. According to Fig. 1 results, it is evidenced that treatments performed for high carburizing temperature (773 K) lead to formation of chromium carbide precipitates, being critical for the stainlessness characteristic purpose of the treated steel.

Optical emission study of guided streamers at atmospheric pressure

T11 Plasma Science and Technology

#PST-1-Or-1

F. Clément¹, K. Gazeli², P. Svarnas³.

¹UPPA Université - Pau (France), ²UPPA - HVL, Université - Pau-Patras (grèce) (France), ³High Voltage Laboratory, Université Patras - Patras (Greece).

In this work, a DBD-based reactor with coaxial electrode configuration is fed by helium gas (axial flow at 2 slm) and driven by sinusoidal high voltage at 10 kHz. The anode electrode is a microfilament stressed up to 12 kV (peak-to-peak) and housed in a capillary dielectric tube. Thus, apart from the radial DBD due to the coaxial configuration [1], guided streamers (commonly called plasma jets or bullets) are generated [1-3]. The present study, realized by means of spatiotemporally-resolved optical intensity measurements and spatially-resolved optical emission spectroscopy, supports the statement that we deal with classical streamers which are guided by the dielectric. They are propagated in the atmospheric surrounding air and copious excited species are produced along their path. The velocity of those ionizing fronts is found herein to be in the order of magnitude of 10⁶ cm/s. On the other hand, the major reactive species are identified, and the spatial evolution of their intensity and rotational temperature is calculated. The above results contribute to the understanding of the physical mechanisms governing the operation of such systems and as well to their parameterization for different applications.

Motivations

Volatile organic compounds (VOCs) are recognized as major contributors to air pollution either, through their toxic nature and/or as participants in atmospheric photochemical reactions. Among VOCs, acetaldehyde (AC) have received great attention. On the one hand, it is an important component of the total VOC reactivity of the atmosphere, providing sources of new radicals that drive ozone formation [1]. On the other hand, it is emitted in high rates from products that are used widely as building materials [2]. Diphasic processes combining an atmospheric pressure plasma at and a catalyst material has gained attention, and several studies reported an enhancement of the VOCs removal efficiency. When using a plasma/catalysis system, the complex nature of the process has to be considered. The VOC removal is obtained through its decomposition in the gas phase as well as on the catalyst surface, and both steps are closely related. This work is an experimental study of AC removal using an atmospheric pressure plasma combined with a nano-structured catalyst. The intermediates of AC adsorption over the catalyst surface were investigated using in situ DRIFTS (Diffuse Reflectance Infrared Fourier Transform Spectroscopy) method.

Experimental procedure

A sinusoidal dielectric barrier discharge is produced in a cylindrical quartz tube filled with the catalyst. Different catalyst/catalyst support were used (SiO_2 , $\text{TiO}_2/\text{SiO}_2$, $\text{Ag}/\text{TiO}_2/\text{SiO}_2$). The gas mixture is composed by AC (5000 ppm), oxygen (5-20 %) and nitrogen (balance) at a total flow rate of 100 mL/min. Gas chromatography is

used to follow AC concentration at the inlet/exit of the reactor. AC oxidation is evaluated by measuring CO, CO₂, and ozone at the reactor exit. By-products formation is followed by GCMS. The nanoparticles were generated in a sol-gel reactor with rapid (turbulent) micromixing [3].

Results and discussion

The experimental results show that more than 97% of the initial pollutant can be removed at room temperature. The evolution of the CO₂ concentration at the reactor exit show that the type of solid immersed in the plasma discharge had no influence on the CO₂ selectivity. On the contrary, the CO selectivity is strongly affected by the solid particle type. This result indicates a strong interaction between the pollutant and the catalyst (Ag/TiO₂). In order to better understand the role of the catalyst, the interaction of AC with the surface was followed in-situ using the DRIFTS method. The results show that when AC is brought into contact with the Ag/TiO₂ surface, an acetylene intermediate is formed. Based on these results, we propose a two-steps removal process of the pollutant, involving heterogeneous surface and homogeneous plasma chemistry.

In the literature, few studies focus on the use of water in plasma discharges. Indeed, despite its potential high reactivity, water is also known to destabilize plasmas. In this study, the reactivity of water at the interface between an atmospheric plasma torch and the surface of the low density polyethylene (LDPE) was investigated. The injection of water in the post-discharge avoids the plasma destabilization, while keeping its reactivity. More specifically, the reactivity of the OH radical for surface grafting will be investigated. LDPE was chosen because of its high capacity to be functionalized.

We characterized in parallel the composition of the gaseous post-discharge and the substrate modifications. The water vapor is injected in the post-discharge of a RF torch by an injection system located just under the ground electrode. The post-discharge is characterized by optical emission spectrometry (OES) to determine the different emitting species. The evolution of each species and the impact of the quantity of water are followed by OES. OH, N₂, O₂⁺, Ar and atomic oxygen were present in the post discharge and the evolution of their behavior was helpful to understand the reactions in the gas phase. Indeed, as shown in Fig 1, the amount of some species increases with the injection of water (such as OH, O₂⁺) whereas it decreases for the other species. The amount of ions can be related to electrical measurements recorded through a copper plate placed downstream of the discharge to determine the ionic current for different plasma conditions and concentrations of water.

The modified LDPE is characterized by static contact angle (WCA), X-ray photoelectron spectroscopy (XPS) and time-of-flight secondary ion mass

spectrometry (ToF-SIMS). The first technique gives access to the surface energy, more specifically its polar component. The functionalization of the surface can be evidenced by the observation of a decreasing WCA. The two others techniques allow to determine the surface chemistry, as well as its in-depth distribution. The use of D₂O for the treatment of the LDPE allows to probe the origin of the functions grafted at the surface of the polymer.

All of these analytical techniques are used to understand mechanisms of the surface functionalization and to predict some reactions in the post discharge and at the surface of the LDPE. This work was supported by IAP – PSI (Physical Chemistry of plasma surface interactions (Belgian Federal Government BELSPO agency)).

Conversion of CO₂ and CH₄ mixtures using a dielectric barrier discharge: gas composition and power effect

T11 Plasma Science and Technology

#PST-P3-13

A. Ozkan, G. Arnoult, P. De Keyzer, F. Reniers.

Université Libre de Bruxelles - Bruxelles (Belgium).

Carbon dioxide is usually considered as an end-product in chemistry because of its high stability. Due to the high quantities of CO₂ produced, its conversion received more and more attention in the recent years [1]. The transformation of CO₂, with CH₄ as second reactant and using atmospheric plasma technology shows that, in appropriate conditions, both gases can be converted into valuable products [2-5]. The conversion of CO₂/CH₄ mixtures was performed using a dielectric barrier discharge (DBD) atmospheric plasma using Argon as the plasmagen gas. Gas Chromatography was used to determine the composition of the gas after plasma treatment and this treatment was carried out in a new type of reactor developed in the laboratory. We demonstrate that the synthesis of syngas (CO and H₂), C₂H₆ and C₂H₄ is possible in this type of discharge. The study is focused on the effect of parameters on the CO₂ and CH₄ conversion rate. The parameters which are evaluated in this work are the ratio of CO₂/CH₄ flow rates and the power supplied. We show that the ratio of CO₂/CH₄ flow rates in the mixture has a significant impact on the conversion rate. On the other hand, as only small amounts of oxygenated organic compounds have been detected, it is suggested that there are no many interactions between the active species of these two molecules. Moreover, the absence of oxygen after CO₂/CH₄ plasma, suggests that atomic oxygen is consumed by the CH₄ present in the plasma. On the other hand, the effect of power is clearly visible, showing a linear increase in the CO₂ and the CH₄ conversion rates and of the syngas production with the supplied power [Fig. 1]. Therefore, an electron-driven mechanism is suggested.

Thanks to its very specific properties (low surface energy, great chemical resistance...) Polytetrafluoroethylene (PTFE) is a polymer used in a wide range of extreme environment applications. However its high cost and poor recyclability limit its use in more general applications. Atmospheric plasma polymerization enables us to quickly and easily deposit PTFE like films on a wide range of materials. This allows us to modify the surface properties of those materials to obtain properties close to the one of pure PTFE while greatly diminishing the use of expensive and non-environmentally friendly fluorinated compounds. Furthermore we use non toxic liquid precursors. This simplifies their handling and the upscaling of the process for industrial applications.

Several types of fluorinated precursor are compared (C_6F_{14} , $C_{12}F_{27}N^1$). The influence of the precursor structure on the deposition speed and the film quality is studied. The influence of the plasma gas (Ar or He) is also studied. Surfaces compositions are determined by X-ray photoelectron spectroscopy (XPS) and surface energy by water contact angle (WCA) measurements. Our results shows that the precursor as well as the plasma gas used have little influence on the final composition and surface energy of the coatings. However a strong difference in the deposition rates is observed.

Further studies using atomic force microscopy might highlight small differences in the films structure depending on the plasma gas used as already shown in the literature². The coating deposited on various substrates present surface composition (XPS) and surface energies (WCA) similar to the one of pure PTFE regardless of the starting composition and surface energy of the substrate (table 1 and figure 1).

Finally the effect of the plasma source is also studied. Films deposited in the plasma using a dielectric barrier discharge (DBD) are compared to films deposited in the post-discharge of a commercial radio frequency plasma torch.

Dry reforming of CO₂ by DBD plasma at atmospheric pressure

T11 Plasma Science and Technology

#PST-05-Or-5a

T. Bieber, G. Arnoult, P. De Keyzer, F. Reniers.

ULB - Bruxelles (Belgium).

Carbon dioxide is usually considered as a waste, unavoidable end-product of many industrial processes. Due to its high chemical stability, carbon dioxide is indeed poorly used as a reactant. It is therefore necessary to develop technologies able to reuse it. In this objective, dry reforming of carbon dioxide by plasma has attracted significant interest to generate carbon monoxide which has an interesting energetic value [1], [2].

We present here a study of the plasma assisted conversion of CO₂ into CO and O₂ in a new Dielectric Barrier Discharge plasma device operating at atmospheric pressure. We focused on determining the influence of several parameters on the conversion efficiency: the input power, the flow rate and finally the presence of oxygen in the input gas mixture. Gas chromatography and mass spectrometry at atmospheric pressure are used to determine the composition of the gas after plasma treatment. Conversion rates for CO₂ can then be extracted.

The conversion rate increases with the power (from 100 W to 300 W), suggesting an effect of the electron density (Fig.1). On the other hand, the conversion rate drops with increasing flow rate, from 1 L/min to 10 L/min. Indeed since the flow rate is inversely proportional to the residence time of the gas in the reactor, increasing it means that the gas spends less time in the plasma. Finally, the presence of oxygen in the input mixture leads to a lower conversion rate, probably due to an increase of the recombination reaction $\text{CO} + \frac{1}{2} \text{O}_2 \rightarrow \text{CO}_2$.

Optical emission spectroscopy is also performed on the plasma during the

experiment in order to try to understand the physical processes at the origin of these results.

For practical reasons, technical plasmas are commonly in the low-pressure range below 100 Pa or at atmospheric pressures. When considering non-thermal plasmas, low pressure plasmas easily allow for low process temperatures due to the non-equilibrium state between “hot” electrons and “cold” neutral gas. The advantage of these plasmas is the high degree of ionization and high degrees of radical formation which can be achieved. At atmospheric pressure, e.g. dielectric barrier discharges are used for non-thermal processes. The advantage of this pressure regime is that no vacuum pumps are required, however, it is difficult to achieve high radical densities and higher ignition voltages are required.

On the first glance, intermediate pressure between 100 Pa and atmospheric pressure bears mostly disadvantages like elevated ignition voltages when compared to low-pressure plasmas and the necessity of pumps when compared to atmospheric pressure plasmas. However, e.g. in the presence of fluids with a vapor pressure above 100 Pa, this pressure regime is an interesting option.

In our paper, we present first spectroscopic measurements in a capillary plasma in the intermediate pressure range with gas mixtures of nitrogen, oxygen, and water which could occur e.g. during processes for water cleaning by plasmas. The species traced in a variety of gas mixtures are nitric oxide, ozone, atomic oxygen, and OH radicals. These molecules are measured by optical emission spectroscopy [1, 2] and laser-induced fluorescence [3-5]. The study of the pressure dependence allows identifying interesting process windows for future applications.

PST-P2-13

Abel inversion technique used for radial measurements of the microplasma in Ar-2%H₂ flow at open atmosphere

T11 Plasma Science and Technology

#PST-P2-13

B. Sismanoglu, R.F. Caetano.

ITA - São Jose Dos Campos (Brazil).

In this work Abel inversion technique was used for radial measurements of the microplasma in Ar-2%H₂ flow at open atmosphere. The gas discharge parameters were investigated using spatially resolved high resolution optical emission spectroscopy (OES) to allow acquisition of OH ($A^2\Sigma^+, v = 0 \rightarrow X^2\Pi, v' = 0$) rotational bands at 306.357 nm, Ar I 603.213 nm line and N₂ ($C^3\Pi_u, v = 0 \rightarrow B^3\Pi_g, v' = 0$) second positive system with the band head at 337.13 nm. The non-thermal plasma was generated between microhollow anode (~ 500 μm inner diameter) and a cathode copper foil, fed by direct current source. The 1.5 mm length cylindrical-shape plasma has an outspread bright disk (negative glow region) near the cathode surface. Besides the gas temperature, the excitation temperature was measured radially for a current ranging from 20 to 100 mA, either from Boltzmann-plot of Ar I 4p – 4s and 5p – 4s transitions of excited argon or from Cu I two lines method of excited cuprum atoms released from the cathode surface. For the N₂ second positive system with $\Delta v = -2$ it was estimated the vibrational temperature for the bright disk (1500 to 5000 K). H β line Stark broadening was employed to define the electron number density of the negative glow (10^{15} cm^{-3}). Microplasma are a novel kind of non-thermal, stable and homogeneous glow discharges, operating at moderate to atmospheric pressure [1]. Both direct current (DC) microplasmas (MP) or atmospheric-pressure microplasmas jet (APMJ) are glow plasmas and the latter operates at atmospheric pressure (AP) air. In APMJ the jet is formed by flowing gas (or a mixture of gases) through an open microhollow or microtube (tungsten-carbide, ~ 500 μm inner diameter). Linear Stark splitting of the seven components of Balmer H β line and spatially resolved OES (SR-OES) measurements were applied to measure the cathode layer thickness of about $dc \sim 70 \mu\text{m}$ [2]. In the present paper we extended the optical characterizations using SR-OES for the negative glow located next to the cathode foil, from 100 to 500 μm

from the cathode. Through Abel inversion, the radial distribution of T_g could be found for this thin region. OES were carried out with Abel inversion technique aiming to determine the microplasma parameters at the bright region in front of the cathode. Measurements show the emission lines from the plasma volume close to the cathode surface, where intense radiation emerges from the negative glow region. One can see in this figure intense Ar I 4p – 4s and 5p – 4s lines. The OH, NO, NH and N₂ spectrum commonly appears as well. The bell-shape radial distribution of the gas temperature at the negative glow for different discharge currents was obtained where the maximum of the temperature is about for $r = 125 \mu\text{m}$ and the minimum occurs at $r = 300 \mu\text{m}$, at the plasma edge. The vibrational temperature (for the plasma disk) was in the range 1500 - 5000 K for a current varying from 20 to 100 mA.

MICROWAVE PLASMA SYSTEM FOR THE SYNTHESIS OF CARBON NANOTUBES

T11 Plasma Science and Technology

#PST-P3-20

L. Szymanski, Z. Kolacinski.

Lodz University of Technology - Lodz (Poland).

There is a lot of nanotubes production methods [1-5]. The paper presents the research results of CNTs synthesis in a microwave plasma system in the atmospheric pressure. Synthesis of carbon nanotubes is followed in a steel chamber on a metal substrate. The substrate is a metal strip, which is ideal for this purpose. The paper presents the calculation results of the reactants composition to produce carbon nanotubes. These allow to determine the optimal composition and plasma parameters. Fig.1. shows the photo of the reactor. Fig. 2 shows the CNT forest and nano carpet on metal strip obtain from plasma reactor.

THE AFTERGLOW OF SURFACE-WAVE MICROWAVE DISCHARGES IN SERVICE OF BIOMEDICINE AND NANOTECHNOLOGY: SECRETS REVEALED BY MODELLING STUDIES

T11 Plasma Science and Technology

#PST-2-In-1

K. Kutasi.

**Research Institute for Solid State Physics and Optics, Wigner Research Center
for Physics - Budapest (Hungary).**

Low pressure flowing afterglows rich in N and O atoms, as well as in nitrogen and oxygen content metastable and UV radiating species, meet several important applications, such as plasma based medical sterilization, functionalization of polymers, surface treatments, thin film synthesis, with further potentials in nanostructuring and biomedicine. With microwave surface-waves high density discharges can be generated. When the discharge is ignited in flowing gas the species created in the discharge can be transported in different size afterglow reactors. By modelling of an afterglow system the species density distributions at different discharge conditions and system configurations can be determined, as well as the flow of the plasma can be visualized, which make possible the understanding of different application processes and the optimization of the system for given applications. The effect on the active species density distributions of the gas flow, system wall material and configuration of the reactor concerning the position of the gas inlet and outlet are revealed by the modelling results.

PST-5-In-1 PLASMA ENGINES FOR INTERPLANETARY EXPLORATION

T11 Plasma Science and Technology

#PST-5-In-1

C. Charles.

Space Plasma, Power and Propulsion Laboratory Research School of Physics and Engineering, The Australian National University - Canberra (Australia).

Commercial space companies and space agencies are responding to society's growing interest in access to space, i.e. satellites on low or geostationary Earth orbits and long term exploratory missions to moons, planets or asteroids. Plasma engines will play a major role in interplanetary exploration as they are good candidates for providing extended lifetime, power scaling and broad choice of propellant (including use of spacecraft systems's residues and propellant mining from planetary visits). Here the physics behind the development of new-generation low-cost plasma space engines will be presented using the example of the Helicon Double Layer Thruster space qualification. New technological challenges (i.e. design of new electronic modules and new space compliant materials) need to be addressed for safe and successful access to space. Applying these technological advances to plasma based thin film processes will be discussed.

RECENT RESULTS IN EUV AND SOFT X-RAY SOURCE DEVELOPMENT

T11 Plasma Science and Technology

#PST-1-In-2

P. Dunne, G. O'sullivan.

UNIVERSITY COLLEGE DUBLIN - Dublin (Ireland).

Extreme ultraviolet lithography requires the development of highly efficient sources emitting within a 2% bandwidth at 13.5 nm for efficient matching to Mo/Si multilayer mirrors. Recent results in source development at this wavelength reflecting the different needs of metrology and high volume manufacturing will be discussed. Current and recent work on effects of target composition and geometry, laser pulse profile and power density etc will be presented and comparisons will be made between theoretical and experimental results.

In addition, the results of recent work, both experimental and theoretical, on sources for 6.x nm operation for beyond EUV lithography and for 'water window' operation in the will be discussed.

PST/SE/TF-1-In-1 COLD ATMOSPHERIC PLASMAS FOR THIN FILM DEPOSITION AND SURFACE TREATMENT

T11 Plasma Science and Technology

#PST/SE/TF-1-In-1

J. Benedikt.

RUHR - Bochum (Germany).

Cold atmospheric plasmas are known for their ability to generate high densities of reactive, excited or ionized species at gas temperature very close to room temperature. It is the result of their non-equilibrium character, where electrons have energies in the range of few electron-volts. We use atmospheric pressure microplasmas to study gas phase reactions (studied for example by molecular beam mass spectrometry) and the interaction of plasma generated species with the substrate. The latter one is achieved in the experiment with several microplasma sources treating rotating substrate. Additionally, a special modification of the jet allows us to separate the effect of plasma-generated photons from the effect of reactive particles. The overview of these experiments and the latest results will be presented.

PST-1-In-1

DIAGNOSTICS OF ACTIVE SPECIES IN ATMOSPHERIC PLEASURE PLASMAS

T11 Plasma Science and Technology

#PST-1-In-1

C. Leys.

GHENT UNIVERSITY - Ghent (Belgium).

Atmospheric pressure plasma jets (APPJs) are being used in a wide range of applications, including (bio)medical. However, the understanding of the underpinning plasma-chemical processes is incomplete. Spatially resolved and quantitative measurements of active species are required to shed some light.

The talk will focus on the application of laser-based diagnostics to atmospheric pressure plasma. The spatial distribution of active species generated in an RF plasma jet in Ar/H₂O and Ar/O₂ mixtures is determined by LIF and TALIF (O₂). Argon metastables produced in the jet afterglow are measured with a diode laser absorption technique. Some problems connected to active and passive laser diagnostics in APPJs will be discussed.

PST-3-In-1 PLASMA PROCESSING OF “SOFT” MATERIALS: REACTIONS BETWEEN ATMOSPHERIC-PRESSURE PLASMAS AND IONIC SUBSTRATES FOR NOVEL MATERIALS APPLICATIONS

T11 Plasma Science and Technology

#PST-3-In-1

M.R. Sankaran.

**Department of Chemical Engineering, Case Western Reserve University -
Cleveland (United states).**

Plasma processing is a well-established technique that typically describes the dry etching and deposition of metallic and semiconducting thin films at low pressures. Plasmas can also be used to modify “soft” materials such as liquids and polymeric films. In this case, the development of atmospheric-pressure plasma tools has facilitated integration with substrates that are often not stable at vacuum conditions. Atmospheric-pressure processing is also compatible with roll-to-roll processing, making it possible to process large areas of polymer films at low cost.

In this talk, I will present our recent investigations of plasmas formed with liquid and polymeric substrates. In particular, I will focus on a specific class of reactions, the reduction of ionic metal precursors by plasma electrons, which can lead to the nucleation of metal nanoparticles either in solution as a colloid, or in films as a nanocomposite. Potential applications of these reactions include the synthesis of metal nanoparticle inks for sensing applications and the direct fabrication of flexible, conductive films for advanced electronics. I will discuss details of our process, hypothesized mechanisms behind the reactions and particle growth, and progress towards applications.

Motivation

Previous studies of plasma discharges in liquid water or gaseous mixtures with water [1,2] have demonstrated that non-equilibrium plasma could produce significant active species such as H₂ or H₂O₂. Nevertheless, the fundamental mechanisms of breakdown, as well as the chemistry of water plasmas at atmospheric pressure are not well understood. Our previous studies [3] have shown that H₂ production was promising. In this work, we focus on intermediate products of the discharge, in particular the hydroxyl radical.

Results and Discussion

The plasma was generated in water vapor at 450 K and atmospheric pressure by 20-ns duration high-voltage (0-20 kV) pulses, at a repetition frequency of 10 kHz [4]. Between two discharges, the time-resolved density of OH was measured by Planar Laser Induced Fluorescence (Fig. 1a). The temperature during the discharge was determined by optical emission spectroscopy from 0-12 ns, and between two pulses by 2-color OH-PLIF (Fig. 1b).

A 150 K preheating effect from the previous pulses is measured, with a maximum temperature elevation of 950 K during the first 8 μs following each pulse. The experimental OH density measurements were compared with chemical kinetics simulations. The decay of the OH density depends on the initial OH density. According to Fig. 1c, the numerical simulations obtained show good agreement with

the experimental data with an initial OH density of 500 ppm is assumed, thus providing a quantification of the OH density produced by the pulses.

Strategies for low-damage plasma etching of advanced k=2.0 porous organo-Silicon glass materials

T11 Plasma Science and Technology

#PST-4-In-1

J. De Marneffe.

IMEC - Leuven (Belgium).

VLSI manufacturing beyond the 14nm technology node requires the introduction of interconnect dielectric materials with dielectric constant k of the order of 2.0 or below (Grill, 2009). Up till now, two classes of materials have been investigated, namely organic dielectrics (polymers) and organo-silicate glasses. In all cases, reaching such a low k value requires to introduce porosity (up to 50% with pore radius up to 3nm), which makes the material extremely sensitive to damage during plasma patterning, leading to unwanted change of their dielectric properties. Plasma damage occurs through the diffusion of reactive radicals into the porous structure and/or VUV photo-induced scissioning of Si-CH₃ groups, both leading to the formation of silanols and moisture absorption (Baklanov et al., 2013). Conventional approaches to solve this issue can be arranged in three categories: first, the optimization of the low- k dielectric material in order to reduce its sensitivity to plasma damage; second the optimization of the plasma etch process in order to make it less damaging; third the development of repair strategies. A novel solution is the sacrificial pore protection approach, where pores are temporarily filled by a protective agent, avoiding diffusion of radicals. This can take place at room temperature (ex-situ pore protection) and require careful selection of the filling agent and filling conditions (Frot, Volksen, Purushothaman, Bruce, & Dubois, 2011). Another approach (in-situ pore protection) is to perform the plasma etch at cryogenic temperatures ($-120 < T < -70^{\circ}\text{C}$), where reaction by-products condensate into the pores (Zhang et al., 2012). An overview will be given on the current state of these various concepts, putting the emphasis on innovative solutions to keep sustaining the pace of the ITRS roadmap.

The effect of two step aging on the compressive residual stress and hardness distribution of the shot peened 7075 aluminium alloy with SiCNH coating

T12 Surface Engineering

#SE/TF-2-Or-12

Ł. Kaczmarek¹, K. Kyzioł², J. Sawicki¹, M. Stegliński¹, B. Januszewicz¹, H. Radziszewska¹, P. Zawadzki¹, R. Wójcik¹, K. Kubacki¹.

¹Lodz University of Technology - Lodz (Poland), ²AGH University of Science and Technology - Cracow (Poland).

This paper describes two stages of optimization of the properties of 7075 aluminium alloys, in particular their resistance to pitting by two-stage artificial aging process (T6I6 or T6I4 treatment) connected with shot peening, of the substrate and SiCNH coating deposition.

After analysis of the measurement of stress gradient one can observe that the relatively high compressive stresses (ca. -170MPa) were present at the depth of approximately 0.15mm. This fact is a consequence of the heat treatment and cold working on surface. The relation between internal stresses and the distance from surface is consistent with the results of studies described in the reference literature [1-3]. On the other hand, the differences in obtained values of internal stresses in analysed samples are influenced by the time of conducting the shot peening process with respect to the two-stage heat treatment. In this case the maximum value of internal stresses on surface layer of analysed samples after T6I6 heat treatment (I stage 393K - II stage 433K) and subsequent shot peening process reached - 280 Mpa ± 5.5MPa. Additionally, the hardness peak reached almost 210 HV. It shows

that there exists a possibility of carrying the aging process of samples formerly subjected to shot peening, by these means virtually eliminating the internal stress relaxation with simultaneous obtainment of the surface hardness of value $\approx 200\text{HV}$. The obtained results of analysis, related to the attainment of maximum strengthening of surface layer with the highest possible compressive stresses, served as the basis for carriage of precipitation processes in the surface layer, together with simultaneous deposition (by radio-frequency chemical vapor deposition method) of low friction (0,05) and low wear gradient layers of SiCNH on 7075 aluminium alloy [4].

In order to check the behavior of obtained materials with coatings in real working conditions a computer simulation with the use of ANSYS software was performed. Numerical simulations were conducted for an existing gear with small module, applied in military spy robot. Analyzing the superposition of stresses it can be observed that the value of compressive stresses in contact point was increased by about 150MPa. Such stress distribution prevents even more the contact fatigue of gear, in such way ensuring the high durability of the discussed system.

This work was supported by the Polish State Committee for Scientific Research under project no. NN 507 269540

Strategies to Design Nonleaching Antimicrobial Materials

T12 Surface Engineering

#SE/PST/TF/BI-1-Or-8

E. Taffin De Givenchy, T. Darmanin, S. Amigoni, F. Guittard.

Université de Nice-Sophia Antipolis - Nice (France).

The battle against nosocomial infections such as, among others, surgical infections, remains one of the major actual challenges of the hospital. Today, Health Personnel are extremely cautious to avoid inert surfaces (catheters, implants, therapeutic equipment, floors...) contamination by micro-organisms. However, despite the use of disinfectants, antibiotics, and the setting of strict hygienic conditions, it seems that nosocomial infections control remains one of the major challenges for medicine. If cautions are numerous to avoid any pollution of inert surfaces (catheters, implants, medical equipments, floors, etc.), the phenomena of resistance developed by the most part of pathogenic organisms requires, on one hand, the elaboration of new biocides agents and, on the other hand, completion of long-term bactericidal treatments of surfaces or, in an ideal case, a permanent biocide effect of the surfaces without releasing of the antimicrobial active agents.

In the perspective to elaborate non leaching biocidal materials, our team has undertaken research works in several ways:

- design and evaluation of new low molecular weight fluorinated biocidal agents [1].
- elaboration of biocidal self assembled monolayers on metallic surfaces [2].
- development of biocidal polymers as coatings on various substrates [3].
- and more recently, a novel approach using the repellent properties of super-hydrophobic surfaces has been envisaged [4].

These strategies will be discussed.

SE/PST/TF/BI-1-Or-9

Highly Functional and Permanent Plasma Polymer Layers Enabling Biomedical Applications

T12 Surface Engineering

#SE/PST/TF/BI-1-Or-9

D. Hegemann, A.G. Guex, A.M. Bühlmann.

Empa - St. Gallen (Switzerland).

Biomedical applications often require stable surface modifications of the used substrates to allow their use in aqueous environments. Electrospun scaffolds for tissue engineering and porous membranes for drug delivery were thus functionalized using plasma polymerization. Nano-scaled plasma polymer layers comprising oxygen or nitrogen functional groups enable the permanent functionalization of the submicron-scaled polymeric substrates without affecting their bulk properties. Hence, the surface chemistry can be modified while maintaining their 3D architecture. For this purpose, however, it is required that both gas phase and surface processes are well controlled during plasma polymerization [1]. While gas phase processes are governed by the energy invested per particle, surface processes also depend on the energy flux during film growth. To enable the modification of structured surfaces with good penetration, however, film growth conditions mainly based on plasma chemical processes have to be explored.

Amino-functionalized plasma polymer layers were investigated for the functionalization of track-etched polyester (PETE) membranes [2]. By varying the $\text{NH}_3/\text{C}_2\text{H}_4$ gas ratio and the energy input, the amount of incorporated amino groups ($\text{NH}_2/\text{C} \approx 0.05$) was optimized. These groups were then utilized to chemically attach thermoresponsive poly(oligo(ethylene glycol) methacrylate) (pOEGMA) copolymers forming brushes. The controlled permeation of caffeine through the membrane was demonstrated. Permeation is enabled at 40 °C, while it is blocked at 20 °C. $\text{CO}_2/\text{C}_2\text{H}_4$ gas discharges were examined on electrospun poly(ϵ -caprolactone) (PCL) scaffolds as used for tissue engineering [3]. Gas ratio and energy input into the plasma were found to influence the incorporation of oxygen-containing groups into the plasma polymer layer. Ultrathin layers are required in order not to affect the stiffness and Young's modulus of the substrate. Functionalized scaffolds showed improved proliferation of C2C12 heart muscle cells and the differentiation of myotubes.

All experiments were performed within a capacitively coupled, low pressure plasma set-up in order to make use of large mean free path lengths. A comparison to atmospheric pressure plasmas was performed, as well, showing similarities, but also differences in surface morphology. Highly functional and permanent plasma polymer layers can thus support different biomedical applications by tailored surface engineering.

SE/TF-P2-01

Influence of 5 eV Collision of O-Atoms on Material Erosions in Low Earth Orbit Space Environment

T12 Surface Engineering

#SE/TF-P2-01

M. Tagawa, K. Yokota.

Kobe University - Kobe (Japan).

Materials used in the exterior surfaces of spacecraft orbiting in the low earth orbit (LEO) experienced severe erosion by the hyperthermal collision with O-atom which is the major atmospheric species in LEO [1]. Due to the high-orbital velocity of spacecraft (8 km/s), the impact energy of O-atom to the spacecraft surface reaches as high as 4.7 electronvolts, which is higher than the interatomic bonding energy of many materials. Thus, the chemical reactions occurred at the spacecraft surfaces are under the effect of high-impact energy. Many flight projects have been conducted to clarify the erosion properties of materials in LEO, for example, Materials International Space Station Experiment (MISSE) [2]. On the other hand, much effort has been paid for simulating the materials degradation in a ground-based facility. A microwave or radio frequency oxygen plasma source has been used for material screening test, however, this type of simulation facility does not simulate the collision energy of atomic oxygen in LEO. In order to simulate the impact energy of O-atom (5 eV), a laser-detonation method has been applied [3]. However, the effect of this impinging energy has not been fully understood.

In this presentation, role of the impact energy on the material degradation is focused. One example of the role of impact energy of O-atom was demonstrated in the temperature dependence of polyimide [4]. It has made clear that the temperature dependence of erosion rate of polyimide showed a discrepancy between ground and space, i.e., no temperature difference was observed in space, in contrast, clear difference was obvious on the ground experiment with thermal O-atom. We have examined the temperature dependence of polyimide erosion by the combination of polyimide-coated quartz crystal microbalance (QCM) and laser detonation hyperthermal O-atom beam source. As a result, a clear difference on the temperature dependence of polyimide erosion was measured depending on the impact energy.

The activation energies of the polyimide erosion were 5.7×10^{-4} eV for the 5.0 eV O-atom beam, whereas 4.5×10^{-2} eV for the 1.1 eV O-atom beam at the temperature range between 253 and 353 K. The effect of impact energy is effective not only in the direct reaction, but also in the trapping desorption. Minton et al. reported that the CO and CO₂ signal from the O-atom reaction increased significantly with increasing the impact energy [5]. The similar result was obvious when Ar beam irradiated the oxidized polyimide surface. This experimental result clearly suggests the role of impact energy of incoming atoms on the desorption process of the reaction products in LEO. This is also confirmed from our recent experiment using velocity selector of the neutral beams. The detail of this experiment will be reported in the presentation.

A part of this study was supported by a Grant-in-Aid for Scientific Research from JSPS.

Nanocomposite coatings for improving the corrosion

T12 Surface Engineering

#SE-2-Or-4

L. Benea.

Dunarea de Jos University of Galati - Galati (Romania).

Metal matrix nanocomposites containing dispersed second-phase particulates usually have various special properties such as dispersion hardening, self-lubricity, high temperature inertness, good wear and corrosion resistance, or tribocorrosion resistance and chemical compatibility. This accounts for the increased application of metal-based nanocomposites in industry applications and open a way to biocompatible coatings. In order to meet the requirement for developing novel metal-based nanocomposites, many preparation techniques have been investigated. As a technique conducted at a normal pressure and ambient temperature and of low cost and high deposition rate, electrodeposition is considered to be one of the most important techniques for producing nanocomposites and nanostructured surfaces. Electrodeposition is exceptionally versatile, so that new and exciting applications are still being invented. The paper presents some results regarding the co-deposition of nano bio ceramic dispersed phases as ZrO₂, CeO₂, SiC, or polymeric dispersed phases as UHMWPE (ultra high molecular weight polyethylene) during cobalt or nickel electroplating process in view of obtaining bio composite layers or resistant industrial coating applications. In Figure 1 it is presented a schematic representation of co-electrodeposition process of insoluble CeO₂ bioceramic dispersed phases with metallic matrix of cobalt.

Fig. 1. Schematic electro-co-deposition process of nano-CeO₂ dispersed phase to obtain Co/CeO₂ (25 nm) nanocomposite coatings: (a) SEM surface of Co/CeO₂ nanocomposite film; (b) Schematic electrochemical process; (c) SEM image of CeO₂ particles.

It is important to adjust the electroplating variables in order to control the properties of the produced nano or micro structured composite coatings that depend on the amount of incorporated particles and their distribution in the metal matrix, as well as, on the micro and nano structural characteristics of the metal matrix. The paper presents challenges and results on ceramic, bioceramic and polymeric dispersed

particles (SiC, ZrO₂, CeO₂, UHMWPE) into cobalt and nickel matrix as well as the properties investigations and performances of composite coatings obtained. The nanoparticles incorporation into the metal matrix usually causes a noticeable grain refinement and thus an increase to the corrosion and tribocorrosion resistance in aqueous or simulating body fluids (SBF) environments.

INVITED PRESENTATION

Self-organized Nanostructuring in Hard Nitride Thin Films

Lars Hultman

Thin Film Physics Division, Department of Physics IFM), Linköping University,
Linköping, Sweden

Designed nanostructuring is presented for enhancing hardness [1] and fracture toughness [2] in wear-resistant transition metal nitride alloy thin films deposited by cathodic arc, reactive magnetron sputtering, and novel hybrid HIPIMS/DC magnetron sputtering [3]. Model systems for metastable alloy nitrides TiAlN, ZrAlN, HfAlN, TiSiN, MoVN, VWN are analyzed by XRD, HREM, FIB, APT, [4] and phase field modeling [5]. *Ab initio* calculations are employed to assess phase stability and decomposition behavior from lattice mismatch and electronic band structure effects. [6]

Superhardening occurs in TiN/Si₃N₄ nanocomposites due to Si segregation forming a few-monolayer (ML)-thick SiN_x tissue phase [7,8], which can be a vacancy-stabilized cubic-SiN_x layer [9]. A hardness maximum at 34 GPa – short of ultrahard - is observed in TiN/SiN_x(001) superlattices at the epitaxial break-down limit for the SiN_x(001) layers. A method based on focused ion beam milling is described for studying the tool–chip interfaces of the rake face of a TiSiN-coated PCBN insert after turning operation. [10]

The concept of age hardening in transition metal nitride alloys [11] is reviewed for appropriate isostructural model systems. Spinodal decomposition is thus established for TiAlN by the formation of cubic-phase nm-size domains in a checker-board-pattern of TiN and AlN [1] at temperatures corresponding to cutting tool operation. The effects of pressure [12], volume mismatch [13] temperature, composition, disorder [14], and stoichiometry [15] will also be discussed.

The CrNV(x) coatings with content of Vanadium (V) in the range of 0.1-32% were obtained using reactive d.c. magnetron sputtering. Two types of the friction tests in wide range of the temperatures (25-700 0C) have been performed: stick-slip and reciprocal ball-on disk experiments. The aim of this work is to study the effect of content of V and the temperature on friction and wear behavior of rubbed surfaces. The interaction between stick-slip phenomena and the friction properties in real (severe) contact conditions will be considered. Amplitude of the friction coefficient and the creep parameter were chosen as the base parameters in the analysis of stick-slip behavior. Spring stiffness, sliding velocity and load were optimized during the preliminary tests. Tribological experiments were also performed using a reciprocating ball-on-flat test machine (SRV-IV, Optimol Instruments). During preliminary tests a frequency of 25 Hz was chosen as the typical frequency. Surfaces at virgin state and after friction were analyzed by XPS, SEM and AFM techniques. The effect of the V content on the fracture toughness was determined. It has been shown that an addition of the V led to decreasing of the grain size and increasing the fracture toughness. With increasing the content of V, the hardness was increased and the tribological properties of coating were improved. The effect of temperature on the friction coefficient and a variation of the structure of surface layers were evaluated. The oxidation of surface layers of coatings with high value of V (25- 32%) led to formation of oxide films of V₂O₅. These oxide film characterized by Magneli structure provides easy shearing similar to that obtained for self-lubricating materials. The coefficient of correlation between in real contact conditions was estimated. Good

correlation between stick-slip parameters and the values of the friction coefficient was revealed. The presented results demonstrate a possibility to use short stick-slip experiments as express method in the analysis of the effect of content of additive and the temperature of contact on the tribological properties of rubbed surfaces.

SE/TF-P2-02

Synthesis and evaluation of smart self-healing plasma electrolytic oxidation coatings on Mg

T12 Surface Engineering

#SE/TF-P2-02

M. Sun, A. Matthews, A. Yerokhin.

The University of Sheffield - Sheffield (United kingdom).

Owing to low density and high specific strength, magnesium and its alloys have been regarded as ideal materials in a broad range of engineering applications such as aerospace, automotive and electronics [1]. However, these materials are prone to corrosion which dramatically restricts their applications [2-3]. Various surface treatments are therefore being investigated to improve the corrosion resistance of magnesium alloys [4-6]. In this work self-healing capacities of plasma electrolytic oxidation (PEO) coating are investigated, with an outlook of improving the sustainability of Mg alloys. Both hybrid and sequential processing routes are explored to load the formed PEO coatings with inhibitors that would provide a self-healing ability to the surface layer during exploitation. The coating morphology, elemental and phase composition are characterised by SEM, EDX and XRD analyses respectively. Mechanical and tribological and properties are evaluated by nanoindentation and reciprocating sliding wear tests. Both immersion and electrochemical corrosion tests are carried out to evaluate the coating corrosion behavior and self-healing capacity. Electrochemical impedance spectroscopy employed to study the evolution of the coating-electrolyte interface during corrosion process. Mechanisms of corrosion protection and potential of self-healing corrosion resistant PEO coatings on Mg in various applications are discussed.

Oxide Films Deposited by Reactive Bipolar High Power Impulse Magnetron Sputtering (HIPIMS)

T12 Surface Engineering

#SE-1-Or-2

S. Kadlec ¹, J. Čapek ², J. Kousal ³, J. Vyskočil ¹.

Reactive bipolar pulsed sputtering from a pair of targets can be used for deposition of dielectric films. However, the power balance of both magnetrons can affect film composition and thickness homogeneity, and also lifetimes of used targets.

Recent study of reactive bipolar pulsed sputtering of Al in O₂ [1] has demonstrated that the balance of power delivered to both magnetrons depends on pulse current levels (corresponding to magnetic field strength) and on ON-times of both magnetrons at constant pulse voltage values, and on the oxygen partial pressure. Moreover, operation in the transition mode has resulted in some negative feedback on the power dissipation compensating the tendency for the power unbalancing. However, the behavior of other target materials, such as Ti, can be different as we demonstrate and discuss in this work. Consequently, the stabilization of the working point for both magnetrons can be important.

Oxide films have been deposited by reactive bipolar pulsed sputtering from two metallic targets in Ar + O₂ gas mixture using a MAGPULS unit. A pair of 2-inch round magnetrons were arranged obliquely in load-lock sputtering system, equipped with two Ti targets for TiO₂ deposition and two Al targets for Al₂O₃. The sputtered flux of material from each magnetron was directed mostly to one of two substrates. Power input for each magnetron was evaluated using oscilloscopic data of pulse voltage and current.

The bipolar HIPIMS regime used frequency range 1 to 10 kHz, relatively short on-times and high off-times. The peak magnetron current was up to 10 A, that is about

350 W/cm² over the entire target area at typical average power of 250W. The deposition of Al₂O₃ and TiO₂ is compared, when the on-time ratio of both magnetrons has been varied between 75% and 125%. Different magnetic field strengths of magnetrons were also simulated by spacers modifying the magnet-to-target distance. The effects on the power balance of both magnetrons are compared with the deposition rates and properties of films, measured mainly by spectroscopic ellipsometry. Aluminium oxide films have also been deposited by bipolar pulsed reactive sputtering in a larger scale machine for solar applications equipped with two rectangular magnetrons.

Selection of metal ion irradiation for controlling Ti_{1-x}Al_xN alloy growth by hybrid HIPIMS/DCMS co-sputtering using synchronized pulsed substrate bias

T12 Surface Engineering

#SE-1-Or-3

I. Petrov ¹, G. Greczynski ², J. Lu ², J. Jensen ², J. Greene ¹, S. Bolz ³, W. Kölker ³, C. Schiffrers ³, O. Lemmer ³, L. Hultman ².

¹University of Illinois - Urbana (United states), ²Linköping University - Linköping (Sweden), ³CemeCon AG - Würselen (Germany).

Metastable NaCl-structure Ti_{1-x}Al_xN is employed as a model system to probe the effects of metal, Al vs Ti, ion irradiation during film growth using a hybrid approach combining high-power pulsed magnetron sputtering (HIPIMS) with dc magnetron sputtering of opposing metal targets and HIPIMS-synchronized pulsed substrate bias V_s . With $V_s = 60$ V and HIPIMS applied to the Al target, Alⁿ⁺ ion irradiation (dominated by Al⁺) of the growing film results in alloys ($0.55 \leq x \leq 0.60$) which exhibit high hardness, $H \sim 30$ GPa, and low stress, 0.2-0.7 GPa tensile.^{1,2} In contrast, films with corresponding AlN concentrations grown with HIPIMS applied to the Ti target, giving rise to Tiⁿ⁺ ion irradiation (with a significant Ti²⁺ component) are two phase (cubic (Ti,Al)N and hexagonal AlN) with low hardness, $H = 18-19$ GPa, and high compressive stress ranging up to 2.7 GPa.

In another set of experiments we grow Ti_{1-x}Al_xN alloys with $x \sim 0.6$ and vary the negative bias V_s in the range from 20 to 280 V. The bias is applied to the substrate in synchronous³ with the metal-ion-rich part of the HIPIMS pulse in order to probe the effects of metal ion momentum. Al-HIPIMS/Ti-DCMS layers deposited under Al⁺ ($m_{Al} = 26.98$ amu) bombardment are single-phase NaCl-structure alloys for $20 \leq V_s < 200$ V, while layers deposited in the Ti-HIPIMS/Al-DCMS configuration with Ti⁺/Ti²⁺ ($m_{Ti} = 47.88$ amu) ion irradiation are two-phase, cubic plus wurtzite, even with $V_s = 20$ V. We find that precipitation of the wurtzite AlN second phase is primarily determined by the average metal-ion momentum transfer to the growing film rather

than by the deposited metal-ion energy. Moreover, in contrast to rare-gas ion irradiation during film growth, the Al ions are incorporated as a film constituent and do not result in excessive compressive stress. The relatively low mass of the Al ion permits manipulating properties of metastable cubic $\text{Ti}_{0.38}\text{Al}_{0.62}\text{N}$ by tuning V_s to vary, for example, the hardness H from 12 to 31 GPa while minimizing ion-induced compressive stress.

With the increased concern over pathogenic bacteria in several clinical, industrial and domestic applications, the quest for effective antibacterial surfaces is at the forefront of research in surface engineering. While several existing materials have shown potential to kill bacteria, they are often not suitable as bulk materials due to their inadequate mechanical properties [1]. Hence, the design of antibacterial materials is now increasingly moving towards surface modification and mainly based on three chief strategies: the reduction of bacterial adhesion, the controlled release of biocides and the grafting of contact-killing surface molecules [2]. Still, when exposed to more severe operating conditions, a typical problem arising with most of these engineered materials is their lack of stability (rapid leaching of biocide agent, loss of surface grafted molecules, etc.), which limits their long-term effectiveness. One possibility to overcome these limitations is offered by plasma technologies. Strongly adherent and cohesive coatings with a tunable set of properties can be deposited on various substrates and loaded with the desired biocides, to act as highly stable antimicrobial surfaces.

In this context, a hybrid Plasma Enhanced Chemical Vapor Deposition – Physical Vapor Deposition (PECVD-PVD) system was developed to deposit silver loaded

Diamond-Like Carbon (DLC) nanothin coatings in a one-step process. DLC, an amorphous carbon-based family of materials, is well-known for its excellent mechanical and tribological properties, chemical inertness and nanosmoothness [3]. Moreover, it can be doped with silver nanoparticles, a highly effective broad spectrum antibiotic. The resulting Ag-DLC coatings are expected to provide an interesting solution as antibacterial surfaces in severe environments due to a dual action against bacteria. This presentation will describe the deposition as well as the structural, mechanical and biological characterization of the deposited coatings. The antibacterial properties were studied at different time scales, in order to better assess the stability and long-term effectiveness of the material.

Hipims CrN process as an alternative for hexavalent Cr based electroplating

T12 Surface Engineering

#SE/TF-P2-03

P. Cosemans, I. Truijen.

Sirris - Diepenbeek (Belgium).

Electroplated hard chromium is a well known and widely used coating in many engineering industries due to its high hardness and excellent corrosion resistance. However, environmental and health regulations on chromates drive the exploration of alternative coating methods, among which physical vapor deposition looks very promising.

The recently developed High Power Impulse Magnetron Sputtering (HIPIMS) PVD technique has been investigated as an alternative process for electroplating of hard chromium. In comparison to DC-Magnetron Sputtering (DC-MS), HIPIMS results in denser coatings with superior mechanical, tribological and wear resistant properties .

In this study, CrN coatings are deposited by means of DC-MS, HIPIMS and a combined DC-MS/HIPIMS technique. Mechanical and tribological properties and corrosion resistance of the different coatings is investigated and compared to electroplated hard chromium.

The best alternative HIPIMS-based coating has been tested in an industrial case as an alternative for electroplated hard chrome.

Time-Resolved Laser Diagnostics in High-Power Impulse Magnetron Sputtering Discharges

T12 Surface Engineering

#SE-1-Or-11

M. Palmucci, N. Britun, S. Konstantinidis, R. Snyders.

Université de Mons - Mons (Belgium).

The results on time-resolved diagnostics of High-Power Impulse Magnetron Sputtering (HiPIMS) discharges by Laser-Induced Fluorescence (LIF) accumulated during recent years are reported. The “short pulse” (5-20 μ s) HiPIMS discharges operating in pure Ar gas while sputtering Ti are considered. The LIF measurements were realized using a dye laser pumped by a YAG:Nd 5 ns pulsed laser, with energy of \sim 10-50 μ J/pulse. The Ar pressure was in the range of 5 - 20 mTorr.

The study is mainly focused on dynamic behaviour of a HiPIMS discharge in terms of relative densities of sputtered particles and their ions, as well as on their velocity distribution function (vdf). The presented laser diagnostics results cover both on- and off-time of HiPIMS plasma.

Among the results we found that the vdf of sputtered species evolves dramatically as a function of time, revealing the abrupt widening during the on-time, changing to a shrinkage in the off-time. The widening happens due to the extensive gas rarefaction at the end of the pulse leading to formation of region with fewer collisions between Ar and the sputtered species. This results in higher measured velocities of sputtered species. On the other hand, the vdf shrinkage in the off-time happens due to gas cooling and refilling effects. These effects are similar for Ti and Ti⁺.

The time- and space- resolved study of sputtered species densities agree well with the described vdf results. In particular, the evolution of Ti density represents a wave of sputtered Ti propagating from the target surface with a velocity of \sim 2 km/s. At higher pressure (20 mTorr), an essential increase of the maximum density is observed for both sputtered Ti and Ti⁺. It can be explained by more intensive sputtering due to a higher electron density, and, as a consequence, higher argon ionization. On the other hand, the decays of Ti and Ti⁺ densities observed after the pulse are different depending on Ar pressure.

The presented time- and space- resolved results on the vdf and relative densities of sputtered species give an overview of the HiPIMS plasma dynamics, clarifying the

time evolution of these discharges in terms of the basic plasma parameters.

Structure formation and photocatalytic activity of HiPIMS and pulsed DC reactively sputtered W doped TiO₂ coatings

T12 Surface Engineering

#SE-1-Or-1

P. Kelly ¹, R. Schmidt ², M. Ratova ¹, M. Wuttig ², G. West ¹.

¹Manchester Metropolitan University - Manchester (United Kingdom), ²Aachen University - Aachen (Germany).

Photocatalytic titania coatings have many potential applications, including self-cleaning surfaces, antimicrobial/hygienic surfaces, air and water purification, and anti-fogging surfaces for lenses or mirrors. However, despite their great potential and the growing scientific interest in this area, the development and take up of commercialised products is slow. One limitation of these coatings is that photocatalytic activity is dependent on the crystal structure of the coating and it is anatase or anatase/rutile mixed structures that generally show the highest levels of activity. However, photocatalytic activity can be influenced significantly by doping with different metallic or non-metallic elements. One of the most promising candidates for doping is tungsten which has been shown to increase the photocatalytic activity significantly [1]. For reactively sputtered coatings, doping can be achieved by sputtering from a single compound target, co-sputtering from two targets or serial co-sputtering [2,3]. Furthermore, the targets can be driven in HiPIMS, pulsed DC or continuous DC modes. Each process and operating mode has different advantages and disadvantages in terms of flexibility, deposition rate, ease of control, etc. Also, the energy delivered to the growing film will vary, which strongly influences the resulting structure of the coating. For example, coatings deposited by DC processes commonly require post-deposition annealing to develop the required structure, whereas photocatalytic activity has been demonstrated by as-deposited HiPIMS coatings [4]. W-doped titania coatings have therefore been deposited onto a range of substrate materials using the processes and operating modes described above and characterised in terms of their structures and compositions using SEM, EDX, Raman spectroscopy and XRD. Photocatalytic activity has been assessed

under UV radiation (365nm) in terms of the degradation rate of methylene blue dye. The results obtained to date are presented here.

Influence of 9 eV Collision of Chemically Inert Molecules on Fluorinated Polymer Erosion in Sub-Low Earth Orbit Space Environment

T12 Surface Engineering

#SE/TF-P2-04

K. Yokota, M. Tagawa.

Kobe University - Kobe (Japan).

Materials used in an exterior of spacecraft orbiting low earth orbit (LEO) experience hyperthermal collision with O-atom which is the dominant species in the upper thermosphere of the earth. A high-collision energy opens a new reaction path as gas-surface reactions at polymer surfaces. Some polymeric materials including polyimide, which has been widely used as spacecraft thermal control material, do not survive well in the LEO space environment. Much effort has been paid for studying material erosion both by flight and ground-based experiments as reported in the companion presentation [1]. A laser-detonation hyperthermal beam method has been used to simulate the O-atom/surface reactions on many materials. It is basically successful to simulate degradation property for many materials, however, inconsistency of erosion yields between flight- and ground-based experiments were reported [2, 3]. One of the reasons for this consistency is the presence of 9 eV collision of N₂ molecules in LEO which occurs simultaneously with 5 eV O-atom collision. It has been suggested from a computational simulation that N₂ molecules in orbit could erode fluorinated polymers with high collision energies [4]. This computational result suggested the importance of N₂ effect even on the ground-based simulations.

In this study, collision energy dependence on the material degradation under hyperthermal Ar beam exposure was experimentally studied by a laser detonation beam source which can generate intense atomic beam pulses with average energy of approximately 5-15 eV [5]. Note that impact energy of N₂ in LEO was simulated by the 9 eV collision of Ar in the ground-based experiment in order to avoid the unexpected decomposition of N₂ in the laser plasma. It was clearly observed that the polyimide does not show any erosion by Ar beam exposure, in contrast, mass of fluorinated polymer decreased with high-energy collision (>6eV) of Ar bombardment. The threshold energy of Ar-induced erosion of fluorinated polymer is lower than the

collision energy of N₂ in LEO, which is the second major composition in the upper atmosphere of the Earth (9 eV). The N₂-induced erosion, which has been ignored for the last 30 years, was confirmed on the fluorinated polymer erosion in LEO and sub-LEO regions. Detail of the experimental procedure and results will be presented. A part of this study was supported by the Grant-in-Aid for Scientific Research from Japan Society for Promotion of Science.

SE-P1-01

Study of Tungsten Erosion in High Power Impulse Magnetron Sputtering Plasma

T12 Surface Engineering

#SE-P1-01

M. Desecures, L. De Poucques, D. Genève, R. Hugon, J.L. Vasseur, J. Bougdira.

Université de Lorraine, Institut Jean Lamour, CNRS-UMR 7198, Faculté des Sciences et Technologies, F-54506 - Nancy (France).

Plasma-wall interactions in fusion devices provide a source of impurities for fusion plasma. In order to diminish the contamination, it is required to use materials with low sputtering yield, such as tungsten (W). The transitory accidental events (such as ELMs-Edge Localized Modes) can generate high fluxes ($\sim 10^{24} \text{m}^{-2} \text{s}^{-1}$) of charged particles towards the surface, in a typical time scale of 100 μs leading to high sputtering of the walls. W physical erosion results in W atoms and dust particles formation subsequently carried into the plasma core which severely degrades the plasma properties required for the fusion reactions. Dust can also be deposited on other chamber walls or components facing plasma (heating antennas, ELM controllers). The comprehension of the plasma-wall interactions requires a broad knowledge of the influence of plasma ions fluxes on W and W-based materials, responsible for W atoms sputtering, and of the dependency with plasma related properties (particles densities, ion and neutral velocities and temperatures, sputtering rate, re-deposition ...). It is possible to use a low pressure magnetron discharge powered by a high power supply which can deliver up to 10 MWm^{-2} during short pulses ($\sim 100 \mu\text{s}$). Exploiting the capabilities of this type of discharge, known as HiPIMS¹ (High Power Impulse Magnetron Sputtering), it becomes possible to generate high ion fluxes ($\sim 10^{24} \text{m}^{-2} \text{s}^{-1}$) and to perform a study on W erosion, oriented towards extreme conditions.

The objective of this work is to study the physical etching of W under high fluxes of different types of relevant ions (Ar, He). Moreover this work focuses on the simultaneous characterization of the high density magnetized plasma (HiPIMS) in

terms of ion bombardment of the W target (magnetron cathode) and in terms of the resulting W sputtered vapor behavior when it crosses the plasma. More specifically, it consists in the characterization of the etching rate of W target, transport of W atoms, W dust formation and W deposition. Both spatial and time resolved measurements are performed by means of optical emission spectroscopy, laser absorption spectroscopy, and Langmuir probes. Atoms in gas phase are assessed by tunable diode laser absorption spectroscopy (TD-LAS), W at 407 nm, Ar⁺ at 668 nm², metastable of He at 1080 nm (no transition can be found for He⁺). The time evolution of the temperature and the density of those species are derived from the Doppler profile during the pulse as well as during the plasma decay³. Furthermore the modification of the W target composition and structure (ions implantations, bubbles and holes formation by He⁺ bombardment) induced by high flux sputtering are performed by surface analysis techniques (MEB, XPS, 2D-profilometry).

Antibacterial Cr-Cu-O thin films prepared by reactive magnetron sputtering

T12 Surface Engineering

#TF/SE-1-Or-5

J. Blazek ¹, J. Musil ², K. Fajfrlik ³, R. Cerstvy ², S. Proksova ¹.

¹NTIS - European Centre of Excellence, Faculty of Applied Sciences, University of West Bohemia, Univerzitní 22, 306 14 - Plzeň (Czech republic), ²Department of Physics, Faculty of Applied Sciences, University of West Bohemia, Univerzitní 22, 306 14 - Plzeň (Czech republic), ³Department of Microbiology, Medical Faculty in Plzeň, Charles University in Praha, E. Beneše 13, 305 99 - Plzeň (Czech republic).

The paper reports on (i) the formation of antibacterial Cr-Cu-O thin films by reactive magnetron sputtering and (ii) the effect of Cu content and thermal annealing on their structure, phase composition, antibacterial activity and mechanical properties. The Cr-Cu-O films were reactively sputtered by a dual magnetron in an Ar+O₂ sputtering gas mixture. The dual magnetron was equipped with two identical Cr/Cu targets composed of Cr circular plate fixed by a Cu ring. The inner diameter of the Cu ring was varied from 34 mm to 28 mm with the aim to control the content of Cu in the Cr-Cu-O film. Contact profilometry, X-ray diffraction, X-ray fluorescence, microhardness indentation and optical spectroscopy were used to analyze the thickness and macrostress, structure, elemental composition, mechanical properties and transmittance of the films respectively. Rapid thermal annealing up to 700°C in a rapid thermal processor was used to investigate the changes in structure and phase composition of the Cr-Cu-O films with increasing temperature. The antibacterial efficiency E of killing Escherichia coli bacteria was evaluated using the plate counting method in the daylight and in the dark. It was found that (1) the content of Cu in the Cr-Cu-O film strongly influences its antibacterial activity, (2) 100 % killing of E. Coli bacteria, i. e. E=100 %, is achieved on the surface of Cr-Cu-O film with Cu content ≥ 15 at.% after 3 hours, (3) the Cr-Cu-O films with high (≥ 15 at. %) Cu content are X-ray amorphous and effectively kill E. coli bacteria both in the daylight and in the dark and (4) these X-ray amorphous Cr-Cu-O films exhibit the following mechanical properties: the hardness $H \approx 4$ GPa, the effective Young's modulus $E^* \approx 80$ GPa and elastic recovery $W_e \approx 35\%$; these mechanical properties are suitable for protective

surfaces.

High Performance SiO₂ Barrier Films Deposited onto Polymer Substrates by RF Reactive Remote Plasma Sputtering

T12 Surface Engineering

#TF/SE-1-Or-4

H. Brown ¹, M.J. Thwaites ², P.J. Hockley ², R.J. Curry ¹, M.A. Baker ¹.

¹University of Surrey - Guildford (United kingdom), ²Plasma Quest Ltd - Hook (United kingdom).

The use of polymer substrates for organic electronic devices has the potential to enable new applications, such as flexible displays, photovoltaics and organic light emitting diodes (OLEDs) and allow manufacturers to employ cost effective high-volume throughput roll-to-roll fabrication. However, these polymer substrates are susceptible to moisture/oxygen permeation and require encapsulation in the form of a thin film barrier layer. Although much research has been carried out on barrier layers, currently no thin film can be grown completely defect free onto plastics to obtain a water vapour transmission rate (WVTR) low enough for OLED applications.

In this work, SiO₂ barrier layers have been deposited using a novel technique, remote plasma sputtering, in the radio frequency (RF) reactive sputtering mode. Remote plasma sputtering can be used to produce dense films on polymer substrates. For single layer thin films, the sputter deposition parameters (RF power and oxygen flow rate) have been varied. Two further specific methodologies have been employed to improve barrier properties through disrupting the growth of extended defects in the growing film. Firstly, the film growth was interrupted at regular intervals during the deposition and the surface of the film exposed to the plasma for short periods. Secondly, a rotating aperture and a planetary conformal coating system were used to relax the growing film and eliminate columnar growth.

The thin films have been characterised using SEM, GAXRD, AFM, XPS and STEM. SEM cross sections and GAXRD data reveal that single and multilayers of SiO₂ can be deposited using remote plasma sputtering with a dense amorphous structure and without columnar growth. AFM and optical images reveal substrate cleanliness and asperities are crucial in achieving good barrier performance. Two methods have

been explored to minimise these issues and their effect on barrier properties have been studied. Firstly, using the plasma itself to modify the polymer surface and secondly, using a sputtered polytetrafluoroethylene (PTFE) to act as smoothing interface layer.

A WVTR of $<2 \times 10^{-2}$ g/m²/day has been achieved for single layer SiO₂ films deposited by remote plasma sputtering. STEM micrographs of SiO₂ with plasma interruptions taken in the secondary electron (SE) mode (shown in Figure 1) clearly display some modification to the film when exposed just to the plasma. Further characterisation results on the barrier film structure and WVTRs for SiO₂ thin films deposited with plasma interruptions, rotating aperture, planetary conformal coating system and PTFE interfacial layer will be presented and discussed.

STEM image in SE mode of SiO₂ with plasma interruptions.

Highly controlled system for injecting organic and bio-molecules from solution into ultra high vacuum chambers

T12 Surface Engineering

#SE/PST/TF/BI-P1-01

J. Sobradovj, J. Martin Gago.

CAB (CSIC-INTA) - Torrejon De Ardoz (Spain).

We have designed a new deposition system of organic and bio-molecules from liquid solution into vacuum systems. The solution is injected inside an ultra high vacuum chamber through a valve with a piezoelectric actuator. Argon is used as the carrier gas controlling the injection time and the differential pressure between the solution and the vacuum experimental chamber. The results are analyzed qualitatively and quantitatively by mass spectroscopy and a quartz crystal microbalance. In particular we have used this system to study the deposition of Adenosine triphosphate (ATP), main molecule in the cellular energy exchange processes, on different surfaces. We have grown layers of controlled coverage of the intact molecule as depicted by X-Ray Photoemission Spectroscopy (XPS) and Scanning Tunneling Microscopy (STM). We have also used this system to study impurities in salt solutions with different molarities.

Super-hydrophobic films synthesis by MOPECVD at Low Temperature

T12 Surface Engineering

#SE/TF-3-Or-5

J. Han ¹, S.B. Jin ¹, J.S. Lee ¹, T. Suzuki ², Y.S. Choi ¹.

¹NU-SKKU Joint Institute for Plasma-Nano Materials, Sungkyunkwan University, 300 Chunchun-dong Jangan-gu - Suwon (Korea, republic of),
²Graduate School of Engineering, Nagoya University - Nagoya (Japan).

Super-hydrophobic film have recently attracted great interests for variety of applications such as self-cleaning, anti-fingerprint, prevention of snow sticking, anti-fog, etc.. It has been known that super hydrophobic surfaces of water contact angles (WCA) higher than 150° can be produced only by micro patterning of the surface with hydrocarbon or fluorocarbon containing low energy film materials deposited mostly at elevated temperature. Structuring of micron-sized roughness of the surface combined with control of chemical composition for low surface energy which is called the Casie-Baxter or fakir is not feasible process and often tends to cause degradation of optical transparency and resistance against external agents, and therefore still limited in broad applications, especially plastic based materials and devices. Super-hydrophobic films having nano-sized roughness are synthesized with process and film design based on fundamental understanding of plasmas discharge of precursors and polymerization behaviors at PEMOCVD processes. Dual film processes were performed to synthesize super hydrophobic coatings of various WCA on plastic substrate at room temperature without any heating for suppression of any thermal heating and damage to the substrate and deposited films. SiO_x film was primarily deposited on plastic substrate by PEMOCVD with OMCTS ((CH₃)₂SiO-) at O₂ partial pressure and then followed by top coating with HMDS, ((CH₃)₃-Si-Si-(CH₃)₃) precursor for hydrophobic and super hydrophobic coatings. WCA was controlled by hydrogen addition which play a role to modulate the surface roughness and passivate defects, such as electrically uncovered polar sites rendering non-hydrophobicity. WCA was controlled in the range of 120° to 160° by adjusting process parameters, especially the hydrogen flow rate and discharge power. Surface roughness analysis by AFM showed that the film with a WCA of 145° has 2.5nm roughness in rms value. All the films showed excellent results in resistance tests at salt water and cosmetics owing to super-hydrophobicity and defect passivation. The formation mechanism and synthesis behavior of super hydrophobic films are

discussed with analysis of discharge behavior of precursors with process conditions and film analysis data.

SE/TF-3-Or-1

Selective nitrogen incorporation in the gamma phase of the single crystalline Ni-based superalloy MC2 by low temperature plasma assisted nitriding

T12 Surface Engineering

#SE/TF-3-Or-1

S. Chollet.

Université de Poitiers - Poitiers (France).

MC2, a single crystalline (γ/γ') Ni-based superalloy, was plasma nitrided at low temperature (400°C) for 1 and 4 hours. The MC2 superalloy is composed by 70 vol.% of γ' cubical fcc precipitates in coherence with a surrounding γ fcc matrix. Thanks to the monomodal size distribution of the γ' cube side (~ 400 nm), MC2 was used as a model material in an attempt to investigate the behavior of γ' precipitates in γ matrix during the nitriding of Ni-based superalloys. The structure and composition of the plasma-nitrided layer were characterized by glow discharge optical emission spectroscopy (GDOES), scanning electron microscopy (SEM), energy and wavelength dispersive spectrometry (EDS/WDS), white-light interferometry (WLI) and X-ray diffraction (XRD). The nitrogen profile obtained in MC2 is significantly different from that obtained in the case of Haynes 230, a Ni-based superalloy without γ' precipitates: instead of a nitrogen plateau slightly decreasing from 25 to 20 at.% over few microns, nitrided MC2 exhibits a highly nitrided (25 at.%) thin top layer of about 200 nm, followed by a plateau of few micrometers, with nitrogen content of about 10 at.%. This low plateau level can be explained by a γ matrix similarly nitrided than in Haynes 230 (up to ~25at.%), producing an expanded γ_N phase, whereas γ' precipitates did not incorporate nitrogen. This is confirmed by XRD results, which has revealed a peak located around $2\theta = 46.3^\circ$ that can be attributed to the $\langle 002 \rangle$ peak from the expanded γ_N phase. EDX cartography has confirm that the γ' precipitates in the nitrided plateau accommodate no more than few at.% of nitrogen. Consequently, the γ/γ' disparity modifies the morphology: the average γ channel width is consequently increased due to the elasto-plastic response to the nitrogen incorporation.

Stainless steel (SS) is a highly versatile and affordable material which exhibits a self-healing corrosion resistance and a biocompatible surface oxide layer, making it an excellent material for applications in medical industry. However, fabricating SS surfaces with specific biofunctional properties is a challenging task. Here, we propose a scalable bottom-up covalent functionalization of SS which can be used to create surface functionalities that promote or hinder biomolecular adhesion.

The aim of this study was to create an organized bifunctional organic monolayer on SS enabling the coupling of biomolecules on SS surface with controlled spatial distribution. Organofunctional silanes (3-aminopropyl)trimethoxysilane (APS) and (3-mercaptopropyl)trimethoxysilane (MPS) were chosen as they form an overlayer on solid substrates via covalent bonding in lateral and vertical directions. The APS/MPS surface can be biofunctionalized with succinimidyl ester (NHS) and maleimide (MAL) terminated biomolecules, respectively. AISI 316L steel was chosen as substrate as it is widely used in biomedical applications, such as cardiovascular stents and medical instruments.

We have previously reported that an electrochemical treatment of SS can enhance APS monolayer formation [1]. In our earlier studies we have also shown that APS/MPS ratio in the silanization solution does not correlate directly with the silane ratio in the deposited layer on SS surface. Furthermore, the concentration of silanes in the solution, hydrolysis and silanization time affect the formation of the overlayer.

Thus, a careful investigation of the fabricated surface structures is required in order to understand the coverage, orientation, APS/MPS ratio and overlayer thickness of the resulting silane films. In this study synchrotron radiation mediated (MAX IV laboratory, BL D1011, Lund, Sweden) and conventional X-ray photoelectron spectroscopy (XPS) have been employed.

In the present study, we establish the chemical composition of silane layers and show that the majority of functional groups point outwards and remain reactive after deposition. Silane layer morphology is determined by analyzing the inelastic electron energy background of photoelectron spectra [2]. According to our experiments, the silanization process facilitates relatively fast and reproducible fabrication of approximately one monolayer thick functional silane films on SS. In addition, the APS/MPS ratio on surface can be controlled by modifying either the silane concentration in the hydrolysis solution or the silanization time.

We also show that the APS/MPS monolayers can be biofunctionalized with NHS-PEG and MAL-PEG-Biotin molecules creating a SS surface that is receptive for specific adsorption of (strept)avidin. Also, compared to uncoated SS our preliminary experiments on silanized SS indicate an improved resistance towards E. Coli. Finally, the surface reactivity can be easily tailored towards specific applications by modifying the topmost functional layer with the help of numerous, commercially available biotinylated reagents.

SE/TF-P2-05

Deposition of High-Entropy Alloys by sputtering powder targets: the influence of the composition

T12 Surface Engineering

#SE/TF-P2-05

B. Braeckman, D. Depla.

Ghent University - Gent (Belgium).

Traditional alloy systems are based on one or two principal metallic elements. For example steel is based on iron, intermetallics are based on Ni-Al, Ti-Al compounds, etc. Since the beginning of the 21st century Yeh et al. [1] introduced a novel approach to alloy design with promising properties. High-Entropy Alloys (HEA) are composed of five or more principal elements in equimolar ratios. Due to the high mixing entropy, solid solutions of many elements will tend to form stable phases. In contrary to conventional alloys, the large number of elements will not lead to complex systems but remain fairly simple, essentially amorphous or fcc and/or bcc. HEA's have excellent properties such as high hardness, high strength, high plasticity and extended ductility, even at elevated temperatures, which makes them suitable for a range of applications.

Due to its flexibility, magnetron sputtering is an excellent deposition technique to study the compositional influence on material properties. There are several options available to deposit multi-component thin films. The multiple magnetron method has the benefit that the film composition is easily adapted by changing the discharge power and/or substrate-target distance. However when the number of elements in the film is high, the geometrical setup becomes complex. The preferred method is to sputter from cold isostatically pressed powder targets. In this way the composition of the target and hence the film is easy to control and there is need of only one magnetron.

This work focuses on the deposition of AlCoCrCuFeNi thin films using powder targets. In a first step the targets are sputtered in the metallic regime while the molar ratio of several elements is varied. In a second step the reactive sputtering (addition of oxygen and/or nitrogen) of the multi-component powder targets is considered. The

crystallographic properties were investigated using XRD while the topography and microstructure were studied with (cross-sectional) SEM.

This abstract is submitted to RSD2013.

SE-2-Or-2

Lattice Ordering Effects on Toughness Enhancement in Transition Metal Nitride Thin Films

T12 Surface Engineering

#SE-2-Or-2

V. Chirita, D.G. Sangiovanni, D. Edström, L. Hultman.

Linköping University - Linköping (Sweden).

Enhanced toughness in hard and superhard thin films is a primary requirement for present day ceramic hard coatings, known to be prone to brittle failure during in-use conditions, in modern applications. In our previous Density Functional Theory (DFT) investigations, we have predicted significant improvements in the hardness/ductility ratio of several pseudobinary B1 NaCl structure transition-metal nitride alloys, obtained by alloying TiN or VN with NbN, TaN, MoN and WN [1, 2]. The initial calculations, which were carried out on model, highly ordered configurations with Cu-Pt ordering on the cation sublattice, reveal that the electronic mechanism responsible for toughness enhancement stems from the high valence electron concentration (VEC) of these alloys, which upon shearing, leads to the formation of alternating layers of high and low charge density oriented orthogonal to the applied stress, and ultimately allows a selective response to tetragonal and trigonal deformations. Recently, these results have been validated experimentally [3]. Single-crystal $V_{0.5}Mo_{0.5}N/MgO(001)$ alloys, grown by dual-target reactive magnetron sputtering together with VN/MgO(001) and TiN/MgO(001) reference samples, exhibit hardness >50% higher than that of VN, and while nanoindented VN and TiN reference samples suffer from severe cracking, the $V_{0.5}Mo_{0.5}N$ films do not crack. However, as there is no evidence of Cu-Pt ordering in the synthesized $V_{0.5}Mo_{0.5}N$ films, here we present new DFT results, which address the issue of lattice ordering effects on the mechanical properties of these pseudobinary alloys. Our investigations concentrate on $V_{0.5}Mo_{0.5}N$, $V_{0.5}W_{0.5}N$, $Ti_{0.5}Mo_{0.5}N$ and $Ti_{0.5}W_{0.5}N$ alloys obtained by alloying TiN and VN with WN and MoN, which are all predicted to have significantly enhanced toughness compared to the parent binary compounds. Our calculations, carried out for structures with increasing levels of disorder, reveal that while the degree of electronic structure layering, i.e. the formation of alternating layers of high and low charge density upon shearing, becomes less pronounced in disordered configurations, the overall VEC effect is not affected. The essential feature in the

disordered alloys, as initially predicted for highly ordered configurations, remains the increased occupancy of electronic d- t_{2g} metallic states, which allows the selective response to tensile/shearing stresses, and explains the enhanced toughness confirmed experimentally for $V_{0.5}Mo_{0.5}N$ films.

Transmission electron microscopy of PM S390 MC high-speed steel

T12 Surface Engineering

#SE/TF-3-Or-2

D. Jenko ¹, S. Šolić ², V. Leskovšek ¹, F. Cajner ², M. Jenko ¹.

¹Institute of Metals and Technology - Ljubljana (Slovenia), ²Faculty of Mechanical Engineering and Naval Architecture - Zagreb (Croatia).

The research deals with the study of the impact of microstructure on the tribological properties of PM S390 MC high-speed steel (Böhler), prepared by powder metallurgy with chemical composition in weight % of 1.64 C, 0.60 Si, 0.30 Mn, 4.80 Cr, 2.00 Mn, 4.80 V, 10.40 W, 8.00 Co and the rest was Fe. Different microstructure conditions of high-speed steel were obtained by heat treatment in two ways: conventional (vacuum hardening, three high-temperature temperings) and deep cooling (vacuum hardening, deep cryogenic treatment, high-temperature tempering). In some experiments, nitriding in plasma of ionising gases was also carried out.

Thin foil specimens for transmission electron microscopy (TEM) were prepared using Jeol EM-09100IS Ion Slicer and further analyzed by TEM (Jeol JEM-2100) using conventional TEM (CTEM) and energy dispersive X-ray spectroscopy (EDS, Jeol JED-2300 Series) at 200 kV electron accelerating voltage. Detailed characterization of the microstructure was performed on thin foil specimens, and electron diffraction method was used as well to carry out the microstructure–crystallographic analysis of the phases. In the martensite microstructure some nanometre sized areas of possible other phase were observed. Further investigation will enable to understand whether these areas are nanometre sized carbide precipitates.

The research showed that the microstructure obtained by deep cooling and nitriding compared to conventional heat treated resulted in an increase of wear resistance of PM S390 MC high-speed steel.

Mechanical, Structural and Tribological Characterisation of High Nickel Content Alloys before and after Arc Activated Plasma Nitriding

T12 Surface Engineering

#SE/ASS-1-Or-5

E. Almandoz, J. Fernández De Ara, J.F. Palacio, G.G. Fuentes, J.A. García, R.J. Rodríguez.

AIN - Cordovilla (Spain).

In this study, a full comparison in terms of mechanical, structural and tribological performance of high nickel content alloys (maraging steel grade 300, Inconel 718 and 800 HT nickel alloy) was carried out. These alloys are widely known for their good mechanical properties and good corrosion properties and fairly good temperature resistance. Also, and with the aim of improving their surface properties, two of these alloys - Maraging 300 and Inconel 718 - have been subjected to an arc activated plasma nitriding. The impact of this process on these two materials, with the nitrogen going several micrometers deep in the surface, is shown.

Furthermore, in order to thoroughly characterise these alloys, a myriad of techniques have been employed: Scanning Electron Microscopy coupled with Electron Back Scattered Diffraction and X-Ray diffraction for the study of the microstructure of the samples before and after nitriding; a Nanoindenter, a micro-hardness tester fitted with a Knoop indenter and a Rockwell C for the evaluation of the mechanical properties; and finally, ball on disk tests in dry sliding and with WC-Co as a counterpart, made at room temperature and high temperature (450 °C- 600 °C) for the evaluation of the tribological performance of such alloys in these conditions.

Ion Implantation Based Surface Modification of TiAl Materials

T12 Surface Engineering

#SE/TF-3-Or-3

A. Kolitsch, R. Yankov.

Helmholtz-Zentrum Dresden-Rossendorf - Dresden (Germany).

Titanium aluminide (TiAl) alloys are attractive lightweight materials for medium-temperature (500°-750°C) structural applications including components such as jet engine and industrial gas turbine blades, turbocharger rotors and automotive engine valves. However, envisaged service temperatures for future advanced applications will have to be in the range of 750° to 1000°C, over which these alloys suffer from both oxidation and oxygen embrittlement. Therefore, development of surface-engineering techniques for preventing high-temperature environmental damage is critical in exploiting the advantages of TiAl alloys to their fullest extent.

Two efficient approaches to protecting candidate TiAl alloys from high-temperature (>750°C) environmental degradation have been developed at HZDR. The first technique involves a single step, namely treating TiAl alloy components directly by plasma immersion ion implantation (PIII) of fluorine using a mixture of difluoromethane and argon (CH₂F₂ + 25% Ar) as the precursor gas. The oxidation performance of the fluorine-implanted alloys has been evaluated by thermal gravimetric analysis (TGA) over the temperature range of 750° to 1050°C under conditions of both isothermal and thermal cyclic oxidation in air, and for times as long as 6000 h. This type of surface modification has been shown to produce a stable, adherent and highly protective alumina scale. The second technique involves the fabrication of a durable protective coating in a two-step process, namely formation of a thin aluminum-rich TiAl layer (Ti-60Al) by chemical vapor deposition (CVD) employing a mixture of inorganic precursors, followed by PIII of fluorine. Subsequent long-term oxidation exposures to air at 900°C of a GE 4822 alloy (Ti-48Al-2Cr-2Nb; alloy composition qualified for aerospace applications) have shown that the coating so developed is able to successfully prevent oxidation damage to the base material while maintaining up to 90% of its initial mechanical properties (strength and ductility).

A new angle on sputtering magnetrons?

T12 Surface Engineering

#SE-1-Or-6

D. Lundin, C. Huo, M. Raadu, N. Brenning.

Royal Institute of Technology - Stockholm (Sweden).

Sputtering magnetrons are usually described in terms of two aspects. (1) Electrons are trapped close to the cathode by a curved magnetic field, and thus have a long mean free path in the plasma. They can therefore ionize more efficiently than in a usual glow discharge plasma and, as a consequence, the device can be operated at desirably low process gas pressure. (2) The energy input to sustain the discharge is mainly by secondary-emitted electrons that are accelerated across the cathode sheath. However, in this work we present new modeling results on high power impulse magnetron sputtering discharges (HiPIMS) along with experimental data that demonstrate that the second aspect has to be revised: Ohmic heating in the plasma can dominate by up to an order of magnitude over cathode sheath energization. Furthermore, the origin of the Ohmic heating is found to be an extended pre-sheath in the dense plasma region, which has been detected in several HiPIMS experiments, as well as in conventional magnetron devices. This is a new, and physically separate, effect of the magnetic field that needs to be added to the standard understanding of sputtering magnetrons.

Advanced tribological properties of TiC/a-C:H coating sliding against PTFE composite

T12 Surface Engineering

#SE/ASS-P2-04

J. Shen, Y. Pei, J.T.M. De Hosson.

University of Groningen - Groningen (Netherlands).

Previous research has made breakthroughs in the design, deposition and characterization of DLC based nanocomposite coatings on various substrates, with ultra-low friction and wear rate [1]. Since both PTFE composite and DLC coating exhibit self-lubrication effects, it is tempting to investigate the tribological performance of a polytetrafluoroethylene (PTFE) composite/DLC sliding couple. Tribological experiments on PTFE composite reinforced with glass fibers and resin were performed against 100Cr6 steel and TiC/a-C:H thin film coated surfaces. In both cases the coefficient of friction (CoF) increases with increasing sliding distance until a steady-state value is reached. Although the CoFs are very similar, the wear rate of the PTFE composite at a long sliding distance is reduced when the steel ball is coated with TiC/a-C:H coating. This behavior is attributed to the lower surface free energy of TiC/a-C:H coating and its smoother surface after long sliding. The wear mechanism of the PTFE composite is a combination of smearing of PTFE fibers, debonding and fragmentation of glass fibers, cracking and fracture of the resin matrix, and generating wear debris and third-body that consists of glass fiber fragments and fractured resin. PTFE transfer films are evident on the surfaces of the hard counterparts, the thickness of which on TiC/a-C:H coated surfaces is measured to be a couple of nanometers by a newly developed method. On the surface of uncoated steel balls, a thicker transfer film is formed and partly covered with thick and scattered polymer flakes.

Wear resistant MoS₂/ta-C coatings for applications in various environments

T12 Surface Engineering

#SE/ASS-1-Or-6

T. Gradt ¹, G. Theiler ¹, A. Brückner ², V. Weihnacht ².

¹BAM - Berlin (Germany), ²IWS - Dresden (Germany).

For vacuum and inert environments MoS₂ is probably the most suitable solid lubricant. However, pure MoS₂ fails in humid air, which is a problem for applications where contact to the atmosphere cannot be avoided. Graphite and most amorphous carbon coatings show the opposite behaviour: good lubricity in air, but high friction and wear in the absence of humidity.

In order to overcome the low endurance of MoS₂ coatings in normal air, double-layer structures with tetrahedral amorphous carbon (ta-C) were produced and tested. The coatings were deposited on steel substrates by laser-controlled, pulsed vacuum arc process [1]. This method generally produces coatings with high density and good adherence. It combines the advantages of a laser for the precise control of the arc-evaporation spot with the high evaporation rate of vacuum arc and enables film deposition under series production requirements. This type of hydrogen-free diamond-like-coating has a high content of sp³-type tetragonal bonds and a hardness up to 75 GPa. Highly inert they are excellent wear protective coatings in humid environment, but without further measures the performance of ta-C generally decreases under dry and vacuum conditions [2].

The tribological behaviour of the MoS₂/ta-C double layer coatings was investigated in ball-on-disk tests in air, vacuum, and hydrogen environment. The maximum Hertzian contact pressure was 1.27 GPa and the maximum sliding velocity 0.5 ms⁻¹. In vacuum environment, the friction coefficient against uncoated steel balls varied between 0.005 and 0.02 depending on the contact pressure. At high contact pressures, the friction coefficient was as low as 0.005 and the wear life between 340,000 and 500,000 cycles.

After sliding a highly oriented MoS₂-layer beneath the sliding surface was detected by TEM. Because the initial film was amorphous, the layered structure was not created by orientation of lamellar MoS₂-platelets, but by friction induced

crystallisation.

The coatings showed best performance in hydrogen environment. Tests were run up to 40 h or 650 000 friction cycles without failure. Pure ta-C also showed a good wear resistivity without coating failure during the test duration. However, a distinct running-in occurred with a COF up to 0.5. The double-layer coating showed smooth sliding without a high initial friction state. Because this coating can be deposited by a well proven industrial method, it is a good candidate for tribologically stressed components in hydrogen technology.

The deposition of Silicon dioxide films onto Titania substrates from a two step DBD process

T12 Surface Engineering

#SE/TF-2-Or-9

S. Dahle ¹, H. Munkert ¹, W. Viöl ², W. Maus-Friedrichs ¹.

¹TU Clausthal - Clausthal-Zellerfeld (Germany), ²HAWK Göttingen - Göttingen (Germany).

The coating of different substrates with silicon dioxide films is of great interest for a variety of applications ranging from gate oxide layers and anti-reflective glasses to protective coatings against influences as reactive gases, sintering during high temperature processes and many more. The use of plasma-based processes for the film deposition may be advantageous over currently used processes concerning these applications. Unfortunately, most of the approaches employing plasma treatments for the deposition of silicon dioxide films suffer some disadvantages. Using monosilane is difficult because it would instantly react with the oxygen needed for the reaction to form silicon dioxide. Thus, many workgroups use either large organometallic precursors, which tend to leave residual carbon within the produced film or make use of inert oxygen providers such as carbon dioxide or nitrogen oxides, which also leads to carbon or nitrogen residuals of these molecules within the film. There against, we recently developed a two step approach depositing the metal from a precursor in a first plasma treatment and using a second one to oxidize it. This approach has been proved to work on titanium dioxide nanoparticles before. The use of the described two step approach on various substrates is currently investigated. In this present contribution, we studied the deposition of silicon dioxide onto metallic titanium as well as titanium dioxide crystals as model substrates for metals and ceramics, as sketched in **Fig. 1**. For both substrates, a strong impact of the process gas pressure is found, leading to the formation of particles at atmospheric pressure but the formation of closed films for low pressure plasma treatments in containing process gases. After the metal deposition onto the substrates we found the depletion of oxygen at the interface of the titanium dioxide substrate with the deposited film. These defects got healed upon the second plasma treatment, indifferent of the used process gas (oxygen or air) or pressure (200 mbar or 1000 mbar). The titanium metal on the other hand revealed an oxidized film at the

interface to the silicon dioxide after complete transformation of the deposited primer film. The investigations were carried out by means of Metastable Induced Electron Spectroscopy (MIES), Ultraviolet Photoelectron Spectroscopy (UPS) and X-ray Photoelectron Spectroscopy (XPS) as well as Atomic Force Microscopy (AFM).

Non-uniform mesh modelling of very high density magnetron discharges. Comparison between DC and HiPIMS regimes.

T12 Surface Engineering

#SE-1-Or-9

A. Revel ¹, C. Costin ², T. Minea ¹.

¹LPGP, Université Paris-Sud 11 - Orsay (France), ²Faculty of physics, A. Cuza University - Iasi (Romania).

The modelling of a magnetron discharge is a delicate issue in DC, but especially in HiPIMS regimes. The high voltage of the cathode (~1 kV) combined with the magnetic field create (~1000 G) a very thin sheath in front of the race-track (where B is parallel to the cathode) and a high plasma density. The Particle In Cell (PIC) method has been chosen because it is able to deal with such complex electromagnetic fields and compatible with the low working pressures (< 1 Pa). However, to correctly describe the sheath behaviour, the mesh size has to be smaller than the Debye length which increases with the density, typically in HiPIMS $n_e > 10^{18} \text{ m}^{-3}$. To better characterize this phenomenon without drastically increasing the computation time, a non-uniform mesh has been implemented. The mesh size has been defined such as it is refined in the cathode layer and rougher far, in the diffusion plasma region. Moreover, in the HiPIMS regime, the time evolution is very fast (> 500 V/microsecond) and this induces a fast rise of the plasma density.

Because of the high particle density near the cathode, the number of macro-particles required for the modelling is very important. In order to reduce it, a second order charge projection has been implemented. The charge density is consequently better defined and so the potential better calculated. This implementation allows us to increase the weight of macro-particles and consequently to decrease their number without lost of accuracy.

This new version of the code has been used to compare the plasma behaviour in both DC and HiPIMS regimes. The two dimensional maps main plasma parameters, electron and ion densities, electrons temperature, ion fluxes to the cathode, etc. will

be presented and discussed. For the HiPIMS case, their evolution in time will be presented.

Flexible diamond-like carbon thin film coated on rubbers

T12 Surface Engineering

#SE/ASS-P2-05

Y. Pei ¹, J.T.M. De Hosson ², J. Shen ².

¹Materials innovation institute M2i, University of Groningen - Groningen (Netherlands), ²University of Groningen - Groningen (Netherlands).

Dynamic rubber seals are major source of friction in lubrication systems and bearings, which may take up to 70% of the total friction. The solution we present is to coat rubbers with diamond-like carbon (DLC) thin film by which the coefficient of friction is reduced to less than one tenth. Coating rubber is very challenging because the film must be flexible and strongly adhered to rubber surface. Here we present and discuss our novel approach by depositing flexible DLC films on various rubbers via self segmentation. By making use of the substantial thermal mismatch between DLC film and rubber substrates a dense crack network forms in DLC films and contributes to flexibility. The size of film micro-segments can be tuned by varying the bias voltage of pulsed DC plasma assisted CVD, which governs the amplitude of the substrate temperature variation during deposition. An analytical model is developed to predict the crack spacing and the result fits well to the measured data. The formation mechanism of crack network and its effect on the flexibility and friction of DLC film coated rubbers are scrutinized. This paper provides generic design rules for the deposition of flexible and ultra low friction DLC films on rubber seals.

In a recent experimental breakthrough, the controlled sliding of two dimensional colloidal crystals over perfectly regular, laser generated periodic or quasi-periodic "corrugation" potentials has been realized in Bechinger's group [1]. Based on realistic molecular dynamics simulations which reproduce the main experimentally observed features, we explore the potential impact of colloid monolayer sliding in nanotribology [2]. The free motion of edge-spawned kinks and antikinks in smooth incommensurate sliding is contrasted with the kink-antikink pair nucleation at the large static friction threshold in the commensurate case. The Aubry pinning/depinning transition is also demonstrated as a function of parameters including the corrugation amplitude. Colloid simulated sliding data allow the extraction of frictional work directly from particles coordinates and velocities as a function of classic friction parameters, primarily speed, and corrugation strength (representing "load"). Analogies with sliding charge-density waves, driven Josephson systems and the sliding of rare gas islands, and other novel features suggest further experiments and insights, which promote colloid sliding to a novel friction study instrument [3].

SE/ASS-1-Or-7 ION BOMBARDMENT OF DUPLEX COATINGS BY NITROGEN

T12 Surface Engineering

#SE/ASS-1-Or-7

B. Skoric ¹, D. Kakas ¹, A. Miletic ².

¹Professor - Novi Sad (Serbia), ²Assistent - Novi Sad (Serbia).

In this paper, we present the results of a study of TiN films which are deposited by a Physical Vapor Deposition and Ion Beam Assisted Deposition..The microstructure of obtained nitrated layer showed differences with regard to the presence or absence of a white layer, its thickness and its ϵ/γ' phase ratio (XRD) and nitrating depth. In the present investigation the samples with duplex coating was studied, and subsequent ion implantation was provided with N5+ ions. The ion implantation was applied to enhance the mechanical properties of surface. The most successful and widespread model for nanoindentation data analysis is one in which the unloading data are assumed to arise from a purely elastic contact. The form most often used is known as the Oliver and Pharr method. This paper describes the successful use of the nanoindentation technique for determination of hardness and elastic modulus. Therefore, in recent years, a number of measurements have been made in which nanoindentation and AFM have been combined. Indentation was performed with CSM Nanohardness Tester. The results are analyzed in terms of load-displacement curves, hardness, Young's modulus, unloading stiffness and elastic recovery. The nanohardness of coating measured by Berkovich indenter is about 42.6 Gpa. The analysis of the indents was performed by Atomic Force Microscope. The stress determination follows the conventional $\sin^2\psi$ method, using a X-ray diffractometer The analyzed AE signal was obtained by a scratching test designed for adherence evaluation. AE permits an earlier detection, because the shear stress is a maximum at certain depth beneath the surface.

Coating is often in tensile stress with greater microhardness. The film deposition process exerts a number of effects such as crystallographic orientation, morphology, topography, densification of the films.The evolution of the microstructure from porous and columnar grains to densel packed grains is accompanied by changes in mechanical and physical properties. A variety of analytic techniques were used for characterization, such as scratch test, calo test, SEM (Figure 1), AFM, XRD and EDAX. Therefore, by properly selecting the processing parameters, well-adherent

TiN films with high hardness can be obtained on engineering steel substrates. The experimental results indicated that the mechanical hardness is elevated by penetration of nitrogen, whereas the Young's modulus is elevated.

The essence of the method is electrochemical oxidation of metal surface at voltages of spark and arc electric discharges. Anodic coatings, which are formed by the PEO method, can involve electrolyte components. Coatings were formed for 2-10 min at 10 A/dm² in a Na₃PO₄ + Na₂B₄O₇ + Na₂WO₄ + Fe₂(C₂O₄)₃ aqua electrolyte-suspension. They have a thickness of 3 -33 μm and coercive force about 100 Oe at room temperature, fig. a. There are crystallites of 50 nm - 1 μm in size containing to 70 at% iron in the pores of the coatings, fig. b. We consider that magnetic properties of the coatings are related with these crystallites. The coatings are of interest as protective electromagnetic screens.

Thermal and plasma treatment effects of ITO anode layer on performance of OLEDs devices

T12 Surface Engineering

#SE/TF-P2-06

Y. Kim, B.H. Choi, J.H. Lee.

National Center for Nanoprocess and Equipments, Korea Institute of Industrial Technology - Gwangju (Korea, republic of).

We have investigated the effect of surface treatment of indium-tin-oxide (ITO) on electrical and optical characteristics of organic light emitting diode (OLED) lighting devices. 150 nm thick ITO anode layer was patterned directly by using shadow mask during sputtering process without employing conventional photolithography patterning method. The sputtered ITO layer was oxygen plasma and thermally treated to reduce sheet resistance and to improve surface roughness. The thermal treatment was carried out at the temperature of 250 and 380 °C. The thermal treatment temperature was chosen not to affect the glass substrates and treated for 1 hour. The measured sheet resistance was decreased from 30.86 to 15.42 ohm/square obtained from thermally treated at 380 °C for 1 hour, followed by oxygen plasma treatment. The surface roughness which was measured in root mean square value was considerably decreased to 3.28 nm by oxygen plasma treatment as shown in Fig. 1. By employing thermal treatment, sheet resistance of shadow mask patterned ITO anode layer was considerably decreased. The spike-like structures formed in shadow mask patterned ITO anode layer were perfectly removed by oxygen plasma treatment. It is worthy while to note that smooth surface and low sheet resistance gives improved electrical and optical characteristics in OLEDs lighting devices. Based on surface treated ITO layer, green phosphorescent emitting OLED devices were fabricated and characterized. Figure 2 shows typical luminance-current density-voltage characteristics of fabricated OLEDs lighting devices fabricated on thermal and plasma treated ITO anode layer. The luminance and current density was the highest from the OLED devices fabricated by using thermally treated at 380 °C for 1 hour and oxygen plasma treated one. Our study shows that ITO anode layer which has low sheet resistance and surface roughness affected high electrical and optical properties on OLED lighting devices.

Asymmetric distribution of ion and electron fluxes measured near the target plane in HiPIMS and DCMS discharges

T12 Surface Engineering

#SE-1-Or-10

M. Panjan, R. Franz, A. Anders.

Lawrence Berkeley National Laboratory - Berkeley (United states).

Plasma instabilities in the magnetron discharge play an important role in the transport of charged particles. They have been documented for high power impulse magnetron sputtering (HiPIMS) [1, 2] as well as for well-established direct current magnetron sputtering (DCMS) [3]. Properties of plasma instabilities have been studied by different plasma diagnostic techniques however, only recently the nature of instabilities in the HiPIMS discharge has been revealed by high-speed camera imaging [4, 5]. Images of magnetron discharges revealed dense plasma regions over the racetrack area, which travel in the direction of $E \times B$ drift (Fig. 1). These structures, called ionization zones or spokes, have periodic or aperiodic arrangement with an arrowhead shape at lower discharge currents and a more globular shape at higher discharge currents. Side-view imaging revealed that the edge of the ionization zones is accompanied by a dense plasma region expanding normal to the surface of the cathode [4].

This talk will focus on charged particle transfer in the plane of the target of a magnetron operated in HiPIMS or DCMS mode. Previous studies showed that flux and energy of ions in the HiPIMS discharge have strong asymmetric distributions with maxima in the direction of the $E \times B$ drift [1, 2]. Based on those studies we performed additional measurements, which show that the transfer of charged particles in HiPIMS is closely related to the occurrence of the ionization zones. Although much weaker, we found evidence that ionization zones also form in DCMS. In the first experiment, two biased collector probes were used to record the evolution of ion and electron fluxes during a HiPIMS pulse. Measurements showed the presence of peaks in the ion and electron fluxes, which correlated with the periodicity

and intensity of the ionization zones. The highest intensity of the particle flux peaks was recorded in the direction of $E \times B$ drift. Asymmetric distributions of ion and electron fluxes along the side of the magnetron were measured both in HiPIMS and DCMS. In a second experiment, ion energy distribution functions were recorded in the plane of the magnetron target by mass and energy analyzer. The measurements confirmed the asymmetric ion distributions in HiPIMS and DCMS discharges with the maximum flux in the direction of the $E \times B$ drift.

Studies on the Internal Stress of Electroformed Ni-base Alloy for High Aspect Ratio Micro Parts

T12 Surface Engineering

#SE/TF-P2-07

S. Son, S.C. Park, H.M. Kim, J.H. Kim, W.S. Lee.

Korea Institute of Industrial Technology - Incheon (Korea, republic of).

Recently, Microelectromechanical systems (MEMS) process has been used in fabrication for high aspect ratio of micro parts, gear and molds. Electroforming is the highly specialized used for MEMS application. The internal stress at the interface between electrodeposit and substrate was important for micro electroforming. Internal stress will be affected by current density, temperature, agitation, plating bath, the metal alloy composition, applied power mode of DC or pulse power and the seed layer of the mandrel cathode. Indeed, there is no one special process variable that influences the deposit internal stress, because many variables described above could mutually have an effect on it. In this study, the micro gear and mold for powder injection molding and micro pin-fin heat sink were fabricated by electroforming of Ni-based alloys. The internal stresses in electrodeposited Ni-base alloys were controlled by concentration of organic additives, and various alloying elements. The internal stress was measured by using strain gauge-type stress meter.

The Ni-Fe alloy of electrodeposits was controlled by various organic additives, and it showed the measured internal stress decreased from 446.3 MPa up to 32.8 MPa. Decrease of internal stress is due to introduction of misfit dislocations at interface, when saccharin was added into electrolyte. a uniform and glossy surface and no cracks and delamination was observed in Ni-Fe alloy layer electrodeposited with an addition of organic additives, while many cracks and delamination were observed inside electrodeposition layer and at the interface between electrodeposited Ni-Fe alloy thin film and substrate, respectively, when no additives were added. The electrodeposited layer by pulse current showed lower internal stress than that by direct current, due to leveling effect and homogeneity of grain size. The micro electroformed gear and mold and micro pin-fin heat sink showed the same shape and size as mandrels fabricated by UV lithography and involutes curve of gear teeth was replicated exactly. Micro powder injection molding was performed using the micro electroformed molds. As a result, it is strongly suggested that micro

electroforming is very useful process to manufacture micro mold with high dimensional accuracy for micro PIM.

¹Veneto Nanotech SCpA - Marghera-Venezia (Italy), ²Universita' di Padova - Padova (Italy), ³LNL - INFN - Legnaro (pd) (Italy).

The aim of this study is to compare the effect of high power impulse (HiPI) and direct current (DC) power supplies in the deposition via magnetron sputtering (MS) of TiC/a-C nanocomposites on composition, structure and mechanical properties in industrial conditions with no sample biasing.

Titanium Carbide films were deposited in an industrial close field apparatus (target size 12"x4.9") by HiPIMS and by DC from a titanium target in acetylene (C₂H₂) reactive atmosphere with no substrate bias. Reactive gas flux was changed in order to obtain C/Ti ratios in the coating from 0.8 up to 2. In order to evaluate the differences between the two processes emission spectra were recorded highlighting the presence of H γ emission line only for the HiPIMS process depending on power and pulsing frequency (fig. 1). The deposition rate scaled linearly with the C₂H₂ flux in the poisoned mode for both DCMS and HiPIMS. Compositional RBS and ERDA characterization also showed lower hydrogen content in HiPIMS coatings than in DC. XRD and TEM characterization showed the presence of TiC nanocrystals with size and spacing dependent on C content surrounded by an amorphous matrix. HiPIMS allows to obtain fine grain TiC nanocrystals at C/Ti ratio closer to 1 than DC allowing for the same carbon content to obtain less amorphous carbon matrix.

The difference between the two deposition techniques were highlighted also by the mechanical properties of the coatings, tested by nanoindentation and microscratch. The deposited coatings showed as a function of the deposition process hardness in the range 10-25 GPa and elastic modulus of about 200 GPa, in particular HiPIMS coatings were characterized by higher hardness values while DC samples were always lower than 15 GPa. An increase of hardness and modulus could be observed for C/Ti content around 1.2-1.3, that was probably related to the nanostructure of the coating. Coefficients of friction showed values lower than 0.2 as a function of carbon coating content and were similar for HiPIMS and DC samples. On the other side

adhesion was improved in HiPIMS samples.

For C/Ti ratios from 1 to 1.4 the resistivity of the HiPIMS samples was around $400 \mu\Omega \text{ cm}$, while DC samples showed a resistivity more than double ($> 1000 \mu\Omega \text{ cm}$).

fig. 1: Optical emission spectra of titanium DC and HiPIMS plasma in C_2H_2 atmosphere as a function of reactive gas flux. Hydrogen emission lines are visible in HiPIMS mode and not in DC mode.

The Zr-B-C films prepared in our laboratories by nonreactive magnetron sputtering have showed an enhanced hardness (37 GPa), high electrical conductivity and resistance against oxidation up to 600°C. In the present paper, the effect of Si and N on high temperature behavior of the Zr-Si-B-C-N films is systematically investigated with aim to extend oxidation resistance of the films to higher temperatures while preserving high electrical conductivity and good hardness. The Zr-Si-B-C-(N) films with hardness ranging from 20 to 30 GPa were deposited on Si(100) substrates by dc pulsed magnetron co-sputtering of a single B₄C-Zr-Si target (with a fixed 15% Zr fraction in the target erosion area) in argon or nitrogen-argon gas mixtures. The Si and N content in the as-deposited films was varied in a wide range by the Si fraction in the target erosion area and by the N₂ fraction in the nitrogen-argon gas mixtures, respectively. The oxidation resistance of the Zr-Si-B-C-(N) films was investigated in synthetic air using a symmetrical high-resolution Setaram TAG 2400 thermogravimetric system. Changes in the structure, elemental composition, electrical resistivity and surface morphology of the films subjected to oxidation tests were analysed by X-ray diffraction, Rutherford backscattering spectroscopy, standard four-point method and optical microscopy. Preliminary results show that the addition of Si positively affects the oxidation resistance of the Zr-B-C films resulting in the reduction of mass gains. The Zr-Si-B-C films deposited with the 20% Si fraction in the target erosion area exhibit high hardness (22 GPa), low electrical resistivity (9×10^{-6} Ωm) and good oxidation resistance up to 750°C. The total mass gain detected at 800°C is less than 0.01 mg/cm². The addition of N into the Zr-Si-B-C films results in a

further shift of the onset of oxidation to higher temperatures. The films deposited with the 20% Si fraction in the target erosion area and with the 5% N₂ fraction in the gas mixture exhibit high hardness (22 GPa), slightly higher electrical resistivity ($4 \times 10^{-5} \Omega\text{m}$) and oxidation resistance up to 1000°C. High hardness and low electrical resistivity are preserved up to 900°C at annealing in air.

Ternary silicon carbon nitrides (SiC_xN_y) are considered as a prospective candidate for high temperature wear protective applications due to their high hardness and thermal stability of structure. In contrast to bulk materials these nitrides with variable composition can be relatively easily produced in the form of coatings by PVD and CVD techniques at low or middle temperatures. Although the understanding the relationship between temperature treatment and mechanical properties is very important for materials exposed to mechanical loading at elevated temperatures there has been no systematic data on composition-related mechanical properties of the SiC_xN_y films after annealing in air. Amorphous SiC_xN_y films with thickness of 2.2 - 2.7 μm were deposited on Si(111) substrates by reactive DC magnetron sputtering. The SiC_{1.15} target was sputtered at various N₂/Ar gas flow ratios (0, 0.04, 0.08, 0.16, 0.32, 0.48). The as-deposited films were additionally annealed at temperatures of 700, 900 and 1100 °C in the air and at 900 °C in vacuum for 30 min. Hardness and elastic modulus (nanoindentation), change of the film thickness, film composition (EPMA, GDEOS) and structure (Raman spectroscopy) were investigated in dependence on the annealing temperature. Increase of N₂/Ar flow ratio results in gradual increase of nitrogen content (up to 40 at.%) in the films at approximately constant C/Si ratio and some reduction of compressive stress. Air annealing results in slight decrease of film thickness for films sputtered at low N₂/Ar and small increase for films sputtered at high N₂/Ar. The most pronounced change of the relative thickness was observed for the film deposited in pure Ar after annealing at 1100 °C. It did not exceed 4 % that corresponds to ~100 nm.

The hardness of as-deposited films decreases along with the growth of N_2/Ar flow ratio. These films annealed in vacuum at 900 °C exhibit significantly higher values of hardness saving the above-mention trend. Besides their hardness almost do not vary with indentation depth in contrast to air annealed films. Air annealing at 700 °C leads to the increase of hardness and elastic modulus values regardless of N_2/Ar ratio, while annealing at 900 and 1100 °C reduces them. As the indentation depth increases the hardness of the films annealed at 700 °C remains almost constant. Hardness of the films annealed in the air at 900 and 1100 °C increases accordingly to the structure (composition) changes from the oxidized top-surface (~250 nm) to the annealed non-oxidized subsurface with the improved structure. These results are supported by GDEOS investigation of profile concentration of elements and Raman spectroscopy. Analysis of Raman spectra of air annealed films clearly points out the effect of nitrogen and oxygen on the facilitation of ordering of the amorphous carbon and onset of graphitization. This together with oxidation is directly reflected by the apparent softening of the films. The hardness and oxidation resistance of the investigated SiC_xN_y films reduce along with increase of N_2/Ar ratio. The highest values of hardness and elastic modulus before and after air annealing up to 1100 °C exhibit films obtained without nitrogen.

The benefits of strontium administration on osseointegration of dental and orthopaedic implants are well-known [1,2], but there is at the same time a great interest for developing functionalized implant surfaces for localized delivery and controlled release rates of factors promoting osteointegration (e.g. Sr) at the defect site [3,4]. By tailoring Sr-functionalized thin film coatings improved healing of bone tissue can be achieved, thereby enabling a shorter healing period for patients, which is of great interest both scientifically and commercially.

In the present study, thin film Sr-Ti-O coatings grown by DC magnetron sputtering in an industrial-scale deposition unit are investigated (Figure 1). The deposition technique enables tailoring of the coating properties, e.g. chemical composition and morphology, by varying a number of different parameters such as e.g. sputtering power, deposition temperature, deposition pressure, film thickness and substrate bias voltage, the latter controlling the kinetic energy of the ion flux bombarding the growing film. The thin films have been characterised by XPS, XRD, SEM and RBS. Adhesion of the coatings has been successfully evaluated by bending tests, Daimler-Benz adhesion test and electron microscopy after press fitting a coated cylinder into polyoxymethylene (POM). Furthermore, the release of Sr from the coatings when immersed in PBS buffer has been investigated by means of ICP-OES. The release of Sr is significantly dependent on the coating microstructure and can be tailored to a specific level. Promising in vivo

studies showing improved bone-to-implant contact and new bone formation will, among other results, be presented from this interdisciplinary project. An in vivo study in osteoporotic rats was initiated in January 2013 and results from this study will also be presented.

Heating with a nanosecond pulsed laser is widely used to the treatment of solid surface and biological applications. However, it is difficult for the real-time measurement of the surface temperature irradiated by a pulsed laser. In order to understand the detailed of surface temperature change, computer models have been developed to simulate the heat-flow conditions during the pulsed laser heating sequence. Kwon et al. refers our simulation result to estimate the surface temperature of carbon nanotube irradiated by a pulsed laser [1,2]. However, detailed physical properties of solid are necessary for computer simulation. The authors have developed the Fraunhofer diffraction method, which could be applied to the measurement of the optical wave diffracted by normal refractive-index waves [3]. This technique has been used to detect the ultrasonic wave generated by the electric discharge [4]. We apply this method to detect the thermal wave and shock wave generated by the irradiation of a pulsed laser to a crystalline silicon surface. Fig. 1 shows the experimental set-up to detect the signal arising from thermal and shock waves produced by a pulsed laser irradiation in air. Si surface was flashed with a single pulse of Nd:YAG laser. The pulsed laser energy density was varied with ND filter until the ablation threshold energy. Diode laser beam was sent towards the free space via a collimator lens 1 through a single mode optical fiber. When a probe laser beam crossed perpendicular to refractive index change with thermal and shock waves, the diffracted waves were generated and propagated to a collimator lens 2. The diffracted waves were then sent to the free space again via a collimator lens 3. The penetrating beam through a Fourier optical lens reached to the observing detector. When Si surface was flashed with a single pulse of Nd:YAG laser, the signals generated by the thermal and shock waves were detected. The intensity of

detected signal and the simulation result of surface temperature were increased with the increase of irradiation energy density. Therefore, we found that surface temperature irradiated by a pulsed laser is possible to estimate from the detected signal.

Structural Characterization of Advanced AlCrN/CrAlN Superhard Multilayer Coatings Prepared using Lateral Rotating Cathodes Process

T12 Surface Engineering

#SE/TF-P2-10

P. Zacková, Ľ. Čaplovič.

**Slovak University of Technology, Faculty of Materials Science and Technology
- Trnava (Slovakia).**

There is an increasing number of applications for hard coatings in the field of surface engineering where the properties of the single layer coating are not sufficient. One way to solve this problem is to use a multilayer coatings system that combines the properties of several coating materials [1]. One of these types of multilayer is AlCrN/CrAlN coating. This multilayer gives higher cutting speeds, feeds and extended tool life in the case of machining, punching or forming higher strength and abrasion resistive steels or non ferrous metals [2,3]. This paper deals with the structural characterization of AlCrN/CrAlN multilayer coating that was deposited onto AISI M36 tool steel substrate. Multilayer was prepared using Lateral rotating cathodes (LARC®) process that enables to deposition of PVD layers with reduction in macroparticles creation. Scanning electron microscopy fitted with EDX spectroscopy will be used for evaluation of microstructure and surface morphology of multilayer. Laser confocal scanning microscopy will be utilized for determination of AlCrN/CrAlN multilayer surface roughness and morphology as well. Concentration depth profiles through the top of the multilayer surface to the base material will be obtained with Glow discharge optical emission spectroscopy. Both X-Ray diffraction and Electron Backscatter diffraction analysis will be performed for the determination of phases presented in deposited multilayers. Indentation testing, nanohardness measurements, scratch and wear tests will be performed to characterize the mechanical properties of this type of multilayer. The influences of structure and composition of the multilayer coating on the mechanical and tribological behavior will be discussed.

Effect of mild oxidation of carbon/carbon composites on the oxidation protective ability of SiC coating

T12 Surface Engineering

#SE/TF-4-Or-2

Q. Fu, Y.J. Wang.

Northwestern Polytechnical University - Xi'an (China).

In order to improve the oxidation protective ability of SiC coating for C/C composites, the C/C substrate was mild-oxidized before coating. The sample had deeper oxidation thickness at 800°C than that at 1100°C after the same time. With the mild oxidation of C/C substrate, large scale gradient transition interface could form at the interface between SiC coating and C/C composites, which is favorable for the interface bonding. Mass loss of SiC coated C/C sample without mild oxidation quickly reached 1.5 %, after oxidation for 3 h. However, the mild-oxidized composites with SiC coating exhibited better oxidation protective ability. The samples still gained weight 0.3 % after oxidation for 14 h, owing to the release of mismatch of thermal expansion.

PVD coatings are widely used as wear resistant protective layers on bulk materials surface, although development of new coatings generation that combine high hardness and low friction coefficient in a wide temperature range is still the challenge. The ability of coatings to demonstrate low friction coefficient and wear rate in a wide temperature range is of great importance for many tribological applications because friction and wear produce essential energetic losses and decrease efficiency of the mechanical systems. Commonly known lubrication coatings based on pure carbon and transition-metal dichalcogenides have a limited range of operating temperatures. Above 350 – 400 °C such coatings oxidize in air, resulting in increased friction and accelerated wear. To overcome this problem multicomponent nanocomposite coatings, which are known to possess a desired combination of properties, could be employed for operations that require solid lubrication.

The aim of this work was to develop coatings for wide temperature tribological applications up to 700 °C and study their structure and properties.

MoCN-Ag coatings were deposited by pulsed magnetron sputtering of Mo and C (graphite) targets and simultaneous sputtering of Ag target using an additional ion

source. The structure and phase composition of the coatings were investigated by means of X-ray diffraction, transmission and scanning electron microscopy, X-ray photoelectron spectroscopy, and glow discharge optical emission spectroscopy. The elemental and phase composition inside and outside of the wear tracks were examined using Raman spectroscopy and EDX analysis. The MoCN-Ag coatings deposited in a gaseous mixture of Ar + 15 %N₂ had nanocrystalline structure consisted of the cubic Mo(C,N) crystallites and metallic silver particles. When deposition experiments were carried out in nitrogen atmosphere, the MoCN-Ag coatings were consisted of four different phases: c-MoN, h-Mo₂C, a-C, and metallic Ag. The nanocomposite MoCN-Ag coatings demonstrated low friction coefficient in the range of 0.3 - 0.4 both at low (25 – 100 °C) and high (400 – 700 °C) temperatures. This observation can be explained by the presence of amorphous carbon which acted as a solid lubricant at low temperatures and the precipitation of MoO_x and silver molybdate Ag₂Mo₄O₁₃ phases which provided low friction above 400 °C. The MoCN-Ag coatings also demonstrated adhesion to cemented carbide substrate above 70 N measured by scratch testing. Fracture toughness and fatigue strength of the coatings were estimated by means of dynamic impact tests. The MoCN-Ag coatings endured the dynamic impact forces of 1300 and 700 N for 10⁴ and 10⁵ cycles, respectively. The coating failures can be attributed to the adhesion strength limit of the MoCN-Ag coating being exceeded, rather than to low fracture toughness itself.

SE-1-Or-7

Time and spatially resolved ion energy distribution function in reactive HiPIMS

T12 Surface Engineering

#SE-1-Or-7

M. Cada, P. Adamek, J. Olejníček, Š. Kment, Z. Hubicka.

Institute of Physics ASCR, v.v.i. - Prague 8 (Czech republic).

The High Power Impulse Magnetron Sputtering System (HiPIMS) equipped with 2" in diameter target has been investigated by means of time-resolved mass- and energy-resolved analyser (plasma monitor) from Hiden Ltd., gridded retarding field energy analyser (RFEA) from Impedans Ltd. and so called modified Katsumata probe. All the methods allow to determine ion velocity distribution functions (IVDF) in forward direction to substrate as a function of retarding electric field. However, except plasma monitor latter methods are not able to resolve the mass of particles. The newly developed modified Katsumata probe uses a static magnetic field created by Sm-Co permanent magnets to intercept the most of plasma electron and pull them away back to the plasma bulk. Furthermore, the plasma monitor and the modified Katsumata probe are characterized in very small angular acceptance in comparison with the gridded RFEA. The high power impulse magnetron sputtering system was equipped with pure metallic targets (titanium or iron). As working gas a mixture of Ar and O₂ was used. The working gas pressure ranging between 0.5 Pa to 5 Pa. All the diagnostic instruments were placed at position of substrate. All the measurements were carried out under the same conditions as the thin oxide films TiO₂ and Fe₂O₃ were deposited. A comparative study of all the aforementioned methods has been carried out.

Results clearly demonstrate an influence of angular resolution on measured IVDF. Unlike gridded RFEA the modified Katsumata probe was able to distinguish different groups of ions coming on the substrate in different times of plasma pulse. The gridded RFEA has angular acceptance more than 70° and ions reaching its input orifice originate from different direction unlike the modified Katsumata probe which accepts ions only from cone of a small solid angle. The temporally resolved investigation with plasma monitor revealed that sputtered particles reach a substrate later on. All the plasma diagnostic methods revealed significantly enhanced energy tail in ion velocity distributions measured in HiPIMS in contrast to dc magnetron or mid-frequency pulsed-dc magnetron. An influence of working gas pressure on velocity distributions of argon, metallic and reactive gas ions specifically on presence

of high-energy tail is discussed. The plasma monitor proved that under certain plasma conditions appearance of double ionized sputtered and working gas particles can be observed.

Preparation and Micro-tribological Behavior of Superhydrophobic Nanofilm on Surface of Ti-6Al-4V Titanium Alloy

T12 Surface Engineering

#SE/ASS-1-Or-10

Z. Kang, G. Fang, Q. Liu, J. Zhang.

South China University of Technology - Guangzhou (China).

A superhydrophobic nanofilm was obtained on Ti-6Al-4V titanium alloy surface through the combination of chemical etching and polymer plating techniques. The hierarchical structured surface was researched by SEM and XRD. The elements, surface topography and wettability of superhydrophobic nanofilm were characterized by XPS, AFM and contact angle meter, respectively. UMT-2 tribometer was utilized to investigate the micro-tribological behavior of the nanofilm. The experimental results show that the surface is coated by organic nanoparticles clusters after polymer plating and the contact angle of distilled water is 155.0°. The friction coefficient of polymer plated surface decreases to 0.21 compared with 0.42 for blank and the wear life is 220 s, therefore the micro-tribological property of Ti-6Al-4V titanium alloy surface is effectively improved.

This work is supported by the National Natural Science Foundation of China (No.51075151) and Key Program of Guangdong Natural Science Foundation (No.10251064101000001).

Ti_nO_{2n-1} , substoichiometric titanium oxides (Magneli phases) are known to present interesting tribological properties for low wear applications [1, 2]. The existence domain of Magneli phases being limited, it remains difficult to synthesise them. In most published studies, films composed of these phases are obtained either by thermal spraying [3], laser chemical vapour deposition [4], or by sol-gel route [5]. However, few papers deal with the deposition of Magneli phases films by physical vapour deposition through controlling the oxygen content.

In this paper, titanium Magneli phases' coatings were synthesized with different thicknesses at a temperature of 873 K by reactive magnetron sputtering. The substrates are AISI M2 high speed steels previously covered with AlTiN coatings obtained by reactive arc deposition. The chemical, structural and mechanical characteristics of the coatings are presented. In particular, the pin-on-disc tests at ambient and high temperatures are performed to assess the wear resistance of those coatings as a function of their thickness.

In a second part, we investigate the deposition of Ti-O coatings as a function of the oxygen flow rate with the same thickness which presents the best wear resistance at the preceding tests. The pin-on-disc tests at ambient and high temperatures are also performed. We finally present relationships between the oxygen flow rate and the

chemical and structural features of the coatings and their effect on the wear resistance of these coatings.

Innovative wear-resistant coating under unlubricated conditions in a wide range of temperature realized by reactive magnetron sputtering

T12 Surface Engineering

#TF/SE-1-Or-12

G. Bouscarrat.

CITRA - Limoges (France).

Nowadays, surface treatments are more and more used in many different industries, especially to enhance wear resistance thanks to better friction coefficient and harder surfaces. Among all technologies, the PVD processes are good solutions for different kind of coatings: TiN, TiC, TiCN, CrN, CrC, TiAlN and DLC mainly, for these applications.

Recently, lots of studies were about tribological issues which represent one of the most important expenses' source for industry. For example, 20 years ago, wear's cost represented in France about 20 billions Euros. In the Unites States of America, American industries estimated the friction loss in the internal-combustion motors to about 0.7% of the global energetic consumption of the USA. Consequently, the realization of highly wear-resistant coatings with low friction coefficient is a point of high interest.

Because of this, an innovative coating was suggested by the Center for Innovative Technology and Research in Advanced coatings (CITRA) in Limoges, France. It was realized by reactive magnetron sputtering using a target mainly made of TiHfCN. Indeed, TiCN coating has a four times higher lifetime than a TiN coating [1] and Hf compounds possess higher melting points than Ti ones [2,3].

Some improvements (i.e. experimental design and parametric study) already lead to the realization of a multilayer coating with enhanced adherence and friction properties. In addition to the advantages of a multilayer-type coating (i.e. multifunctional character, good adherence due to moderate residual stresses, etc.), the increase in nitrogen and carbon concentrations causes a higher wear resistance, low friction coefficient and good substrate adherence. Most of intrinsic characterizations were made using CITRA's equipments and led to the properties summarized in table 1 below.

Crystalline phase	Hardness (GPa)	Young's modulus (GPa)	Wear rate (mm ³ /N/m)	Friction coefficient	Adherence Lc ₁ (N)	Thickness (μm)
HfTiCN	32 ± 2	332 ± 13	1.6 x 10 ⁻⁷	0.05-0.25	18-22	2-4

Table 1 - Coating's properties

Furthermore, some tests confirmed that this coating offers interesting properties until 600°C. Finally, further experimentations will be realized to improve and develop some new layer arrangements adding some metallic elements like chrome and aluminium.

We expect new applications for this multi-purpose coating, especially for extreme temperatures, with or without lubricant.

The purpose of the present study was to comparatively investigate the characteristics of (TiZr)C and a novel multi-principal-element (TiZrCuSiY)C coatings, based on high entropy alloy concept [1,2]. The metals in the films are in almost equiatomic concentrations. For (TiZrCuSiY)C films, the metallic constituents were selected taking into account: atomic radius, mixing enthalpy and valence electron concentration. The films were deposited on Si and C45 substrates through co-sputtering of Cu, Si, Ti, Y and Zr targets in an Ar+CH₄ reactive atmosphere. The films were analyzed for elemental and phase composition, crystalline structure, mechanical characteristics, tribological and corrosion performance in saline solution (3.5 % NaCl). The influence of carbon concentration on film properties was investigated.

While (TiZr)C films exhibited crystalline structures (fcc), the (TiZrCuSiY)C films were amorphous (Fig.1). Fine grained and smooth surface morphologies were observed by AFM. For the same carbon concentration, the multi-principal-element films exhibited lower wear rates (Fig.2) and friction coefficients, and better corrosion resistance, as compared to the (TiZr)C films.

Considering their fine structures, good wear - corrosion resistance and friction characteristics, the multi-principal-element (TiZrCuSiY)C coatings can represent a valuable alternative in various tribological and anticorrosive applications.

As harmful and potentially flammable or explosive compounds, monitoring hydrocarbon vapours atmospheric rates relates to health as well as security issues. Electrochemical sensors are suitable for such an application since they generally exhibit fast response and good sensitivity.

The sensors presented here are built upon thin films of BITAVOX.20 ($\text{Bi}_2\text{Ta}_{0.2}\text{V}_{0.8}\text{O}_{5.5}$) electrolyte, chosen for its ability to conduct oxide ions at moderate temperatures (300°C) and platinum and lanthanum perovskites electrodes. They have been deposited on alumina pellets or MSP 769 commercial sensor platform by reactive magnetron co-sputtering. The influence of the deposition parameters on the electrode/electrolyte interface and on the electrodes microstructure has been investigated by X-ray diffraction and SEM observations. The impact of electrode morphological characteristics as well as this of the sensor design and of its ageing on the detection performance in the amperometric mode and in the potentiometric mode has been assessed using a home-made test bench.

Corrosion Behaviour of Nitrogen-doped Al-Ti-Ni and Al-Cr-Ni Nanostructured PVD Coatings Deposited on Low Alloy Steel

T12 Surface Engineering

#SE-2-Or-1

J. Lawal, O. Fasuba, A. Matthews, A. Leyland.

University of Sheffield - Sheffield (United kingdom).

Low alloy steels (e.g. 4140 and 4145 grades) have found increased application for engineering components as a result of their strength and hardness. They have been used in structural pipe-work and in transport tubing for pressurised fluids (especially in the oil and gas industry). However, such low alloy steel grades have relatively poor corrosion resistance, due mainly to their low chromium content.

Nanostructured PVD coatings comprising a hard nanocrystalline phase embedded in an amorphous matrix have been found to exhibit multifunctional capabilities. These coatings can exhibit unusual combinations of high hardness, long elastic strain to failure, resistance to crack formation – and even exhibit good corrosion resistance (in terms particularly of pitting) [1,2,3,4]. This study investigates the corrosion characteristics of nitrogen-doped Al-(Ti, Cr)-Ni nanostructured coatings prepared by magnetron sputtering. Electrochemical impedance spectroscopy and potentiodynamic polarisation measurements were used to investigate the corrosion behaviour of the coatings in a 3.5 wt. % NaCl environment. This work provides a comprehensive report of the corrosion characteristics of nitrogen-doped Al-Ti-Ni and Al-Cr-Ni nanostructured PVD coatings.

Químicas, Universidad Complutense de Madrid, Ciudad Universitaria s/n, E-28040 - Madrid (Spain).

The constant increase in the world population and in the development degree leads to a high energy consumption. The energy solution is a long standing problem which requires innovative solutions. Nowadays, in combination with other sustainable sources of energy, fusion energy can become within the next two decades a real alternative to fossil fuels. However, the lack of materials able to withstand the severe radiation conditions (high thermal loads and atomistic damage) expected in such reactors is a bottle neck for fusion to become a reality.

The main requisite for plasma facing materials (PFM) is to have excellent structural stability since severe cracking or mass loss would hamper their protection role which turns out to be unacceptable. Additional practical requirements for PFM are among others: (i) high thermal shock resistance, (ii) high thermal conductivity (iii) high melting point (iv) low physical and chemical sputtering, and (v) low tritium retention.

W has been proposed to be one of the best candidates for PFM for both laser (IC) and magnetic (MC) confinement fusion approaches. However, works carried out up to now have identified some limitations for W which have to be defeated in order to fulfill specifications [1,2,3]. Nowadays, the capabilities of ultrafine grain and nanostructured materials for nuclear fusion reactor applications are being investigated [4].

We report on the growth of nanostructured W coatings with a thickness of ~ 2 microns by using DC magnetron sputtering on different kind of substrates (Si, Mo and steel). X-Ray diffraction (XRD) studies show that coatings are pure alfa-phase polycrystalline and present low macro-stress and micro-strain. The influence of substrate on stress is assessed. Scanning electron microscope (SEM) images show that coatings consist of nano-columns with an average diameter of around 100 nm and an inverted pyramidal shape that grows perpendicular to the surface substrate. Nanoindentation tests evidence that the coating hardness is as high as ~14 GPa. The dependence of microstructure, morphology, and mechanical properties on annealing temperature and time ($T \leq 1000$ °C and $t \leq 240$ min.) will be also reported. No significant change in the studied properties is observed for coatings annealed at 400°C for 240 min.

STRUCTURAL CHARACTERISTICS OF PLASMA-NITRIDED LAYERS ON SINTERED IRON SUPERFICIALLY ALLOYING WITH MOLYBDENUM

T12 Surface Engineering

#SE/TF-P2-12

A. Maliska ¹, T. Bendo ¹, J.J.S. Acuña ², K.C. Kleinjohann ¹.

¹UFSC - Florianópolis (Brazil), ²UFABC - São Bernardo Do Campo (Brazil).

During the sintering process using a dc glow discharge, unalloyed iron samples have the surface alloyed with molybdenum (approx. 5 at.%) and after they are nitrided. These samples showed a layer of distinct precipitation between the composite layer and the diffusion layer (Figure 1) with significant increase in the hardness values. The layers characterization was carried out by electron microscopy (SEM and HR-TEM), X-ray diffractometry (XRD) and GDOES (Glow Discharge Optical Emission Spectroscopy). In the XRD analysis was not detected the presence of Mo nitrides or ternary nitrides (Fe-Mo-N) in the nitrided layer, only γ' -Fe₄N and ϵ -Fe₂₋₃N phases were detected, which could be attributed to low Mo concentration (3 at 5 at %) [1]. Analysis of the nitrided layers by selected area electron diffraction (SAED) was performed in order to characterize the different regions in nitrided sample. The TEM investigations provided the formation of γ' -Fe₄N and ϵ -Fe₂₋₃N in white layer. According to [2] in Fe-Mo alloys nitrided between 450-600 °C can be expected compositions γ' -(Fe,Mo)₄N and ϵ -(Fe,Mo)₂₋₃N with some Fe atoms substituted by Mo atoms. The Figure 2 demonstrated the formation of very small precipitates (20 nm) on the surface sample. In these precipitates was detected the presence of Mo (by nano-EDS) in contrast to the XRD analysis. A high nitrogen concentration was found (by GDOES analysis) in the first 3 μ m of surface. The TEM investigations indicate the presence of compounds Fe_xN_{x-1} with 0,40<x<0,50 in superficial layer which may have been formed due to the increased solubility of nitrogen on the surface favored by the presence of Mo [3].

Biocompatibilizacion of a porous structure by lipid coverage

T12 Surface Engineering

#SE/PST/TF/BI-P1-02

J. Benavente ¹, V. Romero ¹, L. Gelde ¹, M.I. Vázquez ¹, J. Hierrezuelo ².

¹Dpto. Física Aplicada I, Facultad de Ciencias. Universidad de Málaga - Málaga (Spain), ²Dpto. Química Orgánica, Facultad de Ciencias. Universidad de Málaga - Málaga (Spain).

Porous structures are nowadays common systems for applications in water treatment, biomedical applications, microfluidics, dialysis, or tissue engineering ... [1]. Particularly, transport through nanoporous supports with well defined structure has received significant attention during the last decade due to their application in processes related with molecular/ion transport control, which is a point of great interest in areas such as biosensors or drug delivery, but requirements on the biocompatibility and the hydrophobic character of the membrane surfaces and their biocompatibility are important factor to be considered, this latter directly related to reduce the membrane fouling, that is, the adsorption or deposition of proteins, macromolecules and colloidal particles on the surfaces of membrane. Surface coverage by lipid compounds can be of significant importance for such applications. This paper presents the surface coverage of a porous polyvinylidenedifluoride (PVDF) membrane by a lipid mixture (glyceryl triestearate (33.5 %), sodium taurocholate (50 %) and L- α -phosphatidylcholine (16.5 %)), and its effect on surface and transport parameters. Membrane surface modification associated to lipid layer was characterized by X-ray photoelectron spectroscopy (XPS) and contact angle (CA) measurements performed with dry samples. However, water and NaCl solutions at different concentrations were used for measurements of transport parameters such as water permeability ($L_p = J_v/\Delta P$), diffusive permeability ($P_s = J_s/\Delta C$) and ion transport number (t_i , or fraction of the total current carrier by the cation), where J_v and J_s represent the water and solute flow, while ΔP and ΔC are the pressure and concentration differences across the membrane. Variations in the characteristic parameter obtained for original and modified membranes give information about changes on membrane pores/porosity. A reduction in the values of both hydraulic permeability (~ 50 %) and NaCl diffusive permeability (~ 30 %) was determined as a result of the lipid coverage of the PVDF membrane, but no permeability dependence on feed solution concentration seems to exist. Moreover, the lipid layer also seems to

modify the electrical character of the membrane surface [2], which affect to both t_{Na^+} values and its dependence with the average concentration of the solutions at both membranes sides. This effect was also supported by the more negative values obtained for zeta potential and surface charge density for the PVDF/lipid modified membrane, which were determined from streaming potential measurements and they also provide us valuable information on the membrane-solution interface [3]. According to these results, the external and internal (pore wall) membrane surfaces of the PVDF/lipid modified samples have been covered by the lipid layer.

We thank to the CICYT for financial support (Project CTQ2011-27770, Spain, FEDER funds) and V. Romero also thanks to MICINN for her FPU scholarship.

TF/SE-1-Or-3

Deposition of mixed oxide coatings by pulsed reactive co-sputtering

T12 Surface Engineering

#TF/SE-1-Or-3

H. Klostermann, F. Fietzke, B. Krätzschar.

Fraunhofer Institut fuer Elektronenstrahl- und Plasmatechnik - Dresden (Germany).

Reactive co-sputtering of elemental targets is a versatile technique to deposit ternary coatings of any composition. In the case of oxide coatings, tailored phase formation can be achieved by proper choice of deposition parameters and fine tuning of the composition through variation of pulse lengths (Fig. 1). However, the high affinity of many metals to oxygen requires a rapid feedback control to stabilize the sputtering process in a transition state with non-poisoned target surfaces. In bipolar pulsed sputtering, the coupling of the targets through the common discharge allows establishing long-term stable deposition processes. The composition of the deposited films can be tuned by adjusting pulse lengths and the entire range of mixed oxides is accessible (Fig. 2). The formation of specific crystalline phases for certain compositions will be presented for the ternary system Al-Zr-O, which is especially promising for high temperature protective coatings for different applications.

Effects of some electrical parameters on the efficiency of the Plasma Electrolytic Oxidation of aluminium alloys

T12 Surface Engineering

#SE/TF-P2-13

J. Martin ¹, A. Nominé ¹, I. Shchedrina ¹, A.G. Rakoch ², G. Henrion ¹, T. Czerwicz ¹, T. Belmonte ¹.

¹Université de Lorraine, UMR CNRS 7198, Institut Jean Lamour - Nancy (France), ²National University of Science and Technology, Moscou Institut of Steel and Alloys - Moscow (Russian federation).

The Plasma Electrolytic Oxidation (PEO), also known as Micro-Arc Oxidation (MAO) is a particular electrochemical process to produce protective oxide ceramic coatings on light-weight metals (such as Al, Mg, Zr, Ti and their alloys). Growth of the oxide layer takes place at potentials above the dielectric breakdown voltage of the insulating oxide layer leading to the development of numerous short-lived micro-discharges (atmospheric micro-plasma in liquid medium) which move randomly over the processed surface¹⁻². The resulting coating exhibits improved surface performances in terms of hardness, wear protection and corrosion resistance. Associated with the use of environmentally friendly diluted alkaline electrolytes, PEO process gains a growing interest in various industrial domains (transport, energy, medicine) to replace conventional chromic or hard anodizing.

Despite the considerable interest in this process, there is still no clear understanding of the underlying discharge mechanisms that make possible metal oxidation up to hundreds of μm through the ceramic layer. Moreover, no clear relationship has been established between the process parameters and the resulting layer characteristics.

Using an AC pulse bipolar current generator to supply the sample to be processed, the aim of the present communication is to give new insight into the influence of

some electrical parameters on the efficiency of the plasma electrolytic oxidation of aluminum alloys. A particular attention was paid to the current density (from 10 to 80 A.dm⁻²) and the current pulse frequency (from 100 to 900 Hz)³. Micro-discharges are characterized during the process by means of optical spectroscopy and fast video imaging (up to 125000 frames/s) with a time and a space resolution of 8 μs and 0.017 mm², respectively. Correlations are established between the micro-discharges characteristics (surface density, spatial distribution, lifetime and size) and the elaborated oxide layers (edge effect, morphology, growth rate, roughness).

Results clearly point out the influence of the current density and the current pulse frequency on the process. Coating growth rate is improved with the combination of the highest current density and the highest current pulse frequency. Within these specific electrical conditions it is observed that the detrimental effects of strong (long-duration up to 0.3 ms and large size up to 0.5 mm²) micro-discharges are minimized.

SE/TF-2-Or-2

Effect of variation in pulse mode of plasma electrolytic oxidation (PEO) on coating characteristics on an aluminium alloy

T12 Surface Engineering

#SE/TF-2-Or-2

A. Jarvis, A.L. Yerokhin, A. Matthews.

Sheffield University - Sheffield (United kingdom).

Abstract:

A study has been made of the effect on the coating characteristics caused by variation in the pulse mode of the power supply used to produce plasma electrolytic oxidation (PEO) coatings on aluminium alloy. Previous work has shown that the PEO coating deposition process is strongly affected by the characteristics of the power supply, ranging from a simple DC Source, to pulsed DC or pulsed AC and onto more complex hybrid AC/DC pulsed systems. Various electrical parameters can be varied in each case, including: the control mode (constant current or voltage), frequency, pulse characteristics (half-wave or full wave, number per packet, frequency, time on and off) and offset. See the Figure below for a description of these terms for a generic bipolar pulsed source. These factors affect both the coating characteristics as well as the overall energy process efficiency. By varying the power supply characteristics one can aim to optimize the coating's tribological, corrosion resistance, and/or mechanical properties as well as its process energy consumption.

In this work, a specially designed bipolar pulsed power source was used that allowed control of the number and frequency of pulses for both the positive and negative packets of the PEO power source. The number of pulses in both the positive and negative pulse packets (see Figure for explanation) were varied and the subsequent effects on the coating characteristics were observed. The coatings were characterized by measuring their composition (including porosity level and phases present), residual stresses, indentation hardness (micro and nano-indentation) and relative wear resistance.

Figure: Schematic of bipolar pulse output of plasma electrolytic oxidation (PEO) power supply unit: t_{on} : positive pulse on time; t_{off} : positive pulse off time; t'_{off} : negative pulse off time; T_p : working time for positive pulse packet; T_N : working time for negative pulse packet; J_m : positive average current density; J'_m : negative average current (after Jiang, Wang 2010)

Engineering, The University of Sheffield, UK

Abstract

Aluminium coatings are promising candidates for the cathodic protection of construction steels. However, their high sensitivity to localised degradation often limits their applications for corrosion protection. Incorporation of transition metals such as Cr allows for the modification and enhancement of the structural and electrochemical properties of aluminium coatings, such that excellent pitting corrosion resistance is achieved for the coating without compromising its cathodic protection capacity.

In this study, AlCr coatings deposited by Electron Beam Physical Vapour Deposition (EBPVD) in N₂ reactive gas of various flow rates were characterised in terms of corrosion behaviour in 3.5 wt. % NaCl solution. The substrate used is 17/4PH precipitation hardening stainless steel. Electrochemical noise and potentiodynamic

polarisation measurements were used to determine the corrosion behaviour of the coatings. Corrosion parameters obtained from the potentiodynamic polarisation tests were compared to the statistical parameters from the signals in time and in the frequency domains of the noise measurements.

Good agreement between data for the different techniques was found. In particular, noise resistance (R_n) values from the noise electrochemical measurements correlate well with corrosion rate (i_{Corr}) values obtained from potentiodynamic polarisation measurements. In terms of pitting corrosion resistance and cathodic protection for the 17/4PH stainless steel substrate, an AlCr PVD coating containing approximately 10 at. % nitrogen proved to be most effective.

SE-1-Or-8

Through-target Study of Plasma Generation and 3-D Analysis of Plasma Transport in High Power Impulse Magnetron Sputtering

T12 Surface Engineering

#SE-1-Or-8

D. Ruzic, L. Meng, H. Yu.

University of Illinois - Urbana (United states).

High power impulse magnetron sputtering (HIPIMS) has distinctive advantages of intense pulse plasma density and high degree of metal ionization suitable for various applications from hard coatings to interconnect metallization in integrated circuits. A fundamental characterization of plasma properties and fluxes of species is critical for the process development. The underlying physics the discharge establishment and plasma transport also need be further explored.

For the first time, the generation of plasma species during the HIPIMS ignition was explicitly measured on the target. To avoid the indirect optical methods or the plasma-disturbing probes, an orifice was created within the target racetrack region, behind which a current-collecting grid and a quartz crystal microbalance (QCM) were placed. The measured ion current didn't show up until a certain delayed point after the pulse beginning. The delay time, ranging from 10 to 40 μs , is a direct supporting evidence for the localization of ionization zone [1] during the HIPIMS ignition. The higher pulse voltage, the shorter was the delay time, suggesting a faster drifting of the localized plasma. Combined with the QCM, high Cu ionization fraction in the vicinity of the target was determined, indicating the self-sputtering effect taking place in HIPIMS.

Triple Langmuir probe was used to measure the time-resolved electron density and electron temperature during HIPIMS. The analysis revealed that it took about 150 μs after the pulse end for the peak of electron density to reach the substrate. Such a plasma expansion was further mapped in three dimensions inside the chamber. The expansion speed was found to depend on pulse parameters as well as the magnetic field configuration. The higher the magnetic field strength, the faster was the

expansion. The plasma potential distribution is believed to be accountable for this effect. A stronger magnetic field (800 Gauss as compared with 200 Gauss) resulted in a larger potential gradient (and thus a stronger electric field) in the bulk plasma region to facilitate the electron diffusion. The Cu ion fractions of up to 60% were measured near the substrate, increased by a higher pulse voltage or a moderate pulse length. A lower magnetic field also gave a higher Cu ion fraction despite a lower plasma density. The relatively flat distribution of plasma potential in the low magnetic field configuration leads to an effective ion release downstream instead of attracting ions back to the cathode.

(This is not part of the abstract, just a note that this paper may also fit into another session T11.01)

Optimizing high power impulse magnetron sputtering processes through computational modeling

T12 Surface Engineering

#SE-P1-02

N. Brenning, C. Huo, M. Raadu, D. Lundin.

Royal Institute of Technology - Stockholm (Sweden).

High power impulse magnetron sputtering (HiPIMS) is a successful sputtering technique that has a variety of industrial applications, including protective coatings, optical coatings and functional coatings for electronic applications. The possibility to independently vary the pulse length, shape, peak power, and duty cycle opens up new wide ranges of parameters to explore and tune for discharge optimization. In this contribution, we present an overview of ongoing HiPIMS modeling based on a recently developed time-dependent ionization region model (IRM) [1], which has been used as a flexible tool in the optimization process [2, 3]. The working principle of the IRM is a set of balance equations tracking the production and loss of electrons, ions, excited species, as well as neutrals present in the HiPIMS plasma. As a model system we have here focused on sputtering of Al in an Ar atmosphere, and used it to examine when effects, such as intense gas rarefaction, high degree of ionization of the sputtered species, deposition rate loss, self-sputtering etc. occur. From an end-user point of view, we will also discuss what to include in the IRM based on the objective(s) of the investigation.

SE/ASS-1-In-1

Atomic-Scale Friction and Wear of Single Asperities

T12 Surface Engineering

#SE/ASS-1-In-1

R. Carpick.

University of Pennsylvania - Philadelphia, Pa (United states).

I will discuss experimental studies of nanoscale single asperity contacts that reveal surprising new insights. First, the behavior of nanoscale contacts with truly 2-dimensional materials including graphene will be discussed. We find that the friction force exhibits a significant dependence on the number of 2-D layers [1]. Surprisingly, adhesion (the pull-off force) does not. However, studies as a function of scanning history reveal further complexities that arise from the combined effects of high flexibility and variable substrate interactions that occur at the limit of atomically-thin sheets.

I will then discuss new insights into nanoscale wear. A better understanding of the physics of wear would allow the development of rational strategies for controlling it at all length scales. As well, wear is a primary limitation of devices such as micro-/nano-electromechanical systems (MEMS/NEMS). We show that ultrastrong materials can be used to greatly reduce nanoscale wear [2,3]. We have also demonstrated the ability to characterize single-asperity wear with a high degree of precision by performing in-situ wear tests inside of a transmission electron microscope. Silicon probes of different initial radii and shape were slid against a flat diamond substrate. The shape evolution and volume loss due to wear are well described by kinetic model based on stress-assisted bond breaking mechanisms, allowing new insights to be gained about the kinetics of atomic-scale wear [4].

Study on the mechanical and corrosion behavior of ceramic coated 2024-Al alloy produced by plasma electrolytic oxidation

T12 Surface Engineering

#SE/TF-2-Or-8

M. Alizadeh ¹, R. Saleh ², S. Bordbar ¹.

¹Department of Metals, Institute of Materials Science and Engineering, Graduate University of Advanced Technology, PO.BOX: 76315-115, Kerman, Iran - Kerman (Iran, islamic republic of), ²Department of Plasma Engineering, Graduate University of Advanced Technology, PO.BOX: 76315-115, Kerman, Iran - Kerman (Iran, islamic republic of).

In general, corrosion damages constrain heavy costs to industries due to destructive nature of this phenomenon. Among wide range of engineering metals, aluminum alloys due to favorable properties such as low weight, corrosion resistance and various mechanical behavior are appropriate options for industrial applications. Although, aluminum alloys represent sufficient corrosion resistance in neutral environment but they are sensitive alloys to pitting and crevice corrosion in presence of chloride ions. Coating is the most common technique to improve corrosion behavior of aluminum made constructions.

In this relation, plasma electrolytic oxidation(PEO) is an efficient and modern method. In this technique, micro-arc plasma appears on the specimen surface due to ionization of the surrounding gaseous in the high voltage. In fact, the electric field of 106 to 108 V/m cause ionized gaseous generation. As results of complex chemical and physical reactions, a dense ceramic layer of Al₂O₃ forms on the substrate surface [1]. The PEO technique improves corrosion behavior of coated specimens by restrict the access of corrosive species to the Al substrate through the ceramic layer [2]. Furthermore, generation of ceramic layer lead to increase the surface hardness. In the present study, the corrosion behavior of coated specimens were investigated by electrochemical impedance spectroscopy (EIS) in 3.5% NaCl solution and generated ceramic layer was analyzed by X-ray diffraction (XRD) method. The main goal of this investigation is to improve corrosion behavior and mechanical properties of 2024-Al alloy by plasma electrolytic oxidation method.

Single Step Process Toward Superhydrophobic Surfaces - Atmospheric Pressure Dielectric Barrier Discharge Deposition Of Hexamethyldisiloxane Coatings

T12 Surface Engineering

#SE/TF-2-Or-10

N. Boscher, D. Duday, P. Choquet.

Centre de Recherche Public - Gabriel Lippmann - Belvaux (Luxembourg).

In the past decade, numerous studies have focused on controlling the surface nano- and microstructure to mimic the dual-scale roughness of superhydrophobic lotus leaves or the high water contact angle (WCA) and large water sliding angle (WSA) of rose petals [1]. Depending on the size of the micro- and nanostructures, which can both be in the Cassie-Baxter [2] or Wenzel state [3], four different wetting states are possible, leading to either “slippy” or “sticky” surfaces with high WCA.

In this work, we present a single step process to the large-scale production of fluorine-free surfaces with high WCA. The surfaces were prepared on various substrates by the atmospheric pressure dielectric barrier discharge (AP-DBD) reaction of hexamethyldisiloxane (HMDSO) in a nitrogen atmosphere. The chemical composition of the coatings was characterised by Fourier-transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS). The coating nanostructure, greatly impacted by the plasma electrical excitation frequency [4], and the substrate roughness were investigated by scanning electron microscopy (SEM), confocal microscopy and atomic force microscopy (AFM) and were shown to strongly influence the hydrophobic behaviour of the surfaces.

Adjustement of the nano- and microroughnesses allow to produce both “slippy” or “sticky” surfaces with high WCA. Water droplets, which remained on the mixed Cassie-Baxter/Wenzel surface with contact angle of 155°, do not slide even when the surface is tilted vertically or turned upside down. In contrast, water droplets, with

WCA up to 168°, were shown to roll-off easily from the surfaces in the Cassie-Baxter state.

Effects of plasma electrolytic oxidation on corrosion fatigue properties of biodegradable cp-Mg

T12 Surface Engineering

#SE/PST/TF/BI-2-Or-3

Y. Gao, A. Matthews, A. Yerokhin.

The University of Sheffield - Sheffield (United kingdom).

Magnesium alloys have been considered as promising biomaterials; however their application in biological area is limited due to their too high reactivity in the physiological environment. Plasma electrolytic oxidation (PEO) technique is beneficial to improve corrosion performance of magnesium alloys, which enables their application as biodegradable implants. Corrosion fatigue is identified as one of the major problems associated with implant failure. It is therefore of great significance to address this performance aspect of PEO-coated biodegradable Mg materials, which is currently not well understood.

In the present study, PEO coatings are fabricated on cp-Mg, using optimised process parameters, i.e. the current mode, and the composition of a biologically friendly electrolyte. The coating morphology and phase composition are characterised by scanning electron microscopy and x-ray diffraction technique, respectively. The corrosion fatigue tests are performed according to ASTM F1801-97(2009). The specimen is immersed in a simulated body fluid at 37°C during corrosion fatigue test. From the test results, corrosion fatigue strength of PEO coated magnesium is evaluated. Fracture topography analysis is used to identify the effects of PEO coating on the failure mechanisms and kinetics. Finally, the perspectives of using PEO-coated cp-Mg for biodegradable implant applications are discussed in terms of corrosion fatigue performance.

Nanocomposite (multi)functional surfaces: various strategies to efficiently incorporate nanoparticles in atmospheric plasma-polymerized thin films

T12 Surface Engineering

#SE/TF-2-Or-11

D. Ruch.

CRP Henri Tudor - Advanced Materials and Structures Department, 5 rue Bommel – ZAE Robert Steichen, - Esch Sur Alzette (Luxembourg).

The success of modern materials is very often (partially or totally) due to the high performances of their functional surfaces. In this frame, the development of high efficient polymer-based coatings and composite thin films is of growing interest when issues linked to flexible microelectronics, adhesion, energy or even healthcare are concerned. The combined recent advances in surface coatings engineering and in polymer science can nowadays lead to the design of increasingly efficient surfaces with functionalities addressing very precise, strict and high level requests depending on the dedicated application.

Atmospheric Plasma polymerization is nowadays considered as a promising and versatile technique allowing to process plasma polymer films with functional properties without affecting the intrinsic properties of the substrate. Usually, the functionality of the plasma deposited layer is mainly determined by the nature of the used vapor precursors or monomers. The molecular structure of the resulting plasma-polymer film can be fine-tuned by a well-advised selection of precursor(s) combined with well adapted plasma parameters. The high performance of thin films grown via atmospheric plasma polymerization lies on very specific approaches aimed at generating well established and well controlled chemical structures and molecular architectures perfectly matching the desired applications. In this frame, Incorporating nanoparticles within plasma polymers could open door for new kind of smart coatings innovative. The present work is mainly focused on the design of nanocomposite functional surfaces. In order to generate this type of hybrid coatings, several

processes will be described: from the direct injection of nanoparticles previously dispersed in the liquid precursor, to the in-situ generation of nanoparticles inside a „reactive“ plasma-polymer thin films used as nanoreactor, or to the use of modified metallic particles as nucleating agent for the growth of the plasma-polymer chains (grafting from).

This contribution will highlight the importance of the control of the chemical structures and molecular architectures at the molecular level in order to reach the expected macroscopic properties and performances and therefore being able to offer new perspectives for atmospheric plasma-polymer coatings, in application domains as varied as corrosion protection, self-healing, or even in the design of alternative electrode materials for PEM fuel-cells...

Formation of thin hydroxyapatite-containing titania coatings on cp-Ti for dental implant applications by plasma electrolytic oxidation

T12 Surface Engineering

#SE/PST/TF/BI-2-Or-4

W. Yeung, Y. Gao, A. Yerokhin.

The University of Sheffield - Sheffield (United kingdom).

Due to good osseointegration titanium implants are widely used in orthodontic surgery; however, long healing time is still a problem. The aim of this study is to form a thin (5...10 micron) coating that could help reducing the healing time of Ti dental implants by plasma electrolytic oxidation (PEO) process. This involves improving the surface morphology of the coating and incorporation of osteoconductive calcium phosphate phases, such as hydroxyapatite (HA). Commercially pure Ti was treated in an electrolyte based on an aqueous solution of a sodium phosphate salt with additions of 0.02M...0.4M HA powder. The PEO treatments were carried out for 4 to 10 min in a pulsed bipolar current mode with both potentiostatic and galvanostatic controls. The coating thickness and surface morphology were examined by an eddy current thickness gauge and scanning electron microscopy (SEM) respectively. The elemental and phase compositions were studied by energy-dispersive X-ray analysis and X-ray diffraction respectively. Effects of the pulse frequency and the negative current component were discussed. It was found that in the studied range of process parameters, the processing time does not significantly influence the coating thickness; however, the introduction of the negative current component appears to improve the coating uniformity and the surface morphology which could be beneficial for osteoconductivity and cell anchorage.

Plasma electrolytic oxidation (PEO) is a relatively novel surface modification technique that provides excellent wear- and corrosion-resistant coatings on light-weight metals, in particular on aluminium. Formation of PEO coatings involves complex phenomena and mechanisms that are difficult to study. A method of in-situ impedance spectroscopy can be used to provide new insights into fundamental characteristics of PEO processes and coating formation mechanisms as well as to develop new means of the process control. This method is based on application of a variable frequency voltage perturbation signal to obtain impedance characteristics of the electrolyser during the PEO processing. The applied voltage signal and the current response are collected and post-processed to verify the system linearity, refine phase, reduce noise and spline the impedance spectra. The obtained spectra are then fitted with appropriate equivalent circuits to reveal mechanisms underlying the PEO process. Physical meaning of various circuit components is verified using specially designed experiments in which certain system characteristics are set up in such way to obtain controllable processing conditions, such as electric field distribution in the electrolyser, electrolyte resistance or coating thickness. The circuit analysis reveals specific RC and RL loops that can be related to individual processes associated with interfacial charge transfer and transport phenomena. Characteristic time constants corresponding to these processes are evaluated and their evolution with PEO treatment time is considered. Correlations of the process kinetics with phenomena observed during the PEO treatment of Al and coating growth characteristics are discussed.

Porous Structure Preparation and Wettability Control on Titanium-related Implant

T12 Surface Engineering

#SE/PST/TF/BI-2-Or-5

Z. Lin.

No.11, Lane 3, WenHua Road, HePing District - Shenyang (China).

Titanium (Ti) osseointegration is critical for the success of dental implants. Previous studies have shown that wettability controls are of great importance for their biomedical application. Only relatively recently have the effects of plasma oxidized surface on cell response been considered. The aim of the present study was to develop a simple and scalable surface modification treatment that introduces plasma oxidation method to the surfaces of Ti substrates without changing the original morphology of other surface features. The controlled micro/nano-structures surfaces of Ti substrates are achieved by using sandblast-acid etching (SLA) process. Then, titanium oxide surfaces are achieved on SLA surfaces by using plasma oxidation base on radio frequency plasma enhanced chemical vapor deposition (RF-PECVD) system, while retaining the starting SLA micro/nano-textures topography. The water contact angle (CA) of this surfaces increase and then decrease with the self-bias voltage. Superhydrophilic TiO₂ (anatase) surface can be achieved when the self-bias voltage is 360V. Such plasma oxidized surfaces showed crystal structure of anatase (101) orientation and possessed elemental compositions of TiO₂, Ti₂O₃ and TiO. MG63 cells were seeded on plasma oxidized Ti disks. The results suggested that the introduction of such plasma oxidized surfaces in combination with micro/nano-structures improves osteoblast attaching and spreading, which, in turn, indicates the potential for improved implant osseointegration in vivo.

Nowadays, textile industry represents an important place in the global economy. In fact the market share of textile will reach 120 billion Euros in 2012 [1]. Textile materials are used in many fields such as clothing, transport, packaging, building... Nevertheless, these materials are highly flammable and very often legislation requires low flammability for them. There are two ways to improve the fire performance of these materials: bulk modification and surface treatment [2]. The simplicity and versatility of Layer-by-Layer (LbL) technique (Figure 1) has led numerous scientists to use it as surface treatment technique. In this study, inspired by Li et al. work [3], (polyallylamine-polyphosphates) intumescent coatings were deposited, via LbL technique, in order to improve the reaction to fire of 0.5 mm thick polyamide fabrics. Thermogravimetric analysis (TGA) results indicate that the presence of such assembly catalyzes (for all coated samples) and changes (only for 10, 15 and 40 BL samples) the decomposition of virgin polyamide fabrics. The fire performance was evaluated by Pyrolysis Combustion Flow Calorimeter (PCFC). The fire results exhibit on the one hand a significant decrease of peak of heat release rate (pHRR) and on the other hand a shift to lower temperatures (catalytic effect) as function of the number of bilayers deposited (Figure 2). In this presentation, we will exhibit the growth, morphology, thermal stability and fire performance of this intumescent coating.

Data validation for impedance spectroscopy studies of discharge phenomena during plasma electrolytic oxidation of Al

T12 Surface Engineering

#SE/TF-2-Or-5

A. Yerokhin ¹, E. Parfenov ², C. Liang ¹, A. Matthews ¹.

¹University of Sheffield - Sheffield (United kingdom), ²Ufa State Aviation Technical University - Ufa (Russian federation).

Discharge phenomena that occur at the metal anode / electrolyte interface during Plasma Electrolytic Oxidation (PEO) of light alloys play important role in the formation of oxide ceramic surface layers with superior protective and useful functional properties. The mechanisms governing discharge behaviour are not well understood and the major research effort is currently directed towards filling in this knowledge-gap. High speed imaging, optical emission spectroscopy and current probe studies of discharge events have been carried out but so far failed to bring about a suitable model of the process. Impedance spectroscopy could provide be a powerful tool for the development of such a model if the problems of system linearisation and time-variance for the PEO process were solved. In this this work we employed fast (0.5s) frequency sweeps of a pulsed voltage signal which approximates an implied single-sine perturbation to obtain its current response and evaluate instantaneous impedance of the PEO process on Al. We developed an original frequency domain method which utilises linear dependency between the spectrum estimates of voltage and current to evaluate the system linearity. We found that non-linear distortions provide minor contribution to the impedance if the process parameters are carefully selected to ensure that (i) the pulsed voltage waveform provides a good approximation of the implied sine wave; (ii) the pulsed PEO voltammogram is adequately approximated by a linear regression and (iii) discrete voltage and current values are well above the vertical bin size of the probes used. For these process parameters, the noise and nonlinearity distortions do not exceed 15%, indicating that the studied PEO system can be considered as a properly linearised object. This validates the obtained impedance data and justifies the application of *in-situ* impedance spectroscopy approach for modelling the PEO process.

On the Effect of Cold Plasma Sterilization on the Surface Properties of Implantable Biomaterials

T12 Surface Engineering

#SE/PST/TF/BI-P1-03

M. Boudifa, F. Lebel, M.P. Gellé, S. Gangloff.

CRITT-MDTS - Charleville-Mézières (France).

Many studies have demonstrated the effectiveness of plasma on microorganism's inactivation with the application of different gas mixtures to various bacteria suspensions.

In a previous work [1], we have shown the efficiency of our innovative low pressure cold plasma sterilization process (Figure 1). Particularly, a specific method has been developed, where the plasmagene elements are only generated in the sterilization pouch. Consequently, the sterile state of the medical device is kept, and makes it ready to use subsequently or in a certain period of time without any additional precautions.

Depending on sterilization process, the surface properties of implant materials can be impacted [2]. Whereas the bacteria inactivation by cold plasma have been well demonstrated, studies about the sterilization effects on their material properties are less well documented, especially, for the plasma sterilization emerging techniques [3].

In this work, the effects cold plasma sterilization on surface characteristics has been studied. The influence of cold plasma treatment on the surface properties of two different materials widely used for prosthetic implant manufacturing was investigated. Ultra High Molecular Weight PolyEthylene (UHMWPE) polymer and TiAl6V4 metallic biomaterials have been subjected to plasma sterilization. Then surface chemical components, hydrophilicity, roughness topology, and morphology have been assessed by mean of X-ray photoelectron spectroscopy (XPS), contact angle measurements, and scanning electron, respectively. The influence of the sterilization pouch has been discussed for samples submitted to the cold plasma sterilization with and without packaging pouch. Thence, the content-containing interactions due to packaging could be taken into account. Preliminary conclusions have been drawn regarding the sterilized biomaterial surfaces.

Influence of the electrolyte composition on the oxide layers grown on Mg alloy by the plasma electrolytic oxidation process

T12 Surface Engineering

#SE/TF-2-Or-3

I. Shchedrina, G. Henrion, J. Martin, D. Veys-Renaux, T. Czerwiec, T. Belmonte.

Institut Jean Lamour - Nancy (France).

Nowadays parts made of magnesium alloys find a wide range of applications in many industrial areas such as transportation or building for example. However because of relatively low corrosion resistance of magnesium alloys in neutral and acid environments, in most of inorganic environments and in the ambient conditions it is necessary to protect it, for example by applying protective coatings on its surface.

Microarc oxidation or plasma electrolytic oxidation (PEO) is a promising process that may advantageously replace conventional anodizing that does no longer comply with the international rules regarding environmental aspects.

Besides the high mechanical and chemical properties (hardness, wear and corrosion resistance, thermal and electrical protection) of oxide layers achieved by PEO, this process has also advantages of requiring single step operation and being environmentally friendly.

However, the PEO coatings generally become protective when their thickness reaches some tens of micrometers, typically greater than 40 μm .

Our work aims at achieving thin ($< 15\text{-}20 \mu\text{m}$) PEO layers on Mg alloy, which would decrease the processing time – and consequently reduce energy consumption – and change the dimensions of the processed parts within acceptable range.

For this purpose, we study the influence of the electrolyte composition on the coating

characteristics.

It can be noted that the addition of potassium fluoride in the electrolyte helps to obtain more coatings with a higher corrosion resistance and with a negligible edge effect – non homogeneity in the layer thickness over the sample surface, with a strong negative gradient from the edge to the centre of the samples. This is due to the strong variation of the electric field in the vicinity of sample edges (edge effect) which results in a much higher number of micro-discharges occurring at these border locations as was shown by high speed video recording of the micro-discharges.

However SEM analyses performed on layer cross sections reveal a high porosity of the layer in all the cases but the addition of sodium silicate helps to achieve less porous coatings in comparison with the others. That also increases the corrosion resistance of the alloy.

Chromogenic multifunctional coatings of hybrid polymeric/TiO₂ by sol-gel

T12 Surface Engineering

#SE/TF-3-Or-4

J. Perez Bueno, L.M. Flores Tandy, Y. Meas Vong.

CIDETEQ - Queretaro (Mexico).

Chromogenic materials have been extensively studied and applied in a variety of fields. There are purely organic, hybrid organic-inorganic, doped inorganics and semiconductors. However, the necessity of chromogenic materials based on compounds of transition metals, for their properties and low costs, makes them a constant interest in materials research. In this work, hybrid and composite organic-inorganic materials based on polyester polymers and titanium hydroxide species had been prepared by sol-gel process. The conjunction of an organic polymeric matrix and hydrolyzed and condensed titanium species resulted in multiple chromogenic materials.

FT-IR, UV-Vis, EPR spectroscopic results show formation of hydrogen bonds between titanium hydroxide and polyester species (Figure 1), $n-\pi^*$ $\pi-\pi^*$ reversible transitions after light excitation (Figure 2), and formation of permanent complexes after thermal treatments of titanium oxide species into polar solvents [1].

Anticorrosive, antiabrasive, hydrophilic and coloration properties of hybrid coatings were also investigated through electrochemical impedance spectroscopy (EIS), salt spray test, Taber test, scanning electron microscopy (SEM) and contact angle measurements. The results of hybrid coatings show good anticorrosive properties at low sol-gel titania concentrations and high boiling point polymer solvents. High abrasion resistance when reinforced with alumina and zirconia particles, highly hydrophilic coatings when combined with aluminum hydroxide sol-gel particles, high velocity of coloration and low velocity of discoloration at UV and solar light exposition.

¹CRP Gabriel Lippmann - Belvaux (Luxembourg), ²Ceratizit Luxemburg S.à.r.l. - Mamer (Luxembourg), ³Department of Physical Metallurgy and Materials Testing, Montanuniversität Leoben - Leoben (Austria), ⁴4MAT, Université Libre de Bruxelles - Bruxelles (Belgium).

Hard nanostructured TiAlN coatings have gained high importance in the field of wear and oxidation resistant coatings. Nevertheless, their use regarding high temperature (>700°C) applications such as dry high speed machining remains a challenging issue. Additional alloying element such as Ta has shown a beneficial impact on those properties [1]. But for better performance of these coatings in such conditions, an in-depth understanding of their oxidation and wear mechanisms over a wider range of temperature is needed which is currently unavailable in literature. This work investigates the wear and oxidation properties of $Al_{0.48}Ti_{0.40}Ta_{0.12}N$ hard coating deposited with a reactive magnetron sputtered at substrate temperature of 250°C. A target with chemical composition $Al_{46}Ti_{42}Ta_{12}$ placed at an angle of 45° with respect to substrate holder was used. The as deposited coatings show a preferential crystallographic orientation of cubic {111} using θ -2 θ X-ray diffraction measurements (XRD) with a columnar microstructure. The oxidation kinetics and mechanisms for these coatings were investigated between 700°C and 950°C in air for various durations (1minute - 15 hours). Transmission electron microscopy investigations show retention of the columnar microstructure for the coating after oxidation. For all temperatures and all durations studied, the original nitride layer could be observed after oxidation with a top oxide layer (maximum thickness ~ 800 nm). An oxidation mechanism switch was observed when the temperature was increased from 700°C to 950°C. By combining dynamic secondary ion mass spectrometry and XRD

measurements, it is possible to show that a single amorphous oxide layer comprising of Ti, Al and Ta oxides formed at 700°C become a bilayer comprising of crystalline Al rich layer (protective Al₂O₃) and Ti/Ta rich oxide layer at 900°C as shown in **fig. 1**. The oxidation mechanism was governed primarily by inward diffusion of O at 700°C while from 800°C onwards outer diffusion of Al and inner diffusion of O controlled the reaction rate.

The wear behaviour was studied by performing wear tests on the coatings deposited on WC substrates at 700°C, 800°C and 900°C. Finally, a correlation was established between the wear behaviour and the oxidation behaviour of the coating at these temperatures.

ENHANCED PERFORMANCE OF CERMET COATINGS FOR HIGH TEMPERATURE OXIDATION AND WEAR RESISTANCE DEPOSITED BY FLAME SPRAY TECHNIQUE

T12 Surface Engineering

#SE/TF-P2-14

I. Cervera, K. Razzaq, J. Saura, M. Damra.

University Jaume I - Castellón (Spain).

NiCrAlY alloys are a family of thermal spray coating materials that are known for their excellent resistance to oxidation and hot corrosion. In this paper a new composition coating has been developed, based on an optimized composition of NiCrAlY/Al₂O₃ cermet.

Both high temperature oxidation and wear resistance were evaluated using a thermobalance and pin-on-disk test. The coatings were applied using an oxifuel gun over a plain carbon steel and studied at three different temperatures.

Oxidation resistance was greatly improved in all the working conditions and so did the wear behaviour of the coatings. A goal of the studied composition is the absence of coupling layers, widely used to avoid thermal mismatches between the substrate and the ceramic layers.

The cermet layers have been examined by a wide range of experimental techniques including SEM, EDS and XRD before and after oxidation process and also a mechanical characterization has been done.

HIPIMS Process for Sputtering Cu Seed Layer in High Aspect Ratio Via and Trench.

T12 Surface Engineering

#SE-1-Or-5

R. Chistyakov, B. Abraham.

Zpulsar LLC - Mansfield (United states).

HIPIMS/HPPMS technology was developed in early 1990s. One of the important features of this technology is the ability to generate IMP (ionized metal plasma). The important applications of HIPIMS/HPPMS could be directional sputtering processes to deposit Cu seed layers into high aspect ratio features (trenches, vias and etc.) for Cu metallization in integrated circuit fabrication process. The experiments were performed with Zpulsar Cyprium™ HIPIMS/HPPMS plasma generator that can generate oscillatory voltage pulse shapes (oscillations frequency is about 20-60 kHz) and deliver up to 2-3 MW during the oscillation. It was found that substrate ion current is a function of voltage oscillations frequency in the pulse. The substrates during all these experiments either had floating potential or were connected to the substrate bias power supply. RF power supply was used as a substrate bias power supply. The RF bias is an important feature for the directional sputtering process for nonconductive substrates. The experimental data about field, side and bottom coverage for Cu and Ta for high aspect ratio trenches and vias will be presented.

The formation of ice on surfaces can lead to several technical problems, e. g. energy losses. An example is ice formation on the wings of wind energy generators, which leads to imbalance and a worse degree of efficiency. For the improvement of energy efficiency surfaces are being developed, that show an improved removal of ice (De-Icing) or can reduce the formation of it (Anti-Icing).

Starting point is the creation of hydrophobic surfaces by plasma coating (PECVD = plasma enhanced chemical vapor deposition). Therefore fluorocarbon or silicone-like films are deposited onto PU-sheets. These surfaces can be further hydrophobied through structuring in the scale of micrometers, which generates so-called superhydrophobic surfaces. With regard to an industrial roll-to-roll process the focus is set to hot stamping of PU sheets.

Analysis of the surface chemistry of the thin films is done by XPS (X-ray photoelectron spectroscopy), the microstructures are examined by digital 3D light microscopy (IGVP) and white light interferometry (HTW Aalen, MPI Stuttgart). The wetting analysis is done by contact angle measurements with water. The contact angle measurements clearly show the water repellency of the plasma coatings (advancing CA = ca. 120°), the hydrophobicity could be further improved by microstructuring (advancing CA = ca. 150°). For determination of the ice adhesion force water droplets are frozen on the produced surfaces in a freezing chamber and the force for removal is then measured by pulling tests. So far the measurement results only show a limited reproducibility.

For reproducible measurement values a new freezing chamber with a more homogeneous temperature distribution is planned. In addition to that it shall be possible to create so-called supercooled large droplets in this chamber, which can lead to ice formation in aviation. Up to date this is not possible with the current freezing chamber. The effects of the impact of these supercooled fluid droplets on the produced surfaces shall be captured optically. First simulations for identifying the proper chamber size and cooling power were done with the software COMSOL Multiphysics.

The effects of hydrophobic coatings and microstructures on ice adhesion have not been fully understood yet. Some simulations on this topic were performed at the Bremen Center for Computational Materials Science (BCCMS) at the University of Bremen, Germany. Complementary simulations of the heat transfer of a water droplet, which is freezing on flat and microstructured surfaces, are planned.

Film deposition from the plasma phase: Origin, management, and use of ion energies

T12 Surface Engineering

#SE-1-In-1

A. Anders.

Lawrence Berkeley National Laboratory - Berkeley (United states).

A scientifically and technologically interesting variant of physical vapor deposition is the deposition from the plasma phase. Instead of depositing films from neutral atoms, film-forming ions are used. They bring very significant kinetic and potential energies to the film growth process, which can be beneficial, for example when films with smooth morphologies are desired. The issue of optimum energy is not trivial because, in a number of cases, excessive ion energy may cause "ion damage," i.e. various forms of defects, high compressive stress, possibly followed by delamination. In this contribution, a brief overview is given on the history and variety of deposition from the plasma phase, which can be traced back to the 18th century. Modern forms include ion plating, cathodic arc deposition, pulsed laser deposition, sputtering combined with radio-frequency ionization, hollow-cathode gas-flow sputter deposition, and deposition by high power impulse magnetron sputtering. The different origins of ion energies are considered, with options to control and manage those energies for the greatest benefit of applications.

A significant enhancement of selective surface reaction kinetics in the nanostructured surface layer in iron has been observed after Surface Mechanical Attrition Treatment (SMAT) with significant improvement of mechanical properties (e.g., see our report in Science 299: 686-688, Jan 31, 2003). By combining SMAT and diffusion based treatments, we have created a new category of interface free nanomaterials with a gradient structure of nano-to-micro sized grains, which resulted in remarkable wear, corrosion, mechanical properties, such as high yield strength and good ductility. We also developed SMAT to obtain high strength and high ductility metallic glasses using and developed new methodologies of investigation of mechanical behaviors of ultrahigh strength materials as a function of atomic structural (e.g. see our report in Nature Materials, 619-623, Aug. 2010). We demonstrated that the relationship between the grain boundary and twin boundary for contributing to the strength and the ductility of nanotwinned materials and obtained outstanding high strength and high ductility nanotwinned materials using SMAT. New materials and structures with atomic, nano-, micro- and macro-scale functional gradients for generating different toughening mechanisms using the non-localization approach are developed. The application in biomedical implants, advanced energy systems and light weight transportation systems will be presented.

SE/TF-3-In-1 NANOSTRUCTURED PROTECTIVE COATING SYSTEMS FOR AEROSPACE APPLICATIONS: FROM MATERIALS ARCHITECTURE TO COATING REMOVAL

T12 Surface Engineering

#SE/TF-3-In-1

J. Klemberg-Sapieha.

Department of Engineering Physics and Thin Film Research Center, École Polytechnique de Montreal - Montréal (Canada).

Material damage caused by solid particle erosion remains a crucial problem in aeronautical engines. Good understanding of materials deterioration allows one to develop appropriate strategies to protect technologically relevant metal substrate materials. Advanced erosion-resistant coatings, ERC, call for an “ideal” combination of the mechanical elasto-plastic, tribological, corrosion, thermal and other characteristics that can only be satisfied by using specifically tailored coating architectures considering nanocomposite, nanolaminate, multilayer and graded layer systems.

In our presentation, we demonstrate that finite element modeling of the coating architecture, combined with the tailored mechanical properties of individual materials of the coating systems including appropriate stress management, opens new opportunities as a predictive tool for high performance of the ERCs. We introduce and discuss the selection rules describing the overall film behavior with respect to their microstructure and their basic elasto-plastic properties. Finally, we describe the processes and approaches suitable for the coating removal and subsequent repair.

The ability to strongly attach biomolecules to surfaces whilst retaining their biological activity underpins a host of biotechnologies, such as biosensors and diagnostic microarrays for early disease detection. Recent work has revealed that radicals embedded in nanoscale carbon rich surface layers by energetic ion bombardment can covalently immobilize bioactive proteins [Proc. Nat. Acad. Sci 108(35) pp.14405-14410 (2011)]. This new approach delivers the strength and stability of covalent coupling without the need for chemical linker molecules and multi-step wet chemistry. Immobilization occurs in a single step directly from solution and the hydrophilic nature of the surface ensures that the bioactive 3D shapes of the protein molecules are minimally disturbed.

Such energetic ion treatments can be applied to any underlying material making it possible to achieve covalent biomolecule immobilization whilst maintaining the physical properties (including mechanical and electrical) of an underlying material. This opens up the possibility of new applications such as integrated microelectronic or photonic biosensing devices, continuous flow reactors for enzymatic chemical, textile, food or biofuels processing. Implantable biomaterials that interact with their host via an interfacial layer of active biomolecules to direct a desired cellular response to the implant and inhibit undesirable responses are also on the horizon.

This presentation will describe the plasma-based approaches for creating buried radicals through energetic ion impacts that we have developed. A kinetic theory model of the biomolecule immobilization process via reactions with long-lived, mobile, surface-embedded radicals and supporting experimental data will be presented. The roles of surface chemistry and microstructure of the treated layer in simultaneously preventing radical annihilation whilst allowing sufficient radical mobility will be discussed. Preliminary applications of this technology to direct cell growth, create biosensors and diagnostic arrays, and to engineer bioactive surfaces for implantable biomedical devices will be reviewed.

Atomistic zone-resolved photoelectron spectroscopy (ZPS)

T13 Surface Science

#SS-8-Or-1

C. Sun.

NTU - Singapore (Singapore).

Interatomic bonding and non-bonding and the associated charge distribution dictate the performance of materials. However, correlation, clarification, formulation, and quantification of them remain challenge. Recent progress on the framework of the BOLS-TB theory[1] and the zone-selective photoelectron spectroscopic (ZPS) technology [2] have enabled new knowledge on: i) Pt and Rh adatoms [3], W, Re, and Rh terrace edges, graphite skin and surface vacancies[4]; ii) fcc(Pd, Rh, Pt, Ag), bcc(W, Fe), hcp(Be, Ru, Re, Ti) and Si surfaces; iii) Ag, Ni, Pt, Cu, Au, Pd nanoclusters as a function of size; and, iv) Ag/Pd, Cu/Pd, and Be/W interfaces[5]. Exercises have led to quantitative information of the local bond length, bond energy, binding energy density, atomic cohesive energy, energy levels of an isolated atom and their bulk shifts. We clarified that: i) perturbation to the Hamiltonian by the mis-coordination-induced bond relaxation, the hetero-coordination-induced bond nature alteration, and the polarization of the nonbonding electrons dictates intrinsically the binding energy shift; ii) the local densification and quantum entrapment results in the globally positive core level shift, of which the extent is proportional to the bond energy change; and iii) the polarization of the nonbonding states by the densely-entrapped bonding electrons screens and splits the crystal potential and hence shifts the binding energy negatively. Most strikingly, it has been uncovered that: i) Pt adatoms and CuPd alloy serve as acceptor-type catalysts because of the dominance of entrapment while Rh adatoms and AgPd alloy as donor-type catalysts due to polarization; ii) the graphitic Dirac-Fermi polarons result from the isolation and polarization of the dangling bond electrons by the densely-entrapped local bonding electrons at the graphite surface defects and the graphene zigzag edges. Findings not only demonstrate the power of the BOLS-TB-ZPS approaches in complementing

STM/S and PES but also the essentiality of the perspective of bond and non-bond formation, dissociation, vibration and relaxation and the associated dynamics and energetics of charge repopulation, polarization, densification and localization in engineering bonds and electrons towards devising functional materials at will.

STM/STS investigation of Ni-Nb bulk metallic glasses surface near in vicinity of phase transition

T13 Surface Science

#SS-2-Or-1

V. Mantsevich ¹, A. Oreshkin ¹, S. Savinov ¹, S. Oreshkin ¹, V. Panov ¹, N. Maslova ¹, D. Louzguine-Luzgin ².

¹Moscow State University - Moscow (Russian federation), ²Tohoku University - Sendai (Japan).

We investigated the structural evolution and crystallization behavior of the Ni-based bulk metallic glass (Ni₆₃:₅Nb₃₆:₅) by means of STM/STS technique. The possibility of different surface nanostructures formation in vicinity of phase transition temperature is shown. We demonstrated that atomic locations in these surface nanostructures differs completely from those formed according to Ni-Nb binary phase diagram in the sample bulk area [1].

The obtained clean amorphous surface (samples were heated at 673K) demonstrates the granular structure consisting of many isolated clusters with an average diameter about 5nm. The normalized tunneling conductivity (TC) reveals the energy pseudogap in the vicinity of Fermi level. For energy values above 0.1eV the normalized TC changes linearly with the increasing of applied bias. This results can be understood within suggested theoretical model based on the interplay between electron scattering on random defects and weak intra-cluster Coulomb interaction [2]. The surface crystallization starts to appear when Ni₆₃:₅Nb₃₆:₅ metallic glass surface was previously annealed at slightly increased temperature (883K), which is still lower than the crystallization temperature. This phenomenon can be connected with surface-induced crystallization. The primary crystallization starts to appear at lower temperatures than eutectic one during step by step metallic glasses heating.

According to Ni-Nb binary phase diagram, two phases should coexist in metallic glass Ni₆₃:₅Nb₃₆:₅ after excess of the crystallization temperature (930K), namely Ni₃Nb and Ni₆Nb₇.

The constant current STM image of the sample annealed at 973K demonstrates a nanostructured eutectic. The analysis of the surface facets structure reveals the presence of three different surface reconstructions: hexagonal, rectangular, and

zigzag. In our opinion, the origin of the hexagonal structure takes place from Ni₆Nb₇ bulk phase, which is a tetrahedral close-packed structure. This is due to the fact that second possible phase is Ni₃Nb which has orthorhombic structure and it is scarcely probable that this kind of structure or its reconstructions can be transformed to new close-packed structure. Rectangular structure most probably corresponds to orthorhombic Ni₃Nb surface reconstruction.

We also obtained the normalized tunneling conductivity spectra above amorphous surface and all three structures. We revealed that the position of peaks in the normalized tunneling conductivity curve does not depend on the local point in the range of chosen structure. Consequently, the I(V) spectra contain a mesoscopic information defined by neighborhood environment, chemical bonding, and domain boundaries. Basically we revealed that, two spectrum corresponding to the rectangular and zigzag structures are very similar. Therefore, we suggest that the rectangular and zigzag structures observed in our STM/STS experiments are two possible surface reconstructions of one Ni₃Nb phase.

To conclude the obtained results shed a light on the growth of the eutectic structure with nanoscale faceted.

Surfaces that are vicinal to high symmetry directions have frequently demonstrated their enormous potential for surface science research and applications. Vicinal surfaces exhibit distinct chemical and physical properties due to the high density of atomic steps, but they are also useful as templates for nanostructure growth, and, more generally, to transmit uniaxial and/or chiral symmetry to epitaxial layers. Moreover, vicinal planes may respond better than high-symmetry surfaces during thin-film growth, e.g., by eliminating azimuthal domains, and hence dislocation boundaries, or by enabling defect-free layer-by-layer growth through “step-flow”.

A curved substrate is an obvious alternative for a fast, thorough surface analysis, i.e., for a rational optimization of physical-chemical and growth properties that are sensitive to atomic steps. Despite the clear advantage of having a tunable surface orientation at hand, the curved crystal approach has barely been used. The reason is mainly the difficulty to fabricate a customized curved surface with high precision, but also the inconveniences that a curved sample imposes, due to its inherent complexity, to surface preparation, data taking, or data analysis. However, the recent evolution of analytical surface science techniques toward laterally-resolved, scan probes at different length scale has brought the curved surface back to the scene in Surface Science.

In the past few years we have used Ag(111), Cu(111) and Au(111) curved noble metal surfaces to test the possibilities of the curved crystal approach to investigate new surface science phenomena[1,2]. In particular, I will discuss with several examples the possibility of tuning the interplay of surface properties, such as electronic, structural and growth phenomena, at critical crystallographic orientations. I

will also show the new ideas that our group is currently exploring around this approach, among them, the use of Ni and Pt curved crystals to tune the growth of graphene.

Inelastic tunneling spectroscopy for magnetic atoms.

T13 Surface Science

#SS-17-Or-2

E. Goldberg ¹, F. Flores ².

¹INTEC-CONICET-UNL - Santa Fe (Argentina), ²Universidad Autonoma de Madrid - Madrid (Spain).

Inelastic tunneling spectroscopy of single magnetic atoms [1-3] and single molecule magnets [4-5] has been recently used to explore the strength, and its anisotropies, of their intrinsic spin. In the single magnetic atom case, Fe or Co have been deposited on a CuN surface, so that the electrons injected with a STM-tip across a single atom interact with the magnetic spin creating spin-flip processes that reveal themselves in the tip-metal tunneling conductance measured as a function of the bias voltage. In this work we address that problem by introducing an ionic Hamiltonian [6] for describing the d-electrons of the magnetic atom, and analyze the tunneling current for a metal/atom/tip configuration using a Green-function Equation of Motion method [7-8]. We analyze in the case of Fe on CuN the possible spin fluctuations between states with $S=2$ and $S=3/2$ or $5/2$ and conclude, from the found asymmetries and marked structures in the conductance, that the $S=2$ to $S=3/2$ fluctuations are dominant and provide a good description of the experimental data. The case of Co is also considered and shown to present, in contrast with Fe, a resonance at the Fermi energy corresponding to a Kondo temperature of 6K. The strong dependence of the spin excitations on magnetic field direction observed experimentally is also well reproduced by our calculations.

The growth of aluminum fluoride (AlF₃) on copper single crystal, Cu(100) face, is characterized by several anomalous features. Among them, we have a large diffusion path length at room temperature, nucleation at both sides of steps and island atomistic arrangement along special directions [1, 2]. In this work we introduce a new diffusion model based only on kinematic properties that allows us to explain all the particular properties of this system. The model is based in the rearrangement of a bi-molecules (Al₂F₆) trying to resemble its vacuum behavior. This rearrangement breaks the expected random trajectories of a molecule diffusing over a surface, privileging not only one diffusion direction but also its sense of movement. Additionally, the contact surface is minimized increasing the surface diffusivity. The model is supported by two different calculations, i.e. Monte Carlo simulations based on empirical potentials [3] and Density Functional Theory (DFT) calculations. In the figure we depict the different structures obtained from DFT as well as their corresponding energies. The structure corresponding to the minimum energy is the responsible of the breaking of the random pathway, as well as of the particular features of the AlF₃ growing system.

SS-P3-22

On the origin of Si(110) 16 x 2 single domain surface formation

T13 Surface Science

#SS-P3-22

T. Ichikawa, H. Tamaki, K. Gomiwa.

Meiji University - Kawasaki (Japan).

When Si(110) surfaces are atomically cleaned by flashing at about 1230 degree C and then annealed at high temperatures, surface reconstruction takes place and 16 x 2 structure forms on the surfaces. Owing to the mirror symmetry of Si(110) 1 x 1 surface, most of the reconstructed surfaces consist of two equivalent domains with the same 16 x 2 structure. However when rectangular strips are cut from Si(110) wafers as specimens whose longer side is oriented in $[1 \ -1 \ 2]$ or $[-1 \ 1 \ 2]$ direction are flashed and annealed at appropriate temperatures by passing DC current along the longer side, the surfaces are covered with either of the two domains [1]. Such surfaces are named single domain surfaces. Yamada et al. concluded from LEED and STM observations that electromigration during annealing was responsible for the single domain formation [1].

It has generally been accepted that surface stress plays an important role on the formation of surface structure and domain growth. When resistive heating by passing DC current in strip specimens is carried out, both the ends of the specimens are fixed on electrodes, e. g. by using tantalum plate springs. The fixing introduces a compressible surface stress on annealing, though its magnitude depends on details of the fixing. So we have an idea that the surface stress may induce the appearance of the single domain surface rather than the electromigration.

In order to substantiate the idea, we cut rectangular specimens whose longer side was oriented in $[1 \ -1 \ 2]$ or $[-1 \ 1 \ 2]$ direction. And we placed the specimens on a ceramics heater and annealed the specimens not to pass DC current by using the ceramics heater, fixing both the end. This annealing surely induced the single domain surface as well as the passing of DC current did. Next we laid the same Si(110) specimens across two electrodes and annealed by passing DC current along the longer side, without fixing both the ends. This annealing always grew surfaces composed of the two domains as expected. Therefore it will be reasonable from these evidences to conclude that the appearance of the single domain surface is due to surface stress rather than to electromigration.

The Si(110) 16 x 2 structure has a very complicated atomic geometry. Its major

structural features are (1) periodic up-and-down terraces extending in the $[1 -1 2]$ or $[-1 1 2]$ direction and (2) pairs of pentagons regularly arranged on the terraces [2]. It is worthwhile to note that the direction of the terraces coincides with the direction of the compressible surface stress. We suppose that a compressible surface stress is present along the terrace in the 16×2 structure and hence the compressible surface stress on annealing is in favor of the single domain growth.

A further step to understand the effect of the surface stress is to estimate quantitatively the magnitude of the surface stress necessary to grow the single domain surface. Therefore we are now constructing a new measuring apparatus. We will present some results, though preliminary, at the coming conference.

Ab initio Modeling of the Hydrogen Adsorption on Pt(111) Surface

T13 Surface Science

#SS-1-Or-1

H. Tran, T. Yoshinari, S. Osamu.

The Institute for Solid State Physics, the University of Tokyo - Kashiwa (Japan).

The hydrogen adsorption on the Pt(111) electrode surface has been intensively investigated. To gain insight into detailed atomistic picture on the equilibrium coverage and structure, we have constructed a lattice gas model by determining the on-site energy and the interaction parameters using the first principles total-energy calculation. Therein atop, fcc, hcp and bridge sites are covered by hydrogen atoms under various coverage conditions ($0\text{ML} < \Theta \leq 1\text{ML}$) and the total-energy calculations are done for the (1x1), (2x2) and (3x3) cells. The total-energies of (3x3) cell, corrected by the zero-point energy (ZPE), are found well fitted to the lattice gas model. With this model, the Monte Carlo (MC) simulation has been performed. The first-principles calculation combined with MC simulation successfully explains the interaction of H atoms on the Pt(111) surface. The active site of the hydrogen adsorption on the Pt(111) surface, which has been hitherto conceptually discussed but has not been shown by an atomistic simulation, has been identified.

Precise control of the Si/SiO₂ interface is crucial because of its important role in semiconductor devices. However at high temperature SiO₂+Si(substrate) → 2 SiO(g) reaction is a dominant process. We examine the interfacial reaction between Si and SiO₂ during high temperature annealing. For this purpose we study the thermal decomposition of SiO₂ thin film covering a crystalline silicon substrate and the interfacial reaction between Si nanoislands on a SiO₂ substrate. We use Low Energy Electron Microscope (LEEM) to follow in-situ the void-opening characteristic of the SiO₂ thermal decomposition mechanism due to the reaction SiO₂+Si(substrate) → 2 SiO(g). We establish experimental scaling laws of the void-growth versus time under different experimental conditions. The LEEM data are completed by in-situ Atomic Force Microscopy (AFM) and/or Scanning Tunneling Microscopy (STM) measurements to control the front profile, the oxide thickness as well as the roughness of the resulting deoxidized Si surface. We also use LEEM to show that Si islands on SiO₂, when annealed at very high temperatures, react on the SiO₂ substrate. The reaction Si(3D) + SiO₂(substrate) → 2 SiO(g) is accompanied by a motion of the Si islands from which results a deep depression in the SiO₂ substrate due to the consumption of the SiO₂ substrate. Following the centre of mass of each nanoparticle we put in evidence that the island motion in the small timescale limit is random whereas at late time nanoparticles get trapped inside the hole formed in the SiO₂ substrate induced by the chemical reaction. A complementary Atomic Force Microscopy study of the profile of the depleted zones give information on the chemical process at work (chemical rate, width of the reactive zone...).

From these kinetics studies, effective diffusion coefficient and activation energy barriers are extracted. Experimental results are supplemented by Kinetic Monte Carlo simulations based on a Solid-On-Solid model including surface diffusion processes and chemical reaction kinetics. The two main ingredients used in simulations are the chemical reaction rate at the interface followed by the gas diffusion towards the triple line (where the SiO gas is expelled). All the results show that the chemical reaction essentially takes place at the triple line.

SS-3-Or-2

Driving Force of Phase Transition in Indium Nanowires on Si(111)

T13 Surface Science

#SS-3-Or-2

J. Cho, H.J. Kim.

Hanyang University - Seoul (Korea, republic of).

The precise driving force of the phase transition in indium nanowires on Si(111) has been controversial whether it is driven by a Peierls instability or by a simple energy lowering due to a periodic lattice distortion. Unlike local and semi-local density-functional theories, the present van der Waals (vdW) corrected hybrid density functional calculation predicts that the low-temperature 8×2 structure whose building blocks are indium hexagons is energetically favored over the room-temperature 4×1 structure. We show that the correction of self-interaction error and the inclusion of vdW interactions play crucial roles in describing the covalent bonding, band-gap opening, and energetics of hexagon structures. The results manifest that the formation of hexagons occurs by a simple energy lowering due to the lattice distortion, not by a charge density wave formation arising from Fermi surface nesting.

Medium energy ion scattering investigation of Pt, Pd and Rh deposited onto Cu(110)

T13 Surface Science

#SS-16-Or-1

M. Cropper, T. Fleming.

Loughborough University - Loughborough (United Kingdom).

Medium energy ion scattering (MEIS) has been used to investigate the deposition of platinum, palladium and rhodium onto the Cu(110) surface. Sub-monolayer quantities were deposited onto the surface near room temperature using a miniature e-beam evaporation source. The structure of these films was investigated in several shadowing and blocking directions, both as-deposited and following subsequent low-temperature annealing.

MEIS is a real space technique with a high degree of sensitivity to surface structure and composition. The experiments were carried out at the UK National MEIS facility using 100 keV H⁺ ions. The films were prepared in an ultra-high vacuum preparation system and transferred under vacuum to the scattering chamber. The ions were aligned parallel to incidence directions giving illumination of one, two and three surface layers; the [-10-1], [-100] and [-2-1-1] directions. Scattered ions were collected across a range of angles that included outgoing blocking dips.

The MEIS data can be presented as energy profiles that give depth profile information and blocking curves that enable the determination of structure. The blocking curves from the two elements present can be separated due to the difference in mass giving different recoil properties. For all three deposited metals the presence of dips in the one-layer blocking curve shows that the deposited metal has occupation of the second layer, indicating either island formation, or of incorporation of the ad-atom into the close packed surface rows followed by decoration by mobile copper atoms from step edges. Quantitative analysis has been carried out by comparison with simulations made by the Monte-Carlo code VEGAS. The relative occupation of different layers has been investigated using reliability factors. For

platinum deposition, the ad-atoms mostly occupy the second layer with a spacing of 123 ± 4 pm.

On reliability of calculated energies and measured enthalpies of interfacial segregation

T13 Surface Science

#SS-2-Or-2

P. Lejcek ¹, M. Sob ², V. Vitek ³, V. Paidar ¹.

¹Institute of Physics, Academy of Sciences of the Czech Republic - Prague (Czech republic), ²Central European Institute of Technology, CEITEC MU, Masaryk University - Brno (Czech republic), ³University of Pennsylvania - Philadelphia (United states).

A very important problem discussed and analyzed extensively for many years until present is the effect of solute segregation on interfacial properties, above all cohesion. Following widespread experimental studies, in particular for grain boundaries (e.g. [1,2]), segregation energies of solutes at interfaces have been calculated in recent years using the density functional theory (DFT). A number of such calculations were published (e.g. [3,4]), which may open new horizons since they can provide not only information on bond strength at grain boundaries as affected by the presence of solutes but also detailed insight into the local charge distribution. Consequently, they can contribute to our understanding of the nature of interfacial cohesion on a qualitatively new level. Unfortunately, when evaluating the energy of segregation an acute problem arises in the case of solutes with low solubility.

Here we demonstrate that the present-day DFT-based calculations of segregation energies are limited to systems with a high solid solubility, provided they employ repeat cells containing about 100 atoms. However, these problems have not been considered in the majority of calculations of segregation energies. Consequently, interfacial segregation energies calculated for systems with low solid solubilities are often dubious. This includes P, C, S and B in α -iron, all of which affect the grain boundary cohesion very significantly and play a major role in steels. On the other hand, even when using repeat cells that are not sufficient for reliable evaluation of the segregation energy the change in the grain boundary cohesion may be inferred with a reasonable accuracy from such calculations [5].

Spin-polarized two-electron spectroscopy, (e,2e) [1], and spin-polarized electron energy loss spectroscopy (SPEELS) provide valuable information on the spin-dependent electronic structure of surfaces and thin films. We applied these spectroscopies to study clean and oxygen covered W(110) surfaces as well as ultrathin layers of Ni, Co, Fe, Au, Ag and bi-layer structures on W(110). Examples of such studies are presented and analysed.

Using (e,2e) spectroscopy one can measure a spin-asymmetry of the Spectral Density Function (SDF) of the sample in the centre of the Brillouin zone [1]. A non-zero value of the spin asymmetry of the SDF indicates an imbalance of spin-up and spin-down states in the valence band of the ferromagnetic metal. If the asymmetries of the (e,2e) spectra measured for non-reversed and reversed target magnetization are denoted AM1 and AM2, then the spin-orbit (ASO) and exchange (Aex) contributions are given to leading order by: $A_{ex} = \frac{1}{2} (AM1 - AM2)$ and $ASO = \frac{1}{2} (AM1 + AM2)$. In such a way the exchange and the spin-orbit interactions in a 3ML Co film on W(110) were identified and located in energy- and momentum- space of the valence band [2].

In contrast to the Co film, a 5 ML Fe film does not show any spin-orbit component in the asymmetry spectrum although a substantial exchange component is observed in the binding energy spectrum and in the energy sharing distribution.

We studied the influence of a thin Au layer on top of the Fe film on the measured asymmetries. The deposition of 1ML of Au on 5 ML of Fe decreases the spin-asymmetry of the SDF from 10% to 7%, still showing a ferromagnetic feature in the

spectrum. At the same time, in the asymmetry of the energy sharing distribution a spin-orbit component of about 2% appeared together with an exchange component of about 7% indicating ferromagnetism in this structure. The ferromagnetic state of the Au/Fe structure is very stable and did not change over a two month period. Since (e,2e) spectroscopy is very surface sensitive this result may indicate a ferromagnetism of the ultrathin Au film on the Fe layer.

A thin Ni buffer layer (1–3 ML) between the 3 ML of Co and the W(110) substrate substantially improves the crystallinity of the Co film and enhances the spin asymmetry of the spectral density function as measured by spin-polarized two-electron spectroscopy.

Spin-orbit splitting of electronic states in W and Au were observed using spin-polarized (e,2e) spectroscopy. The dispersion of these states is measured.

Plasmons in thin Ag films on magnetic and nonmagnetic substrates excited by spin-polarized electrons have been studied using SPEELS.

An asymmetry of Stoner excitations in SPEELS of a thin iron film on a W(110) substrate was used as a measure of the film magnetization to study the influence of the film structure and oxygen adsorption on the magnetic moment of the film.

In addition, the azimuthal dependence of the asymmetry of Stoner excitations can provide information on the magnetic domain structure of a ferromagnetic film.

Clusters of boron hydrides have throughout their history significantly enriched the area of structural inorganic chemistry. These molecules adopt different rigid and robust molecular architectures that make them an interesting, new type of ligands for self-assembled monolayers on metal surfaces. Icosahedral dicarba-*closo*-dodecaborane-thiol derivatives have been introduced and investigated as one of the essential cluster building blocks for SAMs on metal surfaces by our laboratories. Within our research we are concerned with the interactions between these molecules and gold surfaces [1] and also surfaces of silver and copper as substrates with greater commercial potential [2]. Both experimental and computational results covering fundamental characterization of the modified surfaces will be reported. In addition to this we shall present recent results on new, versatile boron cluster molecules from our growing portfolio of cluster modifiers for metal surfaces.

We successfully identified the edge electronic state of a single Bi(111) bilayer, predicted as a 2D topological Insulator [1, 2], by scanning tunneling spectroscopy and first principles calculations. The zigzag-edged Bi(111) islands are grown in triangular shape on a cleaved Bi₂Te₂Se crystal (BTS). The spectroscopic maps directly show enhanced local density of states near the valence band top of the freestanding Bi(111) bilayer [Fig. 1], which agrees well with the calculation for Bi bilayer nanoribbons on Bi₂Te₂Se. In addition, we observed the interfacial states which have modulations around the edges. Our calculation for a Bi(111) bilayer on Bi₂Te₂Se verifies that the interfacial states originate from the hybridization between the electronic states of Bi(111) and the substrate. According to our results, the previous work [3] interpreted the edge modulation of the interfacial state as the signature of the edge state. This work paves an avenue towards the exploitation of quantum spin Hall states.

Precipitation of iron and its oxides on titanium dioxide surfaces

T13 Surface Science

#SS-4-Or-1

A. Busiakiewicz, M. Rogala, Z. Klusek.

University of Lodz - Lodz (Poland).

Titanium dioxide (TiO_2) because of its unique physical and chemical properties is one of the most studied metal oxides. Besides the fundamental reasons, the far-flung investigations are motivated by technological applications of TiO_2 including solar cells [1], self-cleaning coatings [2], water decomposition and hydrogen production [3] among others. However, the doped TiO_2 is also technologically promising considering its bulk and surface properties. Recent studies suggest that Fe-doped TiO_2 can be a candidate for a diluted magnetic semiconductor [4] which could be used in spintronics and magneto-optic devices. In turn, the surface of the Fe/ TiO_2 system is very interesting mainly because of its catalytic properties [5]. The solubility of Fe in reduced rutile TiO_2 crystal and the followed precipitation on the (001) and (110) surfaces have been studied using X-ray photoelectron spectroscopy (XPS) and scanning tunneling microscopy (STM) in ultra-high vacuum. In the first step Fe is dissolved in reduced TiO_2 at 1073 K by thermal diffusion and the saturated solid state solution is formed. A supersaturated solid state solution is then obtained by fast cooling of the sample. In the next step, when this supersaturated crystal is annealed at low temperatures (about 500 K), Fe starts to precipitate on the surface and spherical Fe-rich nanoparticles are formed. At higher temperatures the size of nanoparticles increases and they are transformed into nanocrystals with clearly visible facets. Simultaneously, the number of nanocrystals substantially decreases. Partial oxidation of Fe is also observed around 900 K which is related to strong metal support interaction between precipitating Fe and reduced TiO_2 surface. The XPS and STM results suggest that nanocrystals are mostly composed of mixed Fe/Ti oxides like FeTiO_3 with ilmenite structure (Fig. 1). However, at temperatures close to saturation the nanocrystals disappear which is explained by the restored solubility of Fe cations in reduced TiO_2 . The precipitation and disappearance of Fe-rich nanoparticles and nanocrystals on TiO_2 surfaces is a fully reversible process that can be performed many times and easily controlled by annealing temperature.

Natural clays are key materials in ecological engineering, from the geological storage of long half-time radioactive waste [1] to CO₂ sequestration [2]. With respect to these issues, it is crucial to establish a bridge between the microscopic scale (ionic exchange, ion solvation, ion and matter transport) and the macroscopic scale (swelling, retention capacities). We are interested in the initial stages of water adsorption on external surfaces and interlayers of synthetic hectorite clays which can be considered as “model clay systems” because of their well defined swelling characteristics (figure 1)[3].

NAP-XPS (Near Ambient Pressure X-ray Photoelectron Spectroscopy) brings a new approach with a surface sensitive technique on the water adsorption by clays. Counterions core-level are sensitive to the hydration state (change in binding energy) due to a screening effect of the negatively charged clay layers by water molecules. In the case of Na-hectorite a shift of -0.9 eV of the Na 2s binding energy was observed when relative humidity (RH) was increased to 60% (figure 2). Furthermore, varying the electron mean free path through the excitation energy and analysing the O 1s core level [4] reveal the water thickness in the clay interlayer. These tools help us to understand how the presence of these counterions (of different size and charge as Na⁺, Cs⁺ and Sr²⁺) is affecting the swelling pattern.

Growth of Carbon Nanodiscs through Low Pressure Chemical Vapor Deposition

T13 Surface Science

#NST/SS-8-Or-6

V. Del Campo, R. Henríquez, P. Häberle.

Physics Department, Universidad Técnica Federico Santa María - Valparaíso (Chile).

Carbon nanostructures present important variations in their properties depending on their geometry. Examples of these structures are carbon nanotubes, Buckyballs, graphene and graphene nanoribbons. Here we present the formation of carbon nanodiscs for future characterization of their properties.

We grew carbon nanodiscs on Ru(0001) through Low Pressure Chemical Vapor Deposition (LP-CVD). Then they were characterized with Scanning Tunneling Microscopy (STM). Discs' diameter vary between 20 and 700 nanometers and their height never exceeds 1 nm.

To the best of our knowledge this is the first time carbon nanodiscs are grown by CVD. The most common method for this purpose is hydrocarbon decomposition through pyrolysis. In that case, discs' diameters go from 500 to 4000 nanometers and thicknesses vary between 5 and 70 nm [1]. Growth of carbon nanodiscs through LP-CVD allows the formation of smaller discs and enables the possibility of size control.

Surface Electronic Properties on Magnetite Films on MgO(100)

T13 Surface Science

#SS-P1-16

A. Ikeuchi, S. Hiura, A. Subagyo, K. Sueoka.

Graduate School of Information Science and Technology, Hokkaido University
- Sapporo (Japan).

Magnetite (Fe_3O_4) is a common magnetic iron oxide that has the advantageous properties such as half-metallicity, high conductivity and high Curie temperature of 858 K. Therefore, The Fe_3O_4 films grown on MgO substrates have been expected to be useful for fabrication spin-sensitive devices. However, epitaxially grown Fe_3O_4 films are well known to contain a high density of antiphase domain boundaries (APBs) as investigated by transmission electron microscopy (TEM)[1]. These APBs make the electrical and magnetic properties of the films complicated. The atomic configurations of the APBs in an epitaxial $\text{Fe}_3\text{O}_4(110)$ film and their effects on its magnetic properties have been discussed[2]. Meanwhile on surface of Fe_3O_4 films, three types of the APBs have been observed by scanning tunnelling microscopy (STM)[3]. Moreover, it has been reported that APBs could induce inhomogeneous electronic properties[4]. It is also interesting to study the effect of the APBs on the surface electronic in addition to the magnetic properties. In this work, we have applied scanning tunnelling microscopy and spectroscopy (STM/STS) to investigate the local surface electronic properties around the APBs.

The $\text{Fe}_3\text{O}_4(100)$ films were prepared on MgO(100) substrates by electron beam evaporation of iron in an oxygen atmosphere. The STM image is shown in Fig. 1. The surface of the Fe_3O_4 film was terminated by B-plane, and an APB was clearly observed. Figure 2 is a dI/dV conductance map taken simultaneously with the STM image. The dI/dV map shows different electronic state distribution on the domains separated by the APB. Our results indicate that the APB could modify the surface electronic property.

Graduate School of Information Science and Technology, Hokkaido University
- Sapporo (Japan).

Magnetite (Fe_3O_4) is known to have the advantageous properties such as half-metallicity, high conductivity at room temperature and high Curie temperature of 858 K. These properties look appropriate for spintronics, however the surface has unexpected electronic and spin states that differ from bulk. Some adsorption species affect the surface electronic properties. In some case, surface modification gains spin dependent properties. Recently, it has been verified theoretically and experimentally that hydrogen adsorbed on the clean $\text{Fe}_3\text{O}_4(001)$ surface largely enhances the spin polarization of the surface[1], [2]. So, we have performed doing scanning tunneling microscopy and spectroscopy (STM/STS) experiments on modified $\text{Fe}_3\text{O}_4(001)$ surface and investigating the surface crystallographic and electronic structures.

The epitaxial $\text{Fe}_3\text{O}_4(001)$ films were prepared on MgO substrates by means of electron beam evaporation of iron in an oxygen atmosphere[3], [4]. The films

thickness was 20 nm. The surface showed a ($\sqrt{2} \times \sqrt{2}$)R45° reconstructed structure terminated by B-plane. Figure 1 shows STM image acquired at the $\text{Fe}_3\text{O}_4(001)$ films surface and a superimposed structural model based on Parkinson et al.'s report[5]. We found that bright protrusions in the STM image are attributed to hydroxyl species. They indicate that hydrogen tends to adsorb on O_{NARROW} site and it induces substantial change in electronic states for neighboring surface Fe(B). Moreover, we obtained STS spectra and maps at the surface and observed drastic changes of tunnel current and difference in electronic states between Fe(B) and modified Fe(B) sites (Figure 2).

Since the pioneering work of Faraday on the color of ruby [1], the relationship between morphology and particle properties has been evidenced in many domains, including catalysis [2], magnetism [3] and optics [4]. Nowadays, a major challenge is to shape the particle at a nanoscopic scale to reach specific properties resulting from the combination of reduced dimensionality and controlled morphology, such as the plasmon resonances, the morphological-controlled catalytic or magnetic behavior. A further way to control the physical and chemical properties of nano-clusters is to fabricate alloy clusters. By varying the proportion of the different species in the nanoalloy clusters one can access to new parameters to adjust their properties. Controlling the chemical ordering in nanocluster is however a hard task to achieve due to the large number of intricate phenomena involved during the growth such as segregation or strain for example. During this talk, we will present results concerning the dynamical behavior of nanoclusters supported on a (111) surface of gold[5] and we will conclude by sketching a protocol based on lattice dynamics allowing to induce chemical ordering in the bimetallic nanoclusters (Fig. 1). Pure cobalt, palladium and platinum clusters and some of their alloys will be considered here. We will see that although the thermodynamic equilibrium shape as a function of cluster size is similar for all three pure element clusters and shows a morphology transition from monolayer to bilayer, only Co clusters meet their stable state and undergo a transition. Atomistic simulations on a pico to nanosecond timescale evidence kinetic limitations for Pt and Pd, and allow to understand the experimentally observed morphology for the different species. We will show that stress relaxation, by strongly influencing the energy activation for atom hopping from first to second cluster layer

and the magnitude of vibration of the atoms, is the determinant parameter for the existence or absence of the cluster morphology transition.

Evolution of Topological Surface States in Sb(111) Ultra-Thin Films

T13 Surface Science

#SS-8-Or-2

X. Wang, G. Yao, Z. Luo, W. Xu, J. Sun.

National University of Singapore - Singapore (Singapore).

Based on an inverted bulk band order, antimony thin films presumably could become topological insulators if quantum confinement effect opens up a gap in the bulk bands. Coupling between topological surface states (TSSs) from nearby surfaces, however, tends to degrade or even destroy their novel characters (e.g., spin polarisation). We investigated the evolution of TSS on Sb(111) thin films and their inter-surface coupling as the thickness is reduced from 30 bilayers (BL, 1 BL = 3.75 Å) to 4 BL using in-situ Fourier-transform scanning tunneling spectroscopy (FT-STs) and density functional theory computations. Due to strong distortion in TSS Dirac cone, rich quasi-particle interference (QPI) patterns have been observed in FT-STs mapping. On a 30-BL sample, these patterns are generated by the scattering of TSS on the top surface only. As the thickness decreases, inter-surface coupling degrades spin polarisation of TSS and opens up new scattering channels which show as additional features in the QPI patterns. The strength of inter-surface coupling is found varying dramatically with the wavevector, resulting in spin degenerate states in a large part of the surface Brillouin zone, whereas the TSS survive near the zone centre without opening a gap at the Dirac point for films thickness > 6 BL. Our results also demonstrate quite different behaviors distinguishing SSs, surface resonances, and bulk states as the film changes from thick to ultrathin category. Based on the understanding of these behaviors, the surface energetic and transport properties of Sb films can be tailored for potential applications.

Microscopic origin of Joule heating studied by SP-STM

T13 Surface Science

#SS/NST-1-Or-4

A. Schlenhoff, S. Krause, R. Wiesendanger.

Institute of Applied Physics, University of Hamburg - Hamburg (Germany).

Heat dissipation in electronic devices influences their performance and reliability. As dimensions approach the nanoscale, sensing and controlling heat flow becomes more and more important. The investigation of basic thermal phenomena on the atomic scale is crucial to understand thermoelectric materials and interfacial transport, providing a way to new miniaturized electronic circuits. In scanning tunneling microscopy the atom-size probe tip allows for a very local current injection. By changing the tip-sample distance, the tunnel current can be varied by orders of magnitude while keeping the applied sample bias and thus the energy of the charge carriers constant. As shown recently, spin-polarized scanning tunneling microscopy (SP-STM) allows for the direct investigation of current-induced impacts on nanomagnets consisting of only about 50 iron atoms on a W(110) substrate. They frequently invert their magnetic orientation at a temperature of $T \approx 35$ K due to thermal agitation [1], and by observing their current-dependent switching behavior it has been demonstrated that these nanomagnets may serve as local thermometers [2].

In our studies, we utilize an SP-STM setup to position a magnetic tip above the center of such an thermally switching nanomagnet and inject either low-energy tunneling electrons at a sample bias of $U = 200$ mV or higher-energetic field-emitted electrons at $U = 5$ V [3]. In both cases, increasing the current significantly rises the thermal switching frequency of the nanomagnet, indicating considerable Joule heating. However, our experiments reveal that the effective temperature increase of the nanomagnet per electron depends on the electron energy, and an additional dependence of the Joule heating on the temperature is found. Our results will be presented and discussed within a simple model [4,5] considering temperature-dependent thermal boundary resistance and different phonon excitation probabilities for tunneling and field-emitted electrons. By relating the phenomena of Joule heating to the energy-dependent electron-phonon coupling, our experiments provide insight into the microscopic origin of Joule heating, opening the pathway towards new calorimetric experiments on the atomic scale.

The initial Gd hydriding depends strongly on the native oxide condition and hydroxyl groups adsorbed on the surface impede the dissociative chemisorption of hydrogen and inhibit this reaction [1]. Therefore, understanding and manipulating the surface condition is essential in order to understand and control the initial interaction of hydrogen with metals and alloys.

The interaction of water vapor with polycrystalline gadolinium surface, with water vapor pressure from 2×10^{-8} and up to 18 Torr, was studied by utilizing Direct-Recoils-Spectrometry (DRS), X-ray Photoelectron Spectroscopy (XPS) and Temperature Programmed Desorption (TPD). It has been found that a native Gd surface compound as well as one that was formed by an exposure to 18 Torr H₂O, for 10 minutes, consists of a multilayer hydroxide phase, Gd(OH)₃, transforming into oxide by heating, as depicted by the XPS spectra in Fig. 1, while emitting hydrogen as can be seen from the TPD experiments, presented in Fig. 2. For initial exposures of water vapor on a clean metallic surface, it has been found that initially, full dissociation of the water molecules on the metal surface occurs, for <1 L at 300 K and up to ~3 L at 570 K. On top of the formed oxide there is dissociation to H+OH and hydroxyls are adsorbed, forming, with further exposure, a multilayer hydroxide phase. Dissolution of the oxide/hydroxide layer and enhanced inward diffusion of oxygen into the Gd bulk starts as early as 370 K, similar to results found for oxygen exposures [2].

Moiré patterns are generated by the superposition of two periodic structures with a lattice mismatch or a rotation between them. They have been observed by means of Scanning Tunneling Microscopy (STM) on different systems and their interpretation, in some cases, is not straightforward. The influence, at the atomic scale, of these patterns in the local density of states of the overlayer is not clear.

The growth of graphene on metallic substrates allow us not only control the periodicity of the moiré pattern but also tailor the interaction strength between the carbon atoms and the metallic substrates. This modulation in the interaction gives rise to regions with larger (H-areas) and shorter (L-areas) height of the graphene layer over the Ru(0001) surface. Field Emission Resonances (FERs), which are detected by STM when applying voltages larger than the work function, can be used to explore with nanometer resolution, the inhomogeneities in the local surface potential landscape. Operating the STM in constant current mode implies a constant electric field between tip and sample and the expected energy position for the FERs is gives information about the surface potential.

The dZ/dV curves measured on graphene/Ru(0001) present three unexpected features: (i) the first graphene image state is localized on the H-areas, while it is more extended on the L-areas, (ii) it does not shift in energy following the 0.25 eV increase of local work function from L- to H-areas, and (iii) a new interfacial state at +3 eV appears in the L-areas. To further investigate and understand the origin of

these features we performed first principle calculations based on density functional theory, which explain the experimental behaviour of the first FER in graphene/Ru(0001) as consequence of the splitting and spatial localization of quasi-two dimensional bands due to the modulation of the strength of the interaction between the graphene layer and the metal surface [1]. The interfacial state, resulting from the hybridization of an unoccupied Ru(0001) surface resonance with the first image state component localized in the low areas of the moiré, was suggested to be responsible for the inversion of contrast observed in graphene/Ru(0001) STM experiments at a bias voltage $V_s = +2.6$ V [2] [3].

Atomic orbital character of Cu(111) and Ni(111) surfaces studied by two-dimensional photoelectron spectroscopy

T13 Surface Science

#SS-P1-08

M. Takizawa ¹, Y. Fujioka ¹, H. Namba ¹, F. Matsui ², H. Daimon ².

Stepped surfaces of metals have attracted much attention due to the possible one-dimensional nature. For example, on the Ni stepped surface vicinal to the (111) plane, one-dimensional surface state was found at the step edge [1]. On the Cu stepped surface, on the other hand, two-dimensional surface state was formed, maybe due to the lack of *d* orbital character [2]. In this study, we have focused on the terrace planes, the (111) surfaces of Cu and Ni, to elucidate the atomic orbital character by two-dimensional photoelectron spectroscopy (2D-PES). The experiment was performed at the linearly polarized soft x-ray beamline BL-7 of SR center, Ritsumeikan University [3]. The 2D-PES measurements were performed at room temperature under $\sim 1 \times 10^{-8}$ Pa using a two-dimensional display-type spherical mirror analyzer [4] with synchrotron radiation (SR) light. Figures 1 and 2 show the symmetrized Fermi surfaces (FS) of Cu(111) and Ni(111) taken with $h\nu = 22.5$ eV and 45 eV, respectively. As in the case of previous work [5], both the Cu bulk state around $|\mathbf{k}| \sim 1.5 \text{ \AA}^{-1}$ and the Schockley surface state around the center were successfully observed (Fig. 1). However, the raw photoelectron intensity angular distributions (PIAD) of both Cu and Ni show the symmetry-lowered patterns due to the relation between the polarization vector of the incident SR and the atomic orbitals constituting the FSs. Compared with the simulated PIADs from the atomic orbitals, it is suggested that the Cu(111) Schockley surface state is composed of *s* orbital and/or *p* orbital normal to the surface and that the Ni(111) FS is constituted by a mixture of d_{xy} , d_{yz} , d_{zx} orbitals.

Topological insulators and Rashba systems with spin-split energy band structure induced by strong spin-orbit interaction have attracted a great attention for the dissipationless spin current transport. Such spin split energy band structures have been intensively studied by using a spin- and angle-resolved photoemission spectroscopy (ARPES) mainly for the surface of *sp*-electron systems with C_{3V} symmetry at heavy metals and topological insulators[1]. A material with *d*-derived spin-splitting band remains yet to be explored. Possible strong correlation effects among *d*-electrons in topological insulators and Rashba systems could be important scientific targets.

Here, we pay attention to W(110) well known as the prototype material with strong spin-orbit coupling and *d*-electrons . The surface state on W(110) is formed by *d*-electrons and the surface structure has C_{2V} symmetry in contrast to the systems described above.

In this work, we have clarified that W(110) possesses the spin-polarized Dirac-cone-like surface state with d_{zx} character using the high-resolution ARPES with tunable polarization and spin-ARPES [2]. The constant-energy cuts are found to be strongly flattened compared with what has been observed in the *sp*-electron-based surface Dirac cone with C_{3V} symmetry at the (111) surface plane of some Bi-based chalcogenides [Fig.1 (a)]. This characteristic electronic structure is well reproduced by $\mathbf{k}\cdot\mathbf{p}$ perturbation theory taking into account the C_{2V} symmetry. Interestingly, spin

simulated by this model Hamiltonian are almost oriented along the ΓN direction without out-of-plane spin component [Fig.1 (b)]. This situation differs from well-known

Rashba systems and topological insulators with C_{3V} symmetry that would approach surface states with ideal helical spin texture and shorten the spin relaxation time in the presence of disorder at the surface. On the other hand, the spin texture along the $\overline{\Gamma N}$ direction at the surface with C_{2V} symmetry would generate a quasi-one dimensional edge current along the $\overline{\Gamma H}$ direction. This situation would substantially enhance the spin relaxation time through a persistent spin helix mechanism.

Discovery of quasicrystalline oxide thin films: A STM and LEED study

T13 Surface Science

#SS-16-Or-2

S. Förster, K. Meinel, W. Widdra.

Institute of Physics, Martin-Luther-Universität Halle-Wittenberg - Halle (Germany).

Quasicrystals represent a fascinating class of materials. In the past thirty years after their discovery by Dan Shechtman they have challenged and changed our fundamental understanding of ordered solids. The extraordinary structure of quasicrystals is accompanied by peculiar properties as for example a reduced wetting, a low friction coefficient, high hardness, and unusual transport properties. The fact that most properties are promoted by the surface demands an understanding of the atomically-clean surfaces which can only be provided by surface science. So far, surface science studies on quasicrystals have been limited to bulk quasicrystalline (QC) material. Surface structural analysis of either bulk crystals or of thin film phases have attracted much attention. The growth of thin films of QC material on periodic substrates has been investigated as well as thin films of crystalline material on QC substrates [1,2].

Here we report on the observation of a two-dimensional QC structure that develops from a classical periodic thin film on a periodic substrate for the case of BaTiO_3 on Pt(111). BaTiO_3 is the most studied ferroelectric perovskite oxide which has an easily accessible ferroelectric to paraelectric phase transition at 400 K. Due to matching lattice conditions it can be grown epitaxially on other perovskites as well as on selected metal substrates. On Pt(001) and on Pt(111) periodic thin films of either $\text{BaTiO}_3(001)$ or $\text{BaTiO}_3(111)$ have been grown [3-5]. As we demonstrate here, alternatively an aperiodic QC structure can be formed by annealing an initially 2.8 nm thick BaTiO_3 film on Pt(111). Upon annealing at 1250 K in UHV the material restructures in a QC wetting layer in between a few thicker $\text{BaTiO}_3(111)$ islands. In LEED the QC structure shows bright and sharp spots with dodecagonal symmetry as shown in Fig. 1. High-resolution STM images reveal that the surface structure is composed by an arrangement of quadratic and triangular building blocks. These are the typical elements of a 2D QC lattice with dodecagonal symmetry. The Fourier

transform of the high-resolution STM data is in excellent agreement with the measured LEED pattern. The analysis as performed here demonstrates once more the power of combining both techniques. The FFT is used as the key for correlating the local structural information of STM with the global structural information as derived from LEED.

Reactivity of ethylene on In and Sn saturated Si(001)2×1 surfaces

T13 Surface Science

#SS-12-Or-3

P. Zimmermann¹, O. Krejčí², M. Vorokhta¹, R. Acres³, I. Ošťádal⁴, P. Sobotík⁴.

¹Charles University in Prague - Prague (Czech republic), ²Academy of Sciences of the Czech Republic - Prague (Czech republic), ³Eletra-Sincrotrone - Trieste (Italy), ⁴Charles University in Prague - Prague (Czech republic).

High reactivity of the bare Si(001)2×1 surface is caused by the presence of one dangling bond per surface atom. Adsorption of conjugated organic molecules proceeds by the creation of covalent bonds between the pi electrons of the molecules and the dangling bond of the surface thus leading to various adsorption configurations and distortion of desired molecular properties [1].

We investigate the possibilities of decoupling the molecules from the Si(001) substrate by saturating the Si dangling bonds by indium (group III) and tin (IV) adatoms. Both elements self-organize into linear dimer chains growing perpendicular to the underlying Si dimer rows [2]. At 0.5 monolayer coverage all Si dangling bonds are saturated.

We examine the reactivity of the decoupling layers by exposing them to ethylene which serves as a simple model for the reactivity of more complex conjugated molecules. Based on STM and PES measurements and DFT calculations we observe that ethylene doesn't chemically interact with the indium decoupling layer whereas it does interact with the tin decoupling layer by chemisorbing on top of Sn dimers. We attribute the inertness (reactivity) of the indium (tin) surface to the absence (presence) of a pi bond in the In (Sn) dimer respectively.

Strain-driven self-assembled CrN nanoislands on Cu(001)

T13 Surface Science

#SS-P3-30

F. Komori, P. Krukowski, T. Imori, K. Nakatsuji, M. Yamada.

ISSP, Univ. of Tokyo - Kashiwa, Chiba (Japan).

Self-assembly at solid surfaces is a promising way for preparing nanostructures with regular shape and spacing uniformly in a macroscopic scale. For the assembly, long- and short-range lattice strain is one of the important mechanisms. We have studied self-assembled two-dimensional (2D) arrays of CrN square nanoislands on the Cu(001) surface as a system made by a novel short-range mechanism. So far, the short-range mechanism has been adopted only to the assembly of MnN islands on Cu(001).[1]

The CrN assembly was prepared by using a method similar to that for the MnN assembly. Chromium was first deposited on a nitrogen-adsorbed Cu(001) surface, and then the sample was annealed at a temperature between 410 and 430 °C for 15 min. The assembly critically depends on the annealing temperature and Cr coverage. The surface was investigated by STM, XPS, and LEED at RT.

The self-assembled square islands are shown in Figs. 1 and 2. The islands with the edges oriented along the $\langle 110 \rangle$ directions locally form a 2D square superstructure as in Fig. 1. The magnified image in Fig. 2 indicates two types of the self-assembled islands with different heights marked as α (0.09 nm) and β (0.18 nm). The substrate in Fig. 2 is predominately covered by α islands while most of the islands in Fig. 1 is β . The stoichiometry of chromium nitride was confirmed to be CrN by XPS. The square lattice image in Fig. 2 suggests a NaCl-type crystal with the lattice constant of 0.39 nm, which is smaller than the value (0.4148 nm) of the bulk CrN crystal.

We propose a model previously applied to the MnN islands on Cu(001) [1] for β CrN islands. The substrate is covered by upper and lower sublayers of the CrN mono-atomic layer. The former forms the square island, while the latter is imaged as a depressed grid. Some properties that are different from those of the MnN assembly are attributed to the differences in the lattice constant of the bulk nitride crystals and thermal stability.

Tritium adsorption and desorption measurements using beta-induced X-ray spectroscopy for KATRIN

T13 Surface Science

#SS-P3-08

M. Babutzka, B. Bornschein, F. Priester, M. Röllig, F. Schneck.

Karlsruhe Institute of Technology - Karlsruhe (Germany).

The aim of the KATRIN experiment is the direct measurement of the electron anti-neutrino with a sensitivity of 200 meV/c² (90 % C.L.). The working principle bases on the high precision spectroscopy of the tritium beta decay close to its endpoint at 18.6 keV. The experiment uses a windowless gaseous tritium source (WGTS) with pumping systems magnetically guiding the β -decay electrons towards a tandem spectrometer. The spectrometers analyse by combining magnetic-adiabatic collimation with an electrostatic filter. Finally the the decay electrons that passed the spectrometer are counted by a silicon detector.

The WGTS is electrically terminated by the grounded, gold-coated Rear Wall. It is expected that there will evolve a cold plasma in the WGTS with the high energy decay electrons and low energy and mobile ions and secondary electrons. Hence the conducting plasma will carry changes in the Rear Wall surface potential in time or surface area into the source which can produce a shift in the β -electron energy and consequently a systematic error for KATRIN. Therefore a stable surface potential is critical for the KATRIN experiment.

There are different effects that can modify the Rear Wall surface potential but the most risky effects are caused by the exposure of the gold surface to a tritium plasma containing not only the radiochemical tritium but also charged tritium ions. These ions are expected to have a high sticking coefficient to the gold surface (like atomic hydrogen [1]) but this topic was not yet covered in satisfactory detail in literature. This was the reason to set-up the tritium adsorption and desorption experiment (TriADE).

TriADE provides a possibility to solid samples with arbitrary surfaces in tritium atmosphere. The temperature range of operation is -100 °C to +150 °C controlled by

a cold gas machine and the pressure range is 10^{-8} to 1 mbar with pure tritium, gas mixtures or purge gas. There are two different techniques available to measure the amount of adsorbed tritium: Thermal desorption mass spectroscopy (TDMS) using a quadrupole mass spectrometer (QMS) and beta-induced x-ray spectroscopy (BIXS) with a silicon drift detector (SDD) behind a gold/beryllium window. The later method counts the photons induced by the electrons from the beta-decays of the adsorbed tritium molecules. BIXS as a measurement method to detect small amount of Tritium has been proven by the TriRex Experiment [2]. The geometry suppresses any decay electrons except from the sample surface and the gold surface of the window.

Carbonaceous surfaces have attracted much attention not only because of their technological use but also for their influence on atmospheric chemistry as products of combustion processes. Characterizing the interaction of these surfaces with atmospheric oxidants is thus of great importance because the properties of the resulting oxidized surfaces may differ from those of the bare surface. For instance, the oxidation of soot particles may change their chemical reactivity or their hydrophilic properties, thus modifying their influence on atmospheric chemistry. In the present work, we make use of DFT calculations to characterize the interaction of graphene sheets and large carbonaceous clusters with atmospheric oxidants such as atomic oxygen, O₂, O₃, H₂O and NO molecules. Both perfect and defective surfaces containing vacancies are studied. In a general way, we show that the oxidation of carbonaceous surfaces occurs more likely at defective sites and depends on the type of site considered in the calculations. For instance, carbon atom vacancies characterized by an odd number of missing carbon atoms are more reactive than those where an even number of atoms is missing and, as a consequence, they can be oxidised more easily. These results can be used to better understand oxidation processes that likely occur in carbonaceous systems of environmental or technical interest.

TU Wien - Vienna (Austria).

Zirconia (ZrO_2), in pure and doped form, is an important material in engineering, dentistry, microelectronics, and catalysis, as well as a solid-state electrolyte for gas sensors, solid-oxide fuel cells and oxygen purification. Nevertheless, its surface properties are poorly understood, which is mainly due to the fact that it is an excellent electronic insulator, which makes it impossible to use techniques like scanning tunneling microscopy (STM). This problem is circumvented by studying ultrathin ZrO_2 films.

Growth of ZrO_2 films by reactive evaporation of Zr [1] is a rather cumbersome approach. We have therefore grown ultrathin zirconia films by oxidation of $\text{Pt}_3\text{Zr}(0001)$ [2] and $\text{Pd}_3\text{Zr}(0001)$ substrates and studied them by STM with atomic resolution (Fig. 1), x-ray photoelectron microscopy (XPS), Auger electron microscopy (AES) and density-functional theory (DFT). The films consist of an O-Zr-O trilayer, equivalent to a (111) trilayer of the fluorite structure of cubic ZrO_2 , but with contracted in-plane lattice constant and increased layer spacing. DFT shows significant buckling of the Zr layer, nicely explaining the STM data, and also indicates that the oxide weakly binds to the substrate via its Zr atoms. In spite of a formal valency of 4+, in XPS the Zr atoms in the ZrO_2 film show a chemical shift typical for a suboxide, which is explained by the position of the Fermi level in this ultrathin oxide. Depending on sample preparation, the oxide film can sit on either reconstructed Pt_3Zr , presumably with a Pt-terminated surface, or on an alloy surface; this difference of the support also has some influence on the properties of the oxide.

Adsorption experiments indicate that most gases like O_2 , CO and H_2 do not stick at the surface at room temperature. We observe adsorption of H_2O with a desorption barrier barely high enough for sticking at room temperature (about 1 eV). We will also present first results of small metal clusters grown on the ultrathin oxide.

Ab initio study of non-polar and semipolar GaN surfaces

P. Mutombo, O. Romanyuk*

Institute of Physics, ASCR, Cukrovarnicka 10, 162 00, Prague, Czech Republic.

Gallium nitride materials constitute an important group of compounds which have called the attention of scientists because of their application in the optoelectronic industry. It is known that GaN-based devices grown on non-polar and semipolar substrates achieve a greater performance compared to devices grown on conventional c-plane [1, 2]. This is due to the fact that the internal electric field is significantly smaller in the semipolar and non-polar III-nitrides. Thus, the heterostructures formed on these substrates are very promising for the advancement of science and technology.

To understand the non-polar and semipolar surfaces stability, theoretical methods have been used. We have performed Density Functional Theory calculations to determine the atomic and electronic structures of the non-polar GaN(1-100), (11-20), and semipolar GaN(20-21), (20-2-1) surfaces [3]. We have calculated the surface phase diagrams and the relative stability of the (1x1) structures depending on Ga/N stoichiometry on a surface. The results are discussed with respect to previous theoretical findings.

Quasiparticle interference at epitaxial Silicene

T13 Surface Science

#SS-1-Or-12

H. Hirayama, Y. Aoki, K. Nakatsuji, A. Ohshiro.

Tokyo Institute of Technology - Yokohama (Japan).

Silicene is a newly emerging two-dimensional material which has a honeycomb lattice made by Si. Because of its specific structure, it has been paid much attention as the Si analog of graphene. However, the first successful synthesis of silicene was reported very recently in 2012. Vogt et. al. firstly reported the epitaxial growth of the silicene which has a honeycomb structure (H) with the 4×4 ordering on the Ag(111) 1×1 substrate [1]. Then, the $\sqrt{13} \times \sqrt{13}$ -R13.9° honeycomb and 3.5×3.5 closed packed (T) structures were observed as other phases of silicene on the Ag(111) substrates [2]. The $\sqrt{7} \times \sqrt{7}$ and $\sqrt{3} \times \sqrt{3}$ stacking (relative to the silicene 1×1 lattice) phases were also reported [3]. But, it is still not conclusive whether all these have the true silicene structure and its intrinsic electronic state. Substantially, two groups proposed the structural models of silicene stacking with the 4×4 and $\sqrt{13} \times \sqrt{13}$ ordering on the Ag(111) [1,2], while one group claimed that only the $\sqrt{3} \times \sqrt{3}$ is the true phase of epitaxial silicene and others do not have the silicene structure [3,4].

This problem can be solved by observing the dispersion relation of these phases, since the silicene should reveal the characteristic Dirac electron-like linear dispersion. However, various phases usually appear to coexist as a patchwork in the epitaxial growth of silicene on the Ag(111) surface. Thus, we investigated the dispersion relation of local domains with different phases by observing the quasiparticle interference pattern (surface electron standing wave pattern) in the dI/dV images of STM. As results, no standing wave pattern was observed on the 4×4 (H), closed packed (T), and $\sqrt{13} \times \sqrt{13}$ phases in the epitaxial growth at relatively low temperatures (c.a. 200-250C). However, the 2nd layer revealed the standing waves in the energy +0.5 to +1.2 eV above the Fermi level. The energy dependence of the standing waves showed a linear dispersion with the Fermi velocity of 1.3×10^6 m/s. We regard that the appearance of the standing wave on the 2nd layer is due to the small influence of the Ag substrate which is weakened by the intermediate the 1st layer.

In the epitaxial growth at higher temperatures, the $\sqrt{3}\times\sqrt{3}$ phase widely covered the Ag substrate. However, the $\sqrt{3}\times\sqrt{3}$ plane bended loosely as to be just put lightly on the Ag substrate, although the $\sqrt{3}$ lattice was continuous even on the bended region. The standing wave pattern was clearly observed in the full empty state energy from +0.1 to +1.2 eV above the Fermi level on this high temperature $\sqrt{3}\times\sqrt{3}$ phase. Fourier Transformation of the standing waves revealed specific q-vectors which correspond to the intra- and inter-band transition of the Dirac cones at K and K' points in the Brillouin zone. The energy dependence of the smaller q-vector revealed a perfect Dirac electron's linear dispersion with $v_f=1.2\times 10^6$ m/s and $E_D = -0.3$ eV. The larger q-vector connected K and K' valleys. Judging from these results, this $\sqrt{3}\times\sqrt{3}$ phase is regarded as the true silicene.

Quantum states of proton and positive muon on solid surfaces and in subsurfaces

T13 Surface Science

#SS-1-Or-13

H. Nakanishi, H. Kasai.

Graduate School of Engineering, Osaka University - Suita, Osaka (Japan).

The first principles calculation based on the density functional theory is one of the most successful and powerful methods in the materials physics. And also the first principles molecular dynamics methods have been used for various dynamical behaviors. In the case of small mass atoms like hydrogen atoms, we should treat their nuclei (proton) in a quantum-mechanical manner, in addition to electrons. The quantum behaviors of the nuclei have crucial roles to play in the materials related to today's energy technology: fuel cell and lithium-ion rechargeable battery, and also various catalytic reactions to produce hydrogen fuel, not only from their academic interests [1-4]. Positive muon is also one of our target quantum particles, because it has been used as a magnetic probe particle in materials, mu-SR. The positive muon has the same spin and same charge as a proton and behaves as the very light isotope of hydrogen which has ninth mass of proton. It is important to analyze the quantum behavior of these particles in the materials.

We have been developing the quantum simulation code for the small mass atom nuclei, protons and muons on solid surfaces, in subsurfaces and bulks. These particle-cases are different from the situations of electron in the materials: (1) Because of the larger mass, these particles have the very shorter de Broglie wave length. (2) The potential energy surface for these particles in the materials is normally repulsive around the lattice points. We propose the methods for the quantum state calculation for these particles in materials. In the conference, we will also show our simulation results for muon and hydrogen isotopes on solid surfaces and in subsurfaces, and discuss their quantum mechanical effects [1-5]

Graphene has attracted much interest because of its novel electronic properties due to massless Dirac fermions in the π band states. Modification of its band structure such as carrier doping and band-gap formation is the key for its potential applications. Graphene nanoribbon (GNR) is expected to have a band-gap in the π band due to quasi one-dimensional confinement of the carriers depending on the width and orientations [1]. So far, the band-gap opening and/or the presence of the edge state has been reported only on the GNRs made by lithographic process [2] and CVD growth [3]. In the present study, a high-density array of GNRs with ca. 10 nm width was grown on a vicinal SiC(0001) substrate by molecular beam epitaxy (MBE). The band-gap opening of at least 0.14 eV and its dependence on the GNR width have been confirmed by angle-resolved photoelectron spectroscopy (ARPES) [4].

After high-temperature etching in the H_2 gas, the vicinal SiC substrate 4° -off toward [1-100] direction exhibits periodic arrangement of terrace and step-bunching region with ca. 20 nm period (nanosurface). The C atoms are deposited until the terrace is covered by ($6\sqrt{3} \times 6\sqrt{3}$) $R30^\circ$ buffer layer. A periodic arrangement of GNRs with ca. 10 nm width is obtained by hydrogenation of the buffer layer [5] and confirmed by AFM observations. The polarization dependence in the Raman spectra and the line nodes in the STM images in vicinity of the step edges suggest the existence of arm-chair edges. Figure 1 shows the dispersion relation of the π band along Γ -K-M line which is perpendicular to the GNR direction. A single and linear π band confirms the high-

quality single-layer graphene on the terrace. The dots in vicinity of the K point indicate the peaks in the ARPES spectra. There is no states between the valence band maximum and the Fermi level, and the band-gap at least 0.14 eV is opened at the K point assuming the conduction band minimum at the Fermi level. We have also investigated the 5 nm width GNR which shows slightly larger band-gap opening. This is qualitatively consistent with the carrier confinement in the GNR.

Potential Sputtering from Rare Gas Solid by Low Energy Multiply-Charged Ion Impact

T13 Surface Science

#SS-P3-23

K. Ban, M. Akiwa, K. Koganei, M. Murakami, T. Tachibana, T. Koizumi, T. Hirayama.

Rikkyo University - Tokyo (Japan).

Potential sputtering is the desorption mechanism which is induced by transfer of the potential energy from incident multiply-charged ions to the solid surface. We have reported previously the *relative* ion yields of potential sputtering from solid Ne [1], and demonstrated that the potential sputtering yield is proportional to the potential energy of the incident ion. Here we report the experimental results of the *absolute* potential sputtering yields using a newly developed simple and precise method.

Ar^{q+} ions ($q = 1\sim 6$) were produced in an ECR ion source. The ion beam extracted from the ion source was mass-analyzed and introduced into a main chamber. A rare-gas solid was prepared on a Cu substrate which was cooled to 4.9 K at the center of the main chamber.

Absolute sputtering ion yields Y_{ion} were estimated by measuring the incident ion beam current I_{in} and the desorbed ion current. When the sample is irradiated by the ion beam, the current flowing into the Cu substrate I_{Cu} differs from I_{in} because of the desorption of positive ions from the sample. The desorbed ion current can be estimated from $(I_{\text{in}} - I_{\text{Cu}})$, and Y_{ion} is then calculated from $Y_{\text{ion}} = (I_{\text{in}} - I_{\text{Cu}}) / (I_{\text{in}} / q)$, where q is the incident ion charge.

Fig. 1 shows the absolute sputtering ion yields Y_{ion} from the surface of solid Ne as a function of the incident Ar^{q+} ion energy. To estimate the contribution of potential sputtering, the absolute sputtering ion yields vs. the potential energy of the incident ion are plotted in Fig. 2. It is shown that the potential sputtering ion yields linearly increases with the potential energy of the incident ion, which is consistent with our previous work [1].

Specialities of the group III metals mobility on Si(100) surfaces

T13 Surface Science

#SS-3-Or-1

I. Ošťádal, M. Kucera, F. Rozboril, K. Majer, P. Sobotík, P. Kocán.

Charles University - Prague (Czech republic).

At low coverage group III metals (Al, In, Ga) form on the Si(100) surface one atom wide chains composed of dimers. The metal chains on the silicon surface attract attention for many reasons. They can be used as model systems for experimental investigation of electron structure of low dimensional objects, building blocks of more complex surface structures and templates for growing further materials for functionalizing the surface. Mixing with group IV metals results in formation of bimetallic chain structures of interesting properties.

Binding energies together with surface temperature determine mobility of adatoms and stability of grown chains. Deposition rate together with the adatom mobility and chain stability control growth kinetics. Knowledge of intrinsic growth parameters is crucial for growing desirable mono- and bimetallic structures. The binding energies and hopping barriers were theoretically calculated for all three metals [1, 2]. Kinetic Monte Carlo simulations of experimentally obtained growth characteristics provided the barriers for Ga [3] and In [4]. Direct observations of surface hopping by means of scanning tunneling microscopy (STM) resulted in determination of the barriers and frequency prefactors for In [5]. Diffusion parameters obtained by the various methods contain controversy both in the barrier heights and a character of hopping anisotropy.

We present new STM measurements of growth characteristics (Al, In) and observations of adatom hopping at various temperatures. The data are compared with the parameters already reported elsewhere. The existing controversy is discussed with respect to assumptions at theoretical calculations, a role of a surface reconstruction and thermal fluctuations at higher temperatures. An impact of the adatom mobility and hopping anisotropy on growth is estimated for the particular metals.

SS-P1-09

Green's function approach to the dynamics of image potential resonances

T13 Surface Science

#SS-P1-09

S. Tsirkin, E.V. Chulkov.

Donostia International Physics Center - San Sebastian-Donostia (Spain).

The image potential states on metal surfaces form a Rydberg series of states with energies $E_n = -\frac{1.5}{(n-\delta)^2}$ converging to the vacuum level, where δ is the quantum defect. When the vacuum level lies in the continuum of the bulk states of the metal, image-potential resonances (IPRs) are formed. Recent advances in time-resolved two-photon photoemission allow to study energies and the lifetimes of IPRs with high quantum numbers [4,5].

In the present work we perform a theoretical study the properties of IPRs on a number of close-packed metallic surfaces, such as Cu(111), Ag(111), Al(001) and many others. The binding energies and lifetimes are calculated from the Green's function (GF), using the fact that the electronic excitation corresponds to a pole of the

GF at some complex value ω_n , where $E_n = \text{Re} \omega_n$ is the energy, and $\tau_n = 1/(-2\text{Im} \omega_n)$ is the lifetime of the excitation. The electronic structure of the surface is described by a one-dimensional pseudopotential [3], which was slightly modified for some jellium-like surfaces: Al(001), Al(111) and Mg(0001). The GF of the surface is calculated using the Green's function matching method [4].

Previously the theoretical study of surface resonances and image-potential resonances were performed using the wave-packet propagation method (WPP) [5]. The advantage of the GF approach over WPP consists in the principle possibility of including the many-body interactions via solving the Hedin's equations. However, we show that the IPRs practically do not penetrate inside the metal, and hence inelastic scattering into the bulk is unlikely to affect significantly the lifetimes of excitations in IPRs. Thus, we do not include many-body effects in the present calculations. Nevertheless, inelastic scattering is expected to be important for the

dynamics of excitations in surface resonances, and should be accounted for in the future studies.

The calculated lifetimes for some of the studied surfaces are presented in the Figure.

It is clearly seen, that the lifetimes obey the scaling law $\tau_n \sim n^3$. The present method gives practically the same results, as the WPP method. Our results are also in agreement with recent experimental results[1,2]. For example, the calculated lifetime of the n=2 IPR on Ag(111) $\tau_{calc} = 19$ fs is close to the experimental value $\tau_{exp} = 23 \pm 2$ fs. [2]

Lying down to standing up transitions in self assembly of butanedithiol monolayers on gold and substitutional assembly by octanethiols

T13 Surface Science

#SS-5-Or-4

J. Jia ¹, S. Mukherjee ², H. Hamoudi ³, S. Nannarone ⁴, L. Pasquali ⁴, V. Esaulov ¹.

¹ISMO UNIVERSITE PARIS-SUD - Orsay (France), ²CNR&ICTP - Trieste (Italy), ³NIMS - Ibaraki (Japan), ⁴CNR&Dipartimento di Ingegneria'Enzo Ferrari', Università di Modena e Reggio Emilia - Modena (Italy).

Self assembly of dithiol molecules has been the object of much interest because of the possibility to link the two thiol ends to different metallic entities. This has been used for instance to measure molecular conductance. Interest in self assembly of these molecules on surfaces has similarly been spurred by their use in making diode structures and in superlattices involving multiple layers of dithiol molecules attached to metal nanoparticles. However problems have been encountered related to formation of multilayered dithiol structures by molecular interlinking with formation of disulphide bonds, photooxidation processes and formation of lying down phases with both sulphur ends attached to the substrate, on which the SAM assembly was attempted. This has led to interrogations about the possibility of at all forming a standing phase if first a lying down, doubly tethered phase is formed. However work, by some of us [1-5] for some dithiol molecules, shows that quite well ordered SAMs of standing-up molecules with free -SH groups can be produced, although it seemed not in the case of short chain dithiols[1].

The intent of this work was to address the question of transitions from lying down to standing up phase in dithiol self assembly and whether a standing up phase of short chain dithiol can be formed. Self assembly of butanedithiol (C4DT) monolayers (SAMs) on gold and substitutional assembly by octanethiols(C8T) from a lying down doubly tethered phase of butane dithiol, were investigated in a vacuum evaporation experiment by high resolution photoemission. The vacuum evaporative assembly [4] is particularly interesting since it can be used for reactive surfaces.

The lying down dithiol phase, with both sulphur atoms attached to gold, was formed by evaporation and characterized by high resolution XPS at the BEAR beamline (Elettra synchrotron). It was then exposed to C8T molecules. XPS shows formation of a mixed SAM composed of standing up octanethiol and dithiol molecules. The degree of dithiol replacement, as evidenced by the increasing thickness of the SAM is found to augment slowly with increasing exposure to C8T. These results demonstrate that the existence of a lying down dithiol SAM, doubly tethered by sulfur ends, should not be an impediment for producing a standing up dithiol SAM. Furthermore a standing up C4DT phase was found to be formed upon rapid very large exposure to C4DT. Differences in valence band photoemission between the lying down and standing up phases were noted and can be accounted for theoretically. In all cases measurements indicate more than one possible adsorption configuration as evidenced by different sulphur binding energies.

In recent years selenium and tellurium derived self assembled monolayers (SAMs) have attracted much interest as alternatives to thiol-derived SAMs, in e.g. molecular electronics applications, because of different (Se as compared to S) bonding to the substrate. This is a point of key importance for electronic transport. However studies of the headgroup Se atom interaction with metal surfaces are still rare and a thorough spectroscopic characterization of the Se-metal interfaces is still missing. This would be a useful complement to current investigations on self-assembly. In this work, results of a high resolution photoemission (at Tempo beamline, Soleil synchrotron) and electrochemistry study of Se adsorption on Au(111) and Ag(111) surfaces performed by immersion of pristine samples into an aqueous solution of Na₂Se are presented. Cyclic voltammetry on Au shows formation of selenium adsorbed species and the structures observed in reductive desorption are related to atomic and polymeric Se species observed. In the case of Au(111) XPS spectra in the Se(3d) region indeed show two main features attributed to Se chemisorbed atomically and polymeric Se₈ features. Smaller structures due to other types of Se conformations were also observed. The Au(4f) peak line shape do not show core level shifts indicative of Au selenide formation. In case of silver on the other hand, XPS spectra for Ag(3d) show a broadening of the peak to lower binding energies and a deconvolution into Ag_B bulk like and Ag_{Se} components shows that the Ag_{Se} is located at a lower binding energy: an effect similar to oxidation and sulphidation of Ag. The Se(3d) XPS spectrum is found to be substantially different from the Au case and dominated by atomic type Se, due to the selenide. A smaller intensity Se

structure at an energy similar to the Se_8 structure for Au is also observed. Changes in the valence band region of gold related to Se adsorption are reported.

SS-11-Or-1

Adsorption, nucleation and desorption of rod-like organic molecules (p-hexaphenyl, pentacene) on inert substrates (mica)

T13 Surface Science

#SS-11-Or-1

A. Winkler, L. Tumbek.

Graz University of Technology - Graz (Austria).

Organic thin films have attracted high interest within the last decade, due to their interesting properties for organic electronics. Although significant progress has been made in the understanding and tailoring of organic film growth, there are still many open questions regarding the initial steps of film formation. Here we present experimental data on the initial film growth of the model systems p-hexaphenyl and pentacene on mica. The films were prepared under UHV conditions by physical vapor deposition. Surface analytical techniques (thermal desorption spectroscopy (TDS), X-ray photoelectron spectroscopy (XPS), atomic force microscopy (AFM)) were applied to study the adsorption and desorption kinetics, as well as the nucleation behavior. Mica was used as a substrate because one can easily change its behavior from reactive (freshly cleaved) to inert (sputtered or contaminated). This leads to films of flat lying molecules in the first case, where long needle-like islands form, or to standing molecules in the second case, where terraced, round shaped islands occur. In both cases a bimodal island size distribution was observed in ex-situ AFM (Figure 1). We could show that this is the result of adsorbate-induced subsequent nucleation when the samples were exposed to air [1]. In case of the freshly cleaved mica, islands grow on a wetting layer in vacuum. This layer dewets and forms the small islands upon venting. In case of the sputtered mica substrate an equilibrium exists between the islands and a 2D gas phase. Again, the latter phase nucleates after venting, forming the small islands. Another important aspect refers to the actual nucleation mechanism. Whereas it is generally assumed that nucleation of organic films can be described by diffusion limited aggregation (DLA) we have demonstrated that under special substrate conditions the nucleation has to be described by attachment limited aggregation (ALA) [2]. We believe that this is a rather generic feature for the nucleation of rod-like organic molecules, because the

incorporation of the monomers at the rim of the islands depends on the orientation of the approaching molecules. Similar arguments hold for the initial sticking coefficient of rod-like organic molecules, which has turned out to be smaller than unity, as unequivocally determined for pentacene on mica by TDS.

Using BEEM (Ballistic Electron Emission Microscopy) to probe buried interfaces in metal-organic molecules-semiconductor hybrid heterostructures

T13 Surface Science

#SS-P3-01

A. Junay, S. Guézo, F. Solal, P. Turban, S. Ababou-Girard, G. Delhaye, S. Tricot.

Insitut de Physique de Rennes - Rennes (France).

Ballistic Electron Emission Microscopy (BEEM) is a scanning probe technique derived from STM, which allows characterization of the electronic properties of buried interfaces with a lateral nanometer resolution [1]. In the case of a Schottky contact, hot electrons are injected in the metal layer with an energy defined by the STM tip bias voltage. A small part of the injected electrons crosses ballistically the metal layer and reaches the buried interface. If their energy is high enough to overcome the Schottky barrier height, electrons can enter into the conduction band of semiconductor and be detected as a BEEM current. In molecular electronics, BEEM is an ideal tool to probe local structural and electronic properties of hybrid systems. By using as reference the well-known Schottky contact of Au(110)/GaAs(001) [2], organic molecular layers inserted at metal-semiconductor interfaces [3-5] are here probed by BEEM. The aim of this work is to study organic layers covalently grafted on a single-crystalline substrate of GaAs(001), on which a metal top-contact is deposited. By combining STM/BEEM measurements on these hybrid structures, interface homogeneity, degree of metal penetration through the organic layer and other properties are here discussed.

Spreading of a liquid drop over a plane rigid substrate due to intermolecular forces

T13 Surface Science

#SS-6-Or-1

A. Tyatyushkin.

Institute of Mechanics. Moscow State University - Moscow (Russian federation).

Coating surfaces with monomolecular layers is an important part of many modern technologies. Usually it is preceded by spreading under the action of intermolecular forces. Self-similar solutions of the equation that describes plane spreading due to intermolecular forces represent profiles of drops without contact lines [1]. In the present work, self-similar solutions are found also for axisymmetrical spreading. Both plane and axisymmetrical solutions are matched with the solutions of equations that describe plane or axisymmetrical spreading of monomolecular layers.

A liquid layer spreading over a plane rigid substrate is considered. The equations for its local thickness as function of the distance from the axis or plane of symmetry and time, $\zeta(r,t)$, that describe axisymmetrical and plane spreading due to intermolecular forces and their self-similar solutions are found. For plane spreading, the solutions coincide with those in [1].

When the layer reaches some thickness, h_m , of the order of the molecular size, the liquid forms a monomolecular layer which can be in liquid or gaseous two-dimensional state. The moving boundary between monomolecular and liquid phases is determined by some value, $R_l(t)$, of the variable r for which $\zeta(R_l(t),t) = h_m$.

The liquid monomolecular layer forms a distinct boundary with the uncovered region of the surface of the substrate which is determined by some value, $R_m(t)$, of the variable r . With regarding the surface mass density of the layer, ρ_s , as constant and using the condition of the conservation of the total mass of the spreading liquid, $R_m(t)$ is obtained. At some instant all the liquid is in monomolecular phase and stops spreading.

If the monomolecular layer is gaseous, it has no boundary with the uncovered surface, and the distribution of the surface mass density, $\rho_s(r,t)$, satisfies the differential equation for the surface diffusion with the boundary and initial conditions that follow from continuity of surface mass flux and mass densities on the boundary between the phases and absence of monomolecular phase at $t = 0$. At some instance all the liquid is in monomolecular phase, but continues spreading. The asymptotic behavior of $\rho_s(r,t)$ as t tends to infinity is found.

The functions $R_m(t)$ or $\rho_s(r,t)$ for spreading with formation of liquid or gaseous monomolecular layers can be measured in experiments. In spite of the fact that the proposed models are based on strong simplifying assumptions, one may expect their satisfactory agreement at least with some experiments. In any case, the models allow introducing into consideration various additional physical processes to achieve satisfactory agreement with measured data.

Tiny golden "Eiffel towers" on Si(111)-5x2-Au surface

T13 Surface Science

#SS-3-Or-3

T. Abukawa, Y. Nishigaya.

IMRAM, Tohoku University - Sendai (Japan).

The Si(111)-5x2-Au surface has attracted us because of its strong one-dimensional nature. However, its structure remains as one of the long-standing problems in the surface science. In earlier studies, models with Au coverage of 0.4 ML, were candidates of the structure [1]. Recently, Barke et al. precisely determined the Au coverage on 5x2-Au, and revised the coverage to be 0.6 ML [2]. Then, the model with three gold chains was proposed by a first-principles theory [3]. Here, we have applied Weissenberg reflection high-energy electron diffraction (W-RHEED) [4], and investigated the structure of Si(111)5x2-Au surface [5].

A single-domain 5x2-Au surface was prepared on a Si(111) wafer with an intentional miscut of 1°. A horizontal slice of the three-dimensional (3D) reciprocal map obtained by W-RHEED is shown in Fig.1. 5x1 spots and x2 streaks, which are characteristics of 5x2-Au surface, are clearly visible in Fig.1. Then, a 3D Patterson map was obtained by the Fourier transformation of the 3D reciprocal map. As the conclusion of the structural analysis based on the 3D Patterson map, we propose a new structure model for the Si(111)-5x2-Au. The new model consists of 0.6ML Au, which corresponds to 6 gold atoms in a 5x2 unit as shown in Fig.2. The six gold atoms form a tiny "Eiffel tower" laying on the Si surface. Although the structure of the Si substrate was not optimized in the present study, there is no space for the Si honeycomb chain, which was expected for the 5x2-Au surface [3]. The model is also consistent with the "Y" shape structure commonly observed in STM images [1].

SS-P1-02

Saturation coverage of alkali metal atoms on low-index Si planes evaluated by coverage-dependent SHG signal

T13 Surface Science

#SS-P1-02

T. Suzuki, A. Kokabu, F. Saito.

National Defense Academy - Yokosuka (Japan).

We report the dependence of the alkali metal (AM) densities at the saturation coverage θ_{sat} on the orientation of Si crystal planes by second-harmonic generation (SHG).

AM atoms are known to chemisorb to Si surface up to θ_{sat} at room temperature (RT) with the sticking probability of 1 and physisorption thereafter [1-3]. Desorption is negligible up to θ_{sat} , however desorption was observed from the multilayer Na structures even at RT in a temperature-programmed desorption experiment on Na/Si(111) [2]. To clarify the geometric and electronic structures of the AM-covered silicon surfaces at θ_{sat} , we investigated Rb adsorption by SHG on low-index planes. Clean Si surfaces were obtained by direct resistive heating Si wafers of Si(111), Si(100) and Si(110). Rb was evaporated from well-outgassed dispensers. SHG was obtained by using a Q-switched Nd:YAG laser (pulse energy 1 mJ) at 1064 nm directed at a *p*-polarized incidence angle of 45°. The reflected *p*-polarized SH light was detected using a photomultiplier tube with gated electronics.

Fig. 1 shows the SH intensity for the coverage dependence of Rb/Si under a constant flux. The flux was calibrated by the coverage dependence of Rb/as-received wafer (a). The typical features of SHG reported for AM adsorption are reproduced for all planes including A, the resonance enhancement among AM-derived surface states [3], B, and a dip followed by C, the roughness-induced excitation of surface plasmons [4]. The dip was assigned to θ_{sat} [3], and the adsorption period to the dip was 440 s, 390 s and 320 s for Si(111), Si(100) and Si(110), respectively. Thus, different value of θ_{sat} was obtained depending on the orientation of a crystal plane. The Si atom densities for the corresponding planes are 7.8/nm², 6.7/nm², 9.7/nm², respectively. Thus, the AM density at θ_{sat} for each crystal plane is clearly not correlated with the surface Si density.

In a separate experiment, the SH intensity C for Rb/Si sensitively showed a decrease with increasing sample temperature, and a fast decay after closing the shutter. The decay of the microcrystalline nature of the cold-deposited films by surface diffusion was attributed to the SH decrease. The decay of C fitted by a simple model resulted in the activation energies of ~ 0.2 eV for surface diffusion. The correlation between the AM densities at θ_{sat} and the surface diffusion for each crystal plane will be the next topics to be elucidated.

Initial steps of rubicene film growth on silicon dioxide

T13 Surface Science

#SS-P3-02

B. Scherwitzl, W. Lukesch, G. Leising, R. Resel, A. Winkler.

Graz University of Technology - Graz (Austria).

Studies of the initial stages of organic film growth are of great relevance for the use of organic materials in microelectronic devices. This contribution describes the behavior of rubicene ($C_{26}H_{14}$) film growth on silicon dioxide with respect to sample treatment under UHV conditions. Physical vapor deposition from a Knudsen cell was used to create films with varying thickness, from sub-monolayer up to multilayer range. A number of different analytical methods were used to examine film and substrate properties, namely Auger Electron Spectroscopy (AES) for chemical analysis, Thermal Desorption Spectroscopy (TDS) to determine desorption behavior and Atomic Force Microscopy (AFM) for a subsequent ex-situ analysis of the sample surface. It could be shown that the initial film formation of rubicene molecules on SiO_2 exhibits a quite unusual behavior. First a monolayer of flat lying molecules is formed, followed by a second layer. Further deposition of rubicene leads to a destabilization of this bilayer and to a dewetting process with a subsequent formation of bulk-like 3D islands. Different desorption energies suggest that the binding of the organic molecules to the substrate material is not as strong as among the molecules themselves as shown in Figure 1. This is the reason for the strong tendency to dewet. Another reason for a dewetting of the bilayer is the exposure of such a layer to atmospheric conditions. This has been shown by TDS and AFM measurements. Furthermore, for the island-like film under ambient conditions Ostwald ripening was observed, leading to films composed of few, large crystalline islands. In the case of very thin films most of the material in the small islands even disappeared by vaporization within several days. A further peculiarity of the adsorption system rubicene/ SiO_2 is related to the sticking coefficient. Contrary to common belief the initial sticking coefficient is not unity, even at low substrate temperatures. We measured an initial sticking coefficient of only 0.2 ± 0.05 , depending on the substrate conditions. This low value can be related to the relatively weak interaction energy between the molecules and the substrate, as well as to other reasons such as orientational hindering. Only a weak dependence of the adsorption and desorption behaviour on the substrate chemical composition was observed. Accumulation of

carbon on the surface, due to rubicene dissociation during sample heating, does neither significantly influence the shape of the desorption spectra nor the coverage dependence of the sticking coefficient.

Figure 1. Thermal desorption spectra of rubicene from clean silicon dioxide for different exposures. The exposure is given in Hz, as determined by a quartz microbalance.

SS-P1-03

Oxygen adsorption induced step rearrangement and growth of nano-lattices of Ni-O on Ni(755) and Ni(7911) stepped surfaces studied by STM

T13 Surface Science

#SS-P1-03

H. Namba, K. Yamanaka, N. Fukumoto, Y. Seino.

Ritsumeikan University - Kusatsu (Japan).

On stepped surfaces, a couple of a narrow terrace plane and an atomic step are periodically formed along a specific crystal direction. This step-terrace structure can give one dimensional boundary condition to determine the property of surface electronic states. Indeed, by means of angle-resolved photoelectron spectroscopy, we have found the formation of one dimensional surface states on Ni stepped surfaces. The dispersion relation of the surface states shows strong anisotropy in the direction perpendicular and parallel to step rows[1]. On the other hand, it is well known that steps on surfaces are active to chemisorption of foreign atoms. If foreign atoms are adsorbed selectively at steps or terraces, one dimensional arrays of the adsorbate are formed. So the step-terrace structure on surfaces is a useful template to grow new low dimensional materials in nano-scale. Up to now, many studies of chemisorption and reaction on stepped surfaces have been reported. In those it has been implicitly postulated that the step structure on the clean substrate is maintained through the chemisorption. So stability of the step-terrace structure has been paid little attention. Previously we have reported the first result of step rearrangement on Ni(7911) surfaces induced by atomic hydrogen adsorption[2]. As a function of atomic hydrogen dose, disordering and ordering of the periodic steps are clearly shown in LEED observation. This implies a flexible or soft nature of surface steps in hydrogen chemisorption. Recently we performed a series of oxygen chemisorption studies on Ni stepped surfaces by means of STM, LEED and work function measurements[3]. Two types of the step-terrace structure on stepped surfaces of Ni were chosen as substrate. An ideal model of Ni(7911)[=5(111)x(-101)] surfaces shows repetition of 3- and 4-fold sites at the step edge in [-101]. So the step shape is zigzag. In contrast to Ni(7911), the step on Ni(755)[=6(111)x(100)] has only 4-fold sites. The step along [100] of Ni(755) is smooth. In this conference, we compare the dynamical properties

of surface steps in the process from oxygen chemisorption to formation of low dimensional Ni-O complexes on the surface.

Firstly oxygen selectively adsorbed at step edges on both surfaces. And this induces roughening or disordering of step rows. Further adsorption does not progress step roughening, but recover the step periodicity. Finally, on Ni(7911), nano-lattices with 2x1-like rectangular structure are formed beyond the border due to step edge. On Ni(755), 2x2 hexagonal nano-lattices are formed at each terrace plane, but do not grow beyond the step edge. This forms one-dimensional row of nano-lattices at each terrace plane. The crystal structure of the terrace plane on both stepped surfaces is fcc(111) commonly. Growth of nano-lattices on each surface is clearly different due to the step shape. The present result of roughening or disordering of the step-terrace structure can be very important at growth at elevated temperature. These are key factors to design nano-scale materials.

Growth and magnetic properties of lowdimensional oxide films on a support: CoO/Ir(100)

T13 Surface Science

#SS-7-Or-9

F. Mittendorfer ¹, J. Redinger ¹, R. Podloucky ², M. Weinert ³.

¹TU Vienna - Vienna (Austria), ²Univ. Vienna - Vienna (Austria), ³Univ. Wisconsin-Milwaukee - Milwaukee (United states).

The support of epitaxial films frequently determines their crystallographic orientation, which is of crucial importance for their electronic and magnetic properties. Although the surface stress in the oxide layer is usually seen as the main driving force for its orientation, we could recently show in a combined theoretical and experimental study that the interface chemistry can play a crucial role [1]. This allows for a novel way to alter the film orientation without changing the substrate.

I will present our results for the growth of CoO on the Ir(100) surface, obtained on the basis of DFT calculations with the Vienna Ab-initio Simulations Package (VASP). While the oxide grows in (111) orientation on the bare substrate, the orientation switches to (100) by introducing a single (or a few) monolayer(s) of Co between the oxide and substrate due to the enhanced interaction at the interface.

In addition, I will report on the magnetic ordering in the ultrathin hexagonal c(10x2) CoO(111) film supported on Ir(100). In that case, we find a close relationship between the local structural properties of the oxide film and the induced magnetic order, leading to alternating ferromagnetically and antiferromagnetically ordered segments [2]. While the local magnetic order is directly related to the geometric position of the Co atoms, the mismatch between the CoO film and the Ir substrate leads to a complex long-range order of the oxide.

In-situ production, electrical and surface analytical characterization of pentacene thin film transistors

T13 Surface Science

#SS-11-Or-2

R. Lassnig ¹, B. Striedinger ², A. Fian ², B. Stadlober ², A. Winkler ¹.

¹Graz University of Technology - Graz (Austria), ²Joanneum Research Weiz - Weiz (Austria).

Electronic devices based on organic semiconductors are on the verge of taking over large shares of the markets dominated by inorganic systems. While the possibilities to create and optimize organic devices are clearly present, the underlying principles affecting critical parameters such as performance and lifetime are not fully understood to the present date. In order to contribute a new approach to the vast worldwide research on organic semiconductors, we present an analysis on the formation and stability of the semiconducting layer in organic field effect transistors (OFET) through a unique combination of organic layer deposition and in-situ electrical and surface analytical characterization, all performed under ultra-high vacuum conditions. As a well-established model material for organic semiconductors, pentacene was deposited onto pre-contacted SiO₂/Si samples through physical vapor deposition (PVD) from a Knudsen cell (bottom gate/bottom contact architecture). The whole sample was clamped onto a stainless steel plate, which allowed cooling and heating in the range from 110 K to 800 K (see Figure 1). The thickness of the deposited pentacene layer could be monitored in the range from sub-monolayer to the multilayer regime by parallel exposure of a quartz microbalance. During and subsequent to deposition the OFET devices were characterized through in-situ electrical characterization, yielding output and transfer characteristics, which were monitored as a function of several factors affecting the semiconducting layer growth and performance, such as layer thickness and device temperature. To reach conclusions about the layer growth and possible growth affecting contaminations, in-situ Auger electron spectroscopy and thermal desorption spectroscopy (TDS) were performed throughout the stages of the device fabrication, parallel to the electrical investigations. Ex-situ atomic force microscopy, in combination with in-situ TDS, enabled the differentiation between layer and island-like growth and the corresponding electrical characteristics of analyzed devices.

While the basic reference for all measurements consisted of well-established bottom gold-contact pentacene organic field effect transistors with highly doped silicon substrates and silicon dioxide as a dielectric, our experimental setup allows a wide range of sample modifications. The simple modification of channel and sample dimensions, as well as changes of the semiconducting organic, contact pad and substrate material enables a wide spectrum of possible test device configurations.

In this paper, we present a Rashba system that shows a peculiar non-vortical spin structure around the Γ point. Rashba effect [1] is a novel exotic low-dimensional solid-state property that produces a spin-polarized two-dimensional electron gas from a combined effect of spin-orbit interaction and structural inversion asymmetry even for nonmagnetic materials. In an ordinary Rashba system, the constant energy contour shows isotropic vortical spin structures around the Γ point, with spin polarization vectors lying in the surface plane. Together with its scientific interest, Rashba effect has an interest in the application field since it is the key factor for operating spin field-effect transistor [2] that is one of the most prominent semiconductor spintronics devices. By using spin- and angle-resolved photoelectron spectroscopies, we have measured the Rashba spin bands of a TI/Si(110)-(1x1) surface, a system with a quasi-one dimensional atomic structure and C_{1h} symmetry. So far, symmetry induced peculiar Rashba effects have been discussed on threefold symmetry systems [3-5]. In these systems, peculiar spins were observed at the boundary of the surface Brillouin zone, and the spin structures around the Γ point were vortical like the ordinary systems. These spin structures observed on threefold symmetry systems are completely different from the present result shown in the figure. Taking the polarization vector of the spins along the Γ -X' direction into account, we obtained peculiar upstanding spins at the apex of the elliptical structure. Furthermore, the spin-polarization vectors along the Γ -X' direction indicate that the probability of inter valley scattering would be negligible. We will also discuss the

origins of the peculiar spin structure based on the symmetry of the surface. Furthermore, since the present system is formed on silicon substrates, the present results would provide a significant step toward the readily realization of silicon spintronics devices with high-efficiency.

Heterogeneous catalysts have proven remarkably successful in catalyzing a wide range of important processes, in fuel-cells, exhaust emission control and in hydrocarbon processing. However, the effects of the operating environment on the surface composition, structure and stability of the noble metal catalysts are poorly understood at the atomic-scale. This knowledge will be required to produce the improved catalysts needed for future energy- and materials-efficient technologies.

Atom probe tomography (APT) offers a unique method for studying these materials, providing atomic-scale chemical characterization of the catalyst surfaces and chemisorbed species. We have used APT to show a rich variety of behavior in an extensive range of Pt-group alloys, investigating the effects of high temperature oxidation exposures on these surfaces. The results reveal pronounced surface segregation behavior, strongly dependent on the treatment conditions, crystallographic planes and alloy compositions [1-3]. Recent work has also shown that trends identified in binary alloys often cannot fully explain those seen in ternary alloys, underlining the need for further atomic-scale investigations. Additionally, while subsequent reduction treatments remove any oxides formed, the marked changes to the metallic surfaces remain. Such results suggest using sequential oxidation and reduction treatments as an alternative synthesis method for designing and preparing nano catalysts with controlled surface compositions. A range of results from these systems will be presented to contrast and highlight the unique behaviors.

In parallel to the fundamental work on catalyst alloy wire samples, we have successfully used APT to characterize core-shell nanoparticles as used in real

catalytic applications, uniquely revealing the core-shell structure clearly in the data [4]. These core-shell materials offer the possibility of finely-tuning the surface activity of bimetallic catalysts to maximize their efficiency. Alongside a description of the sample preparation methods, we will discuss a range of results from these materials, highlighting the correlation between catalytic efficiency and the atomic-scale chemical/structural information uniquely provided by APT.

Structural and morphological characterization of self-organized nanoporous oxides: TiO₂, Al₂O₃ layers. Potential applications.

T13 Surface Science

#SS-P1-18

M. Pisarek.

Institute of Physical Chemistry PAS - Warsaw (Poland).

Oxides of titanium (TiO₂) and aluminum (Al₂O₃) have been widely studied around the world in recent years. The high level of interest in these materials is due to their wide application in such fields as photovoltaics, catalysis, lithography, optoelectronics, as protective coatings, self-cleaning coatings, bio-sensors and in biomedicine. Moreover, nanoporous layers of aluminum oxide are widely used as “templates/matrices” for creating metallic nanofibres, semi-conductors and conductive polymers. The use of anodic oxidation (anodic polarization) as a method of forming nanostructured oxide layers on metals affords numerous possibilities for controlling their morphology. The anodic oxidation of Ti and Al in neutral or acidic solutions containing fluorides is a typical electrochemical method of surface modification allowing oxide layers of varying thickness, porous morphology in the form of tubes having a diameter of from teens of nm even to several μm. The thickness of such a oxide layer can be controlled through anodization time and applied voltage. Such a wide range of diameters makes it possible to control the porosity and surface properties of the materials under study. The tubes are oriented at ninety degrees to the substrate. The possibility of self-organized oxide layers fabrication (nanotubes) opens a new field of application of such materials, for example: for preparing composites like materials with different amounts of silver deposit for preparation active substrates for SERS investigations of organic adsorbates, which exhibit antibacterial properties and also can be used as a promising substrate for heterogeneous catalysis. In all applications – SERS, biomedical, catalysis – metal particles play an important role which is crucial for these different functionalities.

The application of graphene in future devices will depend on the possibility to tune its band structure. One desirable way to achieve this is substitutional doping, as this leads to a considerably higher stability than e.g. charge transfer doping by adsorbates. Here we will show different ways to prepare nitrogen- and boron-doped graphene, i.e., via classical CVD approach and in the case of nitrogen doping also via ion implantation. The systems are analyzed with x-ray photoelectron spectroscopy (XPS) and angle resolved photoemission (ARPES). The experimental findings are compared and supported by ab initio density functional calculations. [1] In the case of nitrogen doping we find two chemically different nitrogen species on the surface, namely pyridinic and substitutional nitrogen, whose concentration and relative abundance can be altered by the experimental conditions, see Figure 1. The ARPES measurements show a broadening of the bands and p-doping. In order to decouple the nitrogen-doped graphene from the nickel surface we used gold intercalation, leading to the electronic structure of quasi free standing graphene, while preserving the nitrogen doping. The DFT analysis shows excellent agreement; furthermore, it indicates the possibility to obtain n-doping for substitutionally doped graphene. The introduction of boron in the graphene network leads to solely one chemical species and a strong p-doping. ARPES shows similar effects as for nitrogen, with a broadening of the bands and a retained band structure. From the DFT calculations we find a strong preference of boron-doped graphene for the top-fcc geometry, while in the case of nitrogen doping no preferred site was found. Additionally, we find a buckling of the graphene layer due to the reduced adsorption distance of boron as compared to carbon.

Institute of Applied Physics, University of Hamburg - Hamburg (Germany).

Magnetism in thin films can significantly deviate from commonly known magnetic configurations in bulk systems due to low dimensionality, hybridization effects, a change of the lattice constant, stacking and broken inversion symmetry at interfaces. Both monolayer and double layer systems were recently found to exhibit non-collinear magnetic states such as spin spirals or skyrmion lattices [1-4]. A change on either top or bottom interface may result in different magnetic states. While in the past, magnetism was tuned by the choice of the underlying substrate resulting in various magnetic configurations [1,3,4], here we follow a different approach. We perform spin-polarized STM studies to investigate the influence of non-magnetic adlayers on above mentioned systems. Thus we find interesting magnetic field and temperature dependent behavior.

Lehrstuhl für Physikalische Chemie II, Universität Erlangen-Nürnberg - Erlangen (Germany).

Hydrogen storage in Liquid Organic Hydrogen Carriers (LOHC) is a possible future technology to circumvent the challenges in hydrogen use and storage.^{1,2} The dehydrogenation, i.e. the hydrogen release, of the LOHC dodecahydro-N-ethylcarbazole (H₁₂-NEC) on Pt(111) was studied by high-resolution X-ray photoelectron spectroscopy (HR-XPS) in order to elucidate the relevant elementary steps. H₁₂-NEC was adsorbed under ultra high vacuum (UHV) conditions, and subsequently the reaction was monitored during heating. Although the molecules are quite complex to be studied under surface science conditions, we were able to identify the reaction steps based on a detailed analysis of the C1s and N1s core level spectra. During adsorption at low temperatures the development of monolayer and multilayer peaks was observed. Interestingly, the N1s peak assigned to the multilayer is found at lower binding energy than the monolayer peak. When heating the sample continuously, the multilayer desorbs until temperatures of about 240 K, with the monolayer remaining on the surface. The dehydrogenation of the H₁₂-NEC to NEC occurs between 280 and 500 K. Starting at 390 K, in addition the dealkylation reaction of the NEC to carbazole is observed. Upon further heating to 1000 K decomposition to adsorbed carbon takes place. The reaction scheme, as deduced from the quantitative analysis, is shown in Fig. 1. The dealkylation reaction and the subsequent decomposition of carbazole are detrimental for the concept of using H₁₂-NEC in a regenerable hydrogen storage cycle.

SS-1-Or-8

DFT study of dopamine adsorption on TiO₂ surfaces

T13 Surface Science

#SS-1-Or-8

D. Castillo Malla, J.E. Ontaneda Rojas, A. Stashans.

Universidad Técnica Particular de Loja - Loja (Ecuador).

Titanium dioxide, TiO₂, is of technological interest in applications including photocatalysis, biomaterials, and novel photovoltaic solar cells [1]. The adsorption of large organic molecules on oxide surfaces is rapidly gaining in technological importance, for example, in dye-sensitization of solar cells.

The present theoretical study is devoted to investigate adsorption of dopamine, C₈H₁₁O₂N, on rutile (110) and anatase (101) surfaces, respectively. Using density functional theory (DFT) within the generalised gradient approximation as well as DFT+U approach, we study atomic-scale properties of the dye-TiO₂ interface, such as the molecular orientation, adsorption geometry, and adsorption sites, which are fundamental parameters in the basic understanding of the electron transfer reaction from any dye molecule to the TiO₂ particles.

Geometry of free dopamine molecule consisting of 22 atoms has been successfully reproduced to fit experimental data [2]. In order to study the adsorption phenomenon, a slab of 144 atoms (96 oxygens and 48 titaniums) with eight atomic layers and 12 Å of vacuum space has been used to model the rutile (110) surface. In case of the anatase (101) surface, a supercell of 216 atoms (144 oxygens and 72 titaniums) with 14 Å vacuum space has been exploited.

The first results of our on-going research demonstrate that dopamine molecule is likely to adsorb on the rutile (110) surface by positioning itself vertically, i.e. the plane of the aromatic ring is oriented roughly normal to the surface with the molecule being upright on the surface as shown schematically in Fig. 1. In this particular configuration, each one of the oxygen atoms of the molecule creates a chemical bond with a titanium atom on the surface. While there are several other chemisorption possibilities, we feel that our study illustrates the kind of geometric and electronic effects which are essential to adsorption of large organic molecules on TiO₂ surfaces. The computed Ti-O distances are found to be between 2.30 y 2.40 Å, respectively. We expect similar outcome also for the dye adsorption on the anatase (101) surface.

Results obtained from the Bader charge analysis show that there exists electron

transfer from the dye molecule towards the TiO₂ surface. Performed density of states calculation implies that the dopamine adsorption leads to reduction of the band-gap width from 2.0 eV (pure rutile-TiO₂ crystal) to 1.5 eV (rutile-TiO₂ surface with the adsorbed dye). Such a band-gap reduction is favourable for tentative photovoltaic applications.

Metal-semiconductor eutectics are important for contact formation and control the growth of semiconductor nanowires and related structures through the Vapor-Liquid-Solid process. We have investigated the dynamics of AuSi eutectic formation in non-equilibrium conditions by depositing 12-300 nm Au films on native-oxide passivated Si(100) substrates. When heated to ~ 600° C, the oxide film fails, allowing contact between the Au and Si phases above the 363° C eutectic temperature. Si and Au rapidly interdiffuse, forming a eutectic liquid disk expanding at up to 15 μm/s along with an inverted eutectic pyramid embedded in the Si substrate and bounded by Si {111} planes.[1] Once the liquid disk is larger than ~ 10 μm it becomes unstable and dewets, isolating the bulk Si and Au phases and leaving eutectic droplets on the sample surface and an exposed Si disk with the square surface of the eutectic pyramid in the center. A silicon-rich surface phase also forms on the Au surface around the dewetting disk. (An SEM video is available online [2]). On cooling below the eutectic temperature the liquid regions phase-separate and freeze. We have performed in-situ SEM and high-spatial-resolution Auger experiments to investigate the dynamics of AuSi eutectic phase formation as a function of Au film thickness, the Si-rich Au surface phase, and temperature-dependent surface segregation at the AuSi eutectic-vacuum interface. The eutectic reaction dynamics and the nature of the Si surface phase will be discussed.

Relationship between Strain and Effective Mass in the Metallic Surface State of the $\sqrt{3}\times\sqrt{3}$ -Ag Structure on Si(111) epitaxial layer

T13 Surface Science

#SS-15-Or-1

Y. Shigeta, T. Ishii, A. Tosaka.

Yokohama City University - Yokohama (Japan).

Much interest has been attracted on a microscopic lattice strain, because it has a large possibility to design nanoscale properties. The electronic property of the nanostructure depends on its structure including the lattice strain to stabilize the nanostructure. To make clear the relation between electronic states and strain in nanoscale structure, the study in two-dimensional system is very useful and the results will give possibilities for nano-electronics applications.

We have focused on the quasi two-dimensional electron gas (2DEG) state formed on the $\sqrt{3}\times\sqrt{3}$ -Ag structure, which is typically reconstructed by Ag adsorption (1 ML) on the Si(111) or the Ge(111), because the dispersion of the 2DEG state could be modified with the lattice strain introduced by heteroepitaxial growth such as the Ge/Si(111) or the Si/Ge(111). The compressive strain is induced to the surface layer by the epitaxial growth of the Ge on the Si (111), and the tensile strain is induced by the growth of the Si on the Ge (111). The relation between the surface electronic state and the lattice strain of the strain-induced $\sqrt{3}\times\sqrt{3}$ -Ag structures is investigated by using scanning tunnelling microscopy and angle resolved ultraviolet photoelectron spectroscopy. When the inter-atomic spacing expands (/contracts) about 2.1% (/ -2.7%), the values of effective mass of the 2DEG, m^* changes about 30% (/ -32%), as shown in Fig. 1 [1,2].

Since the change of m^* is consistent with the view of “*d*-band model” on some metal surfaces, qualitatively [3], the detailed relation of the m^* to the amount of the strain from -3% to +3% is not known but very interesting. To measure the detailed relation, we used SiGe buffer layers, whose lattice spacing depend on the ratio of the composition. The preliminary results show that the relationship between the m^* and the strain is not linear relation.

Grafting of Vinylferrocene Molecules onto the Si(111) Surface using Photochemical Preparation

T13 Surface Science

#SS-9-Or-2

M. Herrera, T. Ichii, K. Murase, H. Sugimura.

Kyoto University - Kyoto (Japan).

The Fe atom of ferrocene molecule has two reversible and stable oxidation states. Its oxidation state can increase from + 2 to +3 upon the introduction of potential and can revert back to +2 when grounded. With these characteristics, the ferrocene molecules on semiconductor surfaces are promising materials for the construction of memory storage devices. We are successfully in preparing vinylferrocene-terminated Si(111) using a photochemical preparation technique. The preparation involved illuminating a hydrogen-terminated Si(111), which was immersed in a vinylferrocene-dibutyl ether solution, with visible light. The success of the grafting method was attributed on the presence of photogenerated charges on the silicon surface (Figure 1). The Fe 2p spectra of the samples show that the oxidation state of Fe atoms in the vinylferrocene layer are mainly +2, which are associated with the existence of neutral ferrocene molecules. The AFM images show that the stair-like structure of the hydrogen-terminated Si was preserved even after grafting. This indicates that the vinylferrocene-terminated Si has an atomically flat surface. On the other hand, the sample with n-type substrate has optimum grafting time of 0.5 h while that of p-type substrate is 1 h. At optimum grafting time, both the samples with n-type and p-type substrates have C/Fe ratio of 12.4, which is close to the ideal value of 12. The cyclic voltammograms of the sample show the presence of anodic and cathodic peaks (Figure 2) that signifies that the vinylferrocene molecules are electrically connected with the Si surface. Meanwhile, the separations between the anodic and cathodic peaks are small. This signifies that the redox reaction does not involved diffusion of redox species. In addition, the graphs of peak current density vs. scan rate are linear. This indicates that the oxidation-reduction reaction is confined within the surface of the sample.

New software tool for I-V LEED analysis being applied to model catalysts

T13 Surface Science

#SS-3-Or-5

J. Lachnitt, D. Mazur.

Faculty of Mathematics and Physics, Charles University - Prague (Czech republic).

I-V LEED is an indirect but powerful technique of crystalline surface structure analysis. The experimental aspect of I-V LEED lies in measuring the dependence of diffraction spot intensities on applied voltage (electron energy). Thus we get intensity-voltage (I-V) curves, one for each inequivalent spot. The theoretical part lies in modelling the I-V curves for given surface structures and searching such a structure, I-V curves of which fit best the experimental ones.

I-V LEED can determine the positions of atoms within several topmost atomic layers with the accuracy of about 0.01 Å but it requires a computational processing which is demanding on both the computer and the researcher. SATLEED software package [1], along with Phase shifts package [1], provides all the necessary tools for the analysis. However, SATLEED is, from the contemporary point of view, very user-unfriendly and it requires a lot of user work that can be automated. The presenter of this contribution has developed a software tool called AutoLEED, which realizes this automation.

AutoLEED is a software overlayer on SATLEED, written in Python. The user still has to design the structural models of the studied surface but the input is much simpler and routine operations are done automatically.

With the help of AutoLEED, we analyze several planar model catalysts. These catalysts are also studied by other experimental techniques in our department. The detailed structure information provided by I-V LEED is crucial for the understanding of the principle of catalysis on given surface. This understanding can help in the development of practical catalysts.

The catalysts studied include a V-Rh(110) surface alloy and a thin cubic Ce₂O₃ film on Cu(111) [2]. The results are not known by the time of abstract submission and other catalysts may be studied in the meantime.

The interaction of O₂ with the surface of polycrystalline gadolinium at the temperature range 300–670 K

T13 Surface Science

#SS-P3-09

S. Cohen ¹, N. Shamir ², M. Mintz ², I. Jacob ¹, S. Zalkind ².

¹Dept. of Nuclear Eng., Ben-Gurion University of the Negev - Beer Sheva (Israel), ²Nuclear Research Centre-Negev - Beer Sheva (Israel).

Direct-Recoil-Spectrometry (DRS) and Auger-Electron-Spectroscopy (AES) were applied to study the interaction of O₂ with a polycrystalline gadolinium surface, in the temperature range 300–670 K and oxygen pressure up to 2×10^{-6} Torr. It has been found that the initial uptake of oxygen and surface coverage, as measured by DRS and fitted to the clustering (one site) adsorption model, Fig. 1, results in rapid oxide island formation [1]. The subsurface is believed to be a mixture of oxide and oxygen dissolved in the Gd metal, the latter being the mobile species, even at relatively low temperatures.

Enhanced inward diffusion of oxygen into the Gd starts as early as 420 K and dictates the surface oxygen concentration and effective thickness of the forming oxide. The oxygen accumulation rate at the near-surface region, as measured by the O(KLL) AES signal intensity, goes through a maximum as a function of temperature at 420 K. This is a result of the combination of still efficient oxygen chemisorption that increases surface occupation and slow inward diffusion. The thickest oxide, ~1.7 nm, is formed at 300 K and its effective thickness decrease with increasing temperature (due to oxygen dissolution into the metal bulk). Diffusion coefficients of the oxygen dissolution into the bulk were evaluated from the attenuation of the O (KLL) signal over time, as depicted in Fig. 2. The best fit under our experimental procedure was obtained by the thick layer model [2]. The coefficients that were calculated are $D_0 = 2.2 \times 10^{-16} \text{ m}^2 \text{ s}^{-1}$ and $E_a = 46 \text{ kJ/mol}$ [3].

Tailoring the electronic structures of graphene oxides by low-energy N₂⁺ ion sputtering: reduction and N-doping

T13 Surface Science

#NST/SS-8-Or-10

J. Zhu, L. Zhang.

National Synchrotron Radiation Laboratory, University of Science and Technology of China - Hefei (China).

Doping graphene with heteroatoms (such as N, H and B) provides a promising and feasible way to tailor its unique electronic structures, which is of great importance for its potential applications in nanoelectronics, supercapacitors, sensor devices and fuel cells. In this presentation, we report a facile and catalyst-free method to obtain N-doped reduced graphene oxides (N-RGO) through low-energy N₂⁺ ion sputtering of graphene oxides (GO). The simultaneous reduction and N-doping of GO during the sputtering process were investigated by the X-ray photoelectron spectroscopy (XPS), near edge X-ray absorption fine structure (NEXAFS) and Raman spectroscopy. The degree of N-doping and GO reduction, which can be respectively determined from the N/C and O/C atomic ratios from the quantitative XPS analysis, can be easily controlled by varying the N₂⁺ ion sputtering time. In addition, three different N bonding configurations can be distinguished in N-RGO, namely, the nitrile-like N, the graphitic N and the pyridinic N. This easy and catalyst-free approach offers a great opportunity for fabricating large-area and low-cost N-RGO with controllable N-doping and reduction level for various practical applications in the future.

This work is supported by the National Natural Science Foundation of China (Grant No.21173200) and National Basic Research Program of China (2010CB923302)

Direct Observation of Topological Solitons in a Quasi-1D Charge-Density Wave

T13 Surface Science

#SS-8-Or-4

T. Kim, H.W. Yeom.

Pohang University of Science and Technology - Pohang (Korea, republic of).

In 1834, a naval engineer John Scott Russell first observed a self-reinforcing and constantly traveling solitary wave in the Union Canal in Scotland. This beautiful phenomenon due to the nonlinearity of wave media is now called a soliton and has important roles in modern technology like optical communication. While macroscopic and classical solitons are easily and ubiquitously observed, from tsunami to blood pressure pulses, those in microscopic and quantum world of atoms and electrons are hard to observe. For example, in conducting polymer chains, solitons are known to exist as topological excitation from the degenerate charge-density wave (CDW) ground states with strange spin and charge relationship. While the existence of such quantum solitons were predicted theoretically and evidenced indirectly by the transport and infrared spectroscopy measurements, the direct observation has been hampered by their high mobility and nanometer dimension. In this talk, we clearly image by scanning tunneling microscopy the quantum soliton in the commensurate (2a) CDW ground states of indium atomic wires grown on a silicon surface [1-4]. The solitons exhibit a characteristic spatial variation of the CDW amplitudes with a coherence length of about ~4 nm (see the figure), as expected from the electronic structure of the CDW state. While most of the observed solitons are trapped statically by the defects, moving solitons are also identified when they are trapped transiently. This work paves the avenue toward the microscopic exploitation of the peculiar properties of quantum solitons in solid-state physics.

Understanding the nature of TiOx- Graphene interface for a rational design of advanced nanoarchitectures

T13 Surface Science

#SS-7-In-1

G. Granozzi ¹, M. Favaro ¹, S. Agnoli ¹, C. Di Valentin ², C. Mattevi ³.

¹University of Padova - Padova (Italy), ²University of Milano Bicocca - Milano (Italy), ³Imperial College - London (United kingdom).

Recently, TiO₂/graphene systems have attracted a lot of attention for environmental and energy applications,^{1,2} such as photo-catalytic degradation of pollutants,³ photo-catalytic hydrogen generation,⁴ and electrochemical energy storage.⁵ However, this field is still denoted by a high level of empiricism and a complete understanding of either the atomic structure of these materials or the reason of their advanced properties is still missing. In the present contribution, we present a detailed investigation of the structural properties of the TiOx/graphene oxide interface based on synchrotron radiation photoemission and *ab initio* calculations. The evolution of the C 1s photoemission spectra during Ti deposition in ultra high vacuum by physical vapour deposition, indicates that carboxyl and carbonyl groups disappear after metal deposition, and similarly epoxy and tertiary alcohol species strongly decrease. On the contrary, the sp² C fraction gets more intense indicating the recovery of the honeycomb lattice of graphene. A microscopic view of this process has been determined by density functional calculations: epoxy and hydroxyl groups, the most common surface species present of graphene oxide, interact very strongly with metal Ti leading to the disruption of C-O bond, extraction of the O atom and to the formation of Titanium (hydr)oxide species. Concomitantly C atoms heal the initial defects re-forming perfect graphene.⁶ However, when the available oxygen species on graphene oxide surface are consumed by Ti oxidation, metal atoms can react with the carbon backbone, and form carbides as evidenced by the appearance of new components in the C 1s and Ti 2p photoemission spectra. These results can give important indications about the rational for building atomically precise interfaces exhibiting C-O-Ti or C-Ti bonds which is a fundamental parameter for controlling the electronic transfer in nanocomposite. Moreover, this work demonstrates that the evaporation of an easily reduceable metal can be used as a versatile tool for the reduction of graphene oxide: by its nature, this all-solid-state surface reduction does

not lead to the removal of carbon as CO or CO₂ like in the case of thermal reduction or of other chemical methods, allowing obtaining a fully reduced and complete carbon network. If the evaporation of Ti is performed in oxidative conditions keeping the substrate at a certain temperature, different types of composites can be obtained. In particular, by optimizing deposition conditions (T=650°C, PO₂=10⁻⁶ mar), as determined by a combination of SEM, AFM, XPS, and XAS, it is possible to prepare anatase-graphene systems, where the nanoparticles decorate selectively graphene ripples. This approach paves the way to a new concept in the synthesis of new materials, which consists in the exploitation of the local curvature of graphene as a sophisticated tool for tailoring spatially heterogeneous systems.⁷

Characterization of Pd(100) surface under catalytic conditions with High Energy Surface X-Ray Diffraction

T13 Surface Science

#SS-3-Or-8

M. Shipilin ¹, J. Gustafson ¹, C. Zhang ¹, A. Stierle ², U. Hejral ², U. Ruett ³, O. Gutowski ³, M. Skoglundh ⁴, P.A. Carlsson ⁴, E. Lundgren ¹.

Surface X-ray diffraction (SXR) is a powerful tool to study surface structures, and has been used for many years to determine the exact atomic positions at surfaces. The technique is particularly useful at conditions not accessible with electron based surface techniques. However it has a major drawback of limited amount of reciprocal space that is observable within a reasonable timeframe. In this contribution, we present results from using grazing incidence photons of 85 keV to perform High Energy Surface X-Ray Diffraction (HESXR) combined with a large area X-ray detector. Using high energy photons for diffraction flattens the Ewald sphere to reveal a large part of reciprocal space in a matter of seconds which significantly facilitates the data collection while the small angle of incidence allows to achieve high surface sensitivity. Experiments were carried out at the beamline P07 of Petra III at Deutsches Elektronen-Synchrotron (DESY) [1]. Specially designed UHV chamber/reactor allowing pressures in the 10^{-10} mbar range was used to prepare the samples and to create the desired environment for catalytic reactions [2]. In SXR/HESXR technique the position of surface atoms are probed via so-called crystal truncation rods (CTRs) or in the case of a surface reconstruction or adsorbate surface structure also via superlattice rods. Our study focuses on a Pd(100) single crystal surface under relatively harsh reaction conditions, and in particular on the $(\sqrt{5}\times\sqrt{5})R27^\circ$ surface oxide formed during oxidation. The rotation of the sample in the beam results in a sequence of images covering the significant part of reciprocal lattice and revealing CTRs step by step. By collecting the most intense pixels from

each image, an image representing a comprehensive diffraction pattern from the surface structure can be obtained (fig.). The regular lattice CTRs apparently belong to Pd(100) substrate while the superlattice CTRs represent $(\sqrt{5}\times\sqrt{5})R27^\circ$ surface oxide structure. Analyzing the positions and intensity distribution along the CTRs and the superlattice rods the structure factors can be extracted and the full surface structure can be determined by comparing measured and calculated structure factors. Further, by choosing an appropriate location in reciprocal space and observing the dynamics of diffraction pattern, studies in harsh environments such as catalysis, growth processes, electrochemistry etc can be done with sub-second time resolution.

STM investigation of CO ordering on Pt(111) : from an isolated molecule to high coverage superstructure

T13 Surface Science

#SS-1-Or-2

H. Yang ¹, Y. Kim ², M. Kawai ¹.

¹Univ. of Tokyo - Kashiwa (Japan), ²RIKEN - Wako (Japan).

We report coverage-dependent observation of CO on Pt(111) using scanning tunneling microscopy (STM) in ultra-high vacuum at cryogenic temperature. From a single CO adsorbed on the atop site and its lateral hopping via $2\pi^*$ state[1] characterized with action spectroscopy, to gradual development of overlayer

structures including atop-dominant $\sqrt{3} \times \sqrt{3} R30^\circ$ islands, $c(4 \times 2)$ domain, and 1×1 boundary in $c(4 \times 2)$ -2CO domain were visualized as seen in Figure (a)[2,3]. Bridge species start to appear at the edge of $(3 \times 3)R30^\circ$ islands, significantly where the edge between edge

of $\sqrt{3} \times \sqrt{3} R30^\circ$ islands forms local $c(4 \times 2)$ -2CO structure. With increasing the coverage,

phase transition from $\sqrt{3} \times \sqrt{3} R30^\circ$ islands to wholly covered $c(4 \times 2)$ domain was observed

where the $c(4 \times 2)$ domain including bridge-vacancies aligned to $[1\bar{1}0]$ direction. Where the bridge vacancy exist, the topographic height atop CO in $c(4 \times 2)$ geometry is modulated by the number of adjacent bridge CO (Figure (b)). The origin of height modulation is discussed as the electrostatic interaction between atop and bridge CO due to the opposite direction of dipole.

Interaction of Rh with Rh nanoparticles encapsulated by ordered ultrathin TiO_x film on TiO₂(110) surface

T13 Surface Science

#SS-7-Or-3

A. Berkó ¹, R. Gubó ², L. Óvári ¹, Z. Kónya ¹.

¹MTA-SZTE Reaction Kinetics and Surface Chemistry Research Group, Hungarian Academy of Sciences - Szeged (Hungary), ²Department of Applied and Environmental Chemistry, University of Szeged - Szeged (Hungary).

Deposition and thermal stability of Rh were studied on TiO₂(110) surface covered partially by TiO_x-encapsulated ribbon-like Rh nanoparticles by scanning tunneling microscopy and spectroscopy (STM-STs). These giant Rh particles of approximately 30 x 150 nm² lateral size, 20 layer thick and flat top facet of (111) were grown on a clean TiO₂(110) surface by physical vapour deposition (PVD) of Rh (appr. 7 ML - equivalent monolayer) at room temperature (RT) and annealing at 1050 K for a few minutes. The region of the TiO₂(110) surface occupied by Rh was approximately 35 % of the total area and the Rh(111) top facets of the nanoparticles were completely covered by ultrathin (UT) and well ordered hexagonal "wagon-wheel" TiO_x encapsulation film (hUT-TiO_x)^{1,2} (Figure 1). This configuration made it possible to follow parallelly the particle formation both on the encapsulation layer and the atomic terraces of clean TiO₂(110). On the effect of deposition of Rh onto this surface at RT, the oxide encapsulation film becomes strongly disturbed without any sign of ordering at the lowest coverage regime (0.01-0.03 ML) studied. It was found that even at larger coverages (up to 1 ML), one monolayer thick 2D adparticles are formed on the encapsulation film at RT. Their lateral size increases gradually from 1 nm up to 15-20 nm in the temperature range of 500-1000 K, attributable to thermally activated Ostwald-ripening. Below 700 K, the top facet of these 2D particles exhibits unordered chemical contrast suggesting mixed composition, while above this temperature the constant height STM images indicate the development of well ordered hexagonal "wagon-wheel" structure even on the top of the newly formed nanoparticles. The formation of hUT-TiO_x film on the top of the adparticles becomes to be completed at appr. 800 K, where a Rh_{particle}-Rh_{ad}-Ti-O layer-sequence can be assumed. These results are in good harmony with those obtained by low energy ion scattering measurements indicating a partial outmost position of Rh up to 700-800 K. The

electronic characterization of the adparticles by STS was also performed in the different stages of the annealing treatment and will be evaluated in the light of the structural model suggested.

A full reaction scheme of photocatalytic methanol oxidation to CO on a rutile TiO₂(110) surface with solid spectroscopic evidence

T13 Surface Science

#SS-7-Or-10

W. Huang, Q. Yuan.

University of Science and Technology of China, Department of Chemical Physics - Hefei (China).

Photochemistry of methanol acts as a prototype system for the fundamental understanding of complex photocatalytic reactions, but its fundamental understanding is still limited to the photocatalytic oxidation of methanol to formaldehyde on rutile TiO₂(110) surface. Here we report the full reaction scheme of photocatalytic methanol oxidation on rutile TiO₂(110) to CO acquired by TDS and XPS. Irradiated by UV light, methanol can sequentially be converted to methoxy group, formaldehyde and formate; Formate can undergo three different reaction pathways: photocatalytic cross coupling with methoxy to form methyl formate, photooxidation to CO, thermally catalytic self-coupling to form ethylene. The role of oxygen vacancy on rutile TiO₂(110), and the difference behaviors of thermally catalytic and photocatalytic oxidation of formaldehyde on rutile TiO₂(110) surface will also be discussed.

The effect of an altered charge state of Pt on methanol decomposition and CO dissociation: studies of Pt nanoclusters supported on a thin film of Al₂O₃/NiAl(100)

T13 Surface Science

#SS-12-Or-6

M. Luo, C.S. Chao, Y.D. Li, T.C. Hung.

National Central University - Jhongli (Taiwan, republic of china).

Methanol decomposition on oxidized Pt nanoclusters on an ordered Al₂O₃/NiAl(100) thin film was studied with a variety of surface probe techniques, including STM, IRAS, TPD, RHEED and synchrotron-based PES. The Pt clusters, with a mean diameter 2.3 nm and height 0.4 nm, were grown by vapor deposition onto the thin film Al₂O₃/NiAl(100) at 300 or 430 K, and oxidized to a state of Pt²⁺ by annealing the sample to 650 K. The annealed clusters remained structurally ordered but became partially encapsulated by inert alumina; the bare surface Pt remained (30 % of the original) were mostly low-coordinated but reactive. Methanol adsorbed on these oxidized Pt decomposed predominantly through dehydrogenation to CO and secondarily through C-O bond scission, as observed on pristine Pt clusters, whereas the reaction channels were selectively hindered by the altered electronic state of Pt. The produced CO and hydrogen from dehydrogenated methanol per surface Pt on the oxidized clusters amounted to only 50 % of those on pristine Pt clusters; in contrast, the oxidation of Pt has little effect on the C-O bond scission: both temperature of the bond-scission and quantity of the produced methane per surface Pt are similar on the oxidized and pristine clusters. The CO dissociation to elemental carbon was significantly enhanced on the oxidized Pt; the dissociation began at a much lower temperature (200 – 300 K) than that on pristine clusters and thus most molecularly adsorbed CO dissociated, instead of desorbing, with increased temperature.

Controlled self-assembly of complex supra-molecular surface architectures has considerable potential for application in many fields within the quickly-emerging area of nanoscience and technology, including heterogeneous catalysis, gas storage, chemical sensing, surface-templating, molecular recognition, opto-electronics, guest-host chemistry, and so on. [1-4]

In this study, we investigate metal-organic self-assembly of perylene-3,4,9,10-tetracarboxylic-diimide (PTCDI) and Ni on the Au(111) surface using high-resolution STM under UHV conditions. The molecule PTCDI and its derivatives are technologically relevant owing to interesting opto-electronic properties,[5,6] and their adsorption properties have been investigated on a wide range of substrates as fundamental model systems understanding the interaction of large aromatic molecules with inorganic surfaces. [eg. 7-8]

We demonstrate that it is possible by delicately tuning the co-adsorption conditions to synthesize three distinct self-assembled Ni-PTCDI nanostructures from zero-dimensional (0-D) nano-dots over one-dimensional (1-D) chains to a two-dimensional (2-D) porous network. In general, the ability to generate a diverse range of nanostructures of different dimensionality from the same elementary building blocks is important since it may help to simplify synthesis of nanostructures for practical applications.

To achieve a full picture of the interactions driving the formation of the observed Ni-PTCDI structures, we have performed molecular mechanics and quantum chemical calculations, as well as STM image calculations. A unifying motif for the 1-D Ni-

PTCDI chains and the 2-D Ni-PTCDI network is found to be double N-H...O hydrogen bonds between PTCDI molecules arranged in staggered rows, similar to the situation found in surface structures formed from pure PTCDI. Most interestingly, we find that while Ni co-deposition with PTCDI is essential to form the observed structures, the role of the Ni ad-atoms is not to participate in metal-organic coordination bonding as cationic centers. Rather, the Ni ad-atoms acquire a negative partial charge through interaction with the substrate and the Ni-PTCDI interaction is entirely electrostatic.

Microkinetic Analysis of Ammonia Oxidation on the RuO₂(110) Surface

T13 Surface Science

#SS-12-Or-7

J. Jiang, C.C. Wang, J.Y. Wu.

National Taiwan University of Science and Technology - Taipei.

We simulated the ammonia oxidation on the RuO₂(110) by microkinetic analysis, where all the thermodynamic and kinetic parameters were obtained from density functional theory (DFT) calculations. There are 25 elementary steps, including adsorption, surface reaction and desorption processes, adopted in microkinetic models. The rate constants of adsorption and desorption processes were estimated by collision theory, and those in surface reactions were calculated by transition state theory (TST). Recently, the ammonia oxidation on ruthenium dioxide surfaces has been studied by different experimental methods: batch type reaction,¹ and steady-state ammonia oxidation.^{1,2} In this microkinetic simulation, we established two models, batch type and continuous type reactions, to investigate the differences between the two experimental methods. In the simulation of batch type ammonia oxidation, the NH₃ and O₂ molecules were pre-adsorbed on the RuO₂(110) surface at 90 K, and then heating up the system under high vacuum environment. In the model of continuous type reaction, the temperature (from 480 K to 670K) and partial pressure of NH₃ and O₂ were set to be constant during the oxidation, and the selectivity of each product were recorded at the steady-state. These two microkinetic models are based on the same elementary reaction steps, but they showed a significant difference in selectivity to oxidation products, which consists with experimental observations. In ammonia oxidation experiments by Wang et al.,¹ there was no N₂O produced during the oxidation; however, in steady-state oxidation by Pérez-Ramírez et al.,² N₂O could be one of major oxidation products. According to our simulations, we suggest that N₂O should be produced during the ammonia oxidation, and the partial pressure, O₂/NH₃ ratio and temperature will vary its selectivity from 0% to 30%. By analyzing the microkinetic models, we clarified the mechanical differences between the two methods, and showed how experimental conditions influence the oxidation selectivity.

Computer simulation of thermodynamic equilibrium in adsorption monolayer of 1,4-cyclohexadiene on Si(001)-2x1 surface

T13 Surface Science

#SS-12-Or-8

V. Gorbunov, V. Fefelov, A. Myshlyavtsev, M. Myshlyavtseva.

Omsk state technical university - Omsk (Russian federation).

Over the last two decades complex organic molecules such as cyclic unsaturated hydrocarbons have been used for the fabrication of ordered organic adsorption monolayer on Si(001) surface [1]. The organic-semiconductor interface has attracted much attention because it provides the possibility of combining the wide range of functionality of organic molecules with the modern silicon based infrastructure. It is known that such systems have a number of potential applications mostly for various functional coatings, chemical and biological sensors.

Most research efforts in this area are intended to: 1) learn to control an adsorption state of the molecule and the monolayer structure; 2) creation of a stable adsorption monolayer. Theoretical research in this area often limited to quantum chemical calculations and there are no works devoted to the study of phase behavior of the adsorption monolayer as a whole.

In this work we have investigated the formation of equilibrium ordered structures of adsorption monolayer of 1,4-cyclohexadiene on Si(001)-2x1 surface with Monte Carlo method and transfer-matrix technique in the framework of lattice gas model. In the constructed model [2] we took into account the possibility of three adsorption states: π -complex, di- σ complex and double di- σ complex bonded with 1,2 and 4 adsorption sites, respectively.

We have calculated the phase diagram of the adsorption monolayer which reproduces qualitatively the most general features of formation and the phase behavior of real adsorption monolayer of 1,4-cyclohexadiene on Si(001) surface. It is shown that only two ordered structures appear in the adlayer in its pure form: the structure consisted of only π -complexes and the ordered structure consisted of only double di- σ complexes. Additionally, there is nonmonotonous changing of coverage

when increasing of chemical potential (gas phase pressure) in this adsorption system [3].

Tuning a nanostructure: self-organised growth of oxygen on Cu(110) modified by sulphur co-adsorption

T13 Surface Science

#SS-1-Or-3

F. Wiame, C. Poulain, Z. Budinska, V. Maurice, P. Marcus.

CNRS/Chimie ParisTech - Paris (France).

Self-organised nanostructures grown on surfaces have been the object of much interest in recent years due to their potential applications in the nanotechnology industry as possible alternative to standard lithography techniques. Kern *et al.* [1] demonstrated that a submonolayer coverage of oxygen deposited on Cu(110) may form periodic stripes aligned along the [001] direction and that the periodicity of the system essentially depends on the coverage. However, although this method appears very promising for the growth of nanostructured materials, the applications are limited due to the relatively small domains of periodicity and size as defined by the Marchenko-Vanderbilt model [2] generally admitted for this system. For oxygen coverages θ_{O} in the range $0.1 < \theta_{\text{O}} < 0.4$ (the fully-covered (2×1) surface corresponding to $\theta_{\text{O}} = 0.5$), the periodicity only varies from 6.5 nm to 11 nm and the oxide band width from 2 nm to 9 nm. We will show that these ranges can be significantly increased by the adsorption of very small amounts of sulphur at the surface. Although surfaces significantly diverging from the Marchenko-Vanderbilt model have been evidenced in the past [3], no systematic method have been reported yet.

The new preparation method presented here, which consists in the partial coverage of the surface by sulphur before annealing of the oxidised surface, enables us to significantly enlarge the domain of accessible periodic structures. Periodicity up to 100 nm and oxide band width up to 30 nm can be reached in a straightforward, reproducible and controlled way. The band width and periodicity dispersions are not modified by the sulphur adsorption. Moreover, while the structure of the O/Cu(110)- (2×1) is fully determined by the surface coverage, our method allows us to define the periodicity independently of the oxygen coverage by adjusting the sulphur amount at the surface. The classical Marchenko-Vanderbilt model, used to explain the common case, has been modified in order to take into account the presence of sulphur at the

surface. It appears that the elastic constant of the system is varying continuously with the amount of sulphur. We attribute this variation to a change in the formation energy of the boundary between the two phases.

This new system may be used for fundamental studies in order to gain information on the elastic and electrostatic properties that are underlying the self-organisation phenomena. Moreover, it represents also an ideal playground to test the change in the reactivity of a surface as a function of its structure as it enables a systematic study of the influence of the periodicity and coverage on the surface reactivity [4].

Surface coordination chemistry has been studied intensively over the last few years [1], because traditional bulk coordination compounds have very interesting magnetic, electronic, optical or catalytic properties [2]. Different chemical groups have been used for the formation of the coordination bonding. The most commonly used group is the carboxylic one, which can make coordination bonds with metal ions after deprotonating, changing into a carboxylate group. A few reports have also used nitrogenated moieties (cyano, pyridyl) for the linking to the metal atoms. In particular, Mn-TCNQ and Ni-TCNQ have been reported [3]. However, in spite of all these previous works, many questions remain open about the nature of such coordination bond when a metal surface is involved.

We have carried out a combined experimental (STM - Scanning Tunneling Microscopy, XPS - X-Ray Photoelectron Spectroscopy) and theoretical (DFT) work to characterize the electronic and structural configuration of an Fe-DCNQI coordination network on a Ag(111) surface. DCNQI (Dicyano-p-quinodiimine) is a strong electron acceptor with two cyano groups that link to the Fe atoms to form two types of coordination networks: the first one (Figure 1b) is formed by an array of 1D parallel chains, while the second one is a surprising new kind of apparently random 2D network, none of which has a counterpart in bulk metal-DCNQI coordination compounds. In addition, both XPS and DFT seem to indicate that the "oxidation state" of the Fe atoms in this system is close to +2 (Figure 2).

Department of Physics, Tokyo University of Science - Tokyo (Japan).

Carbon nanotubes (CNTs) known as a material with incredible electrical, optical, and mechanical properties are synthesized by chemical vapor deposition (CVD) using catalytic nanoparticles on a substrate. Up to now, many efforts have been made to improve CVD process and realize several types of CNT growth. Previously, our group showed thermal embedment of metal nanoparticles into amorphous oxide substrates during the CVD process [1]. Metal particle formation in the subsurface of oxide is considered to play an important role for vertically aligned CNT growth mode [2]. However, the subsurface substrate diffusion mechanism is still not clear due to lack of microscopic knowledge about material transport.

In this study, we observed the thermal behavior of a metal layer sandwiched by silicon oxide (SiO_2) using transmission electron microscopy (TEM). SiO_2 /metal (Co or Fe)/ SiO_2 /Si(100) layers prepared by DC magnetron sputtering were annealed at 670-870°C in Ar/ H_2 (100: 3 in volume) atmosphere for 5 min. Figure 1 shows a TEM image of a Co sandwiched layer after annealed at 870°C. The Co layer turns to nanoparticles of uniform size and they line up in original position perfectly. On the other hand, an Fe layer is changed to segregated nanoparticles at both interfaces of SiO_2 after annealing (Fig. 2). The results show that iron atoms tend to diffuse into SiO_2 , and they move in the potential which has local minima at the surface and interface of SiO_2 .

Thiol and asymmetric disulfide self assembled monolayers (SAMs) on gold surfaces have a wide range of applications including surface patterning and metal contact-organic semiconductor interface modification in organic electronic devices. Here we will present our studies about the low coverage phases of long chain alkanethiol SAMs(CH₃(CH₂)₁₇SH, CH₃(CH₂)₉SH and HO(CH₂)₁₁SH) and asymmetric disulfide SAMs (CH₃(CH₂)₁₇S-S(CH₂)₁₁OH and CH₃(CH₂)₉S-S(CH₂)₁₁OH) on Au(111) surface, grown in vacuum by supersonic molecular beam deposition. Crystal structures, phase behaviors and desorption energies of these films determined by helium atom diffraction technique will be discussed.

Graphene is a 2D material that shows a variety of interesting electronic properties. One important method for the fabrication of graphene is chemical vapor deposition (CVD) of hydrocarbon precursors on transition metal surfaces^{1,2}.

In our study graphene was grown on a Rh(111) single crystal surface by chemical vapor deposition of propylene at elevated temperatures. The growth process was observed by fast XPS performed at the synchrotron facility BESSY II. The quality of the produced graphene sheets was checked by LEED. Different preparation parameters such as propylene pressure and preparation temperature were varied in order to investigate the influence of these parameters on corrugation and regularity of the produced graphene sheet. The lattice mismatch of graphene on the Rh(111) surface induces corrugation of the graphene sheet leading to two separated signals in the C 1s region.³ The binding energy separation of the two species becomes more distinct at lower temperatures and varies depending on the preparation parameters mentioned above.

The oxidation of graphene was investigated depending on oxygen pressure, temperature and graphene layer quality. We found sigmoidal reaction kinetics indicating the following reaction mechanism: The oxidation starts at defect sites, inducing a slow induction period. With more free adsorption sites the reaction rate increases until most of the graphene is oxidised. The remaining carbon decays exponentially according to pseudo first order kinetics. The strong influence of the graphene layer quality on the reaction rate supports the assumption that oxidation starts at the defect sites.

SS-P3-10

Autocatalytic effect of Cu nano-islands on the reaction of water with the oxygen covered Cu(110) surface.

T13 Surface Science

#SS-P3-10

K. Bobrov, L. Guillemot.

CNRS - Orsay (France).

We present a detailed STM study on the reactivity to water of the oxygen covered Cu(110) surface at 200K. This reactive interaction is known to produce hydroxyls. We found that the hydroxyl chemical state is a key factor regulating further chemical reactions and causing a strong re-structuring of the surface. Parts of the hydroxyls are originally produced on the surface in the form of highly mobile copper-hydroxyl [Cu-OH] complexes. We demonstrate that interaction of the [Cu-OH] complexes with the substrate governs the surface restructuring. The hydroxyl complexes can dissociate either on step sites of the surface, incorporating Cu to the substrate and releasing hydroxyls (OHs) either, remarkably, condensate on the terraces shaping two-dimensional monoatomic height Cu islands possessing under-coordinated sites at their borders. We show that nucleation and growth of these nanometer scaled islands significantly enhance the surface reactivity towards water. Indeed, the Cu islands providing under-coordinated sites enhance water adsorption and furthermore produce a local effect favoring diffusion of the water molecules towards the more reactive sites.

²Institut Jean Lamour - Nancy (France).

Complex metallic alloys (CMAs) are intermetallic compounds whose crystallographic structure differs from that of usual alloys. In particular, their unit cell contains from several tens to a few thousands atoms, which are typically arranged into highly symmetric clusters. They are usually considered as stable approximants of quasicrystals [1]. Al-based CMAs offer great opportunities in the field of catalysis, including flexible chemistry thanks to the huge variety of CMA compositions and tuning of d band centre by selection of CMA composition and structure.

In this work, X-ray Photoelectron Spectroscopy (XPS), Low Energy Electron Diffraction (LEED) and Scanning Tunnelling Microscopy (STM) have been used to investigate under ultrahigh vacuum the first oxidation stages of the γ -Al₄Cu₉(110), Al₉Co₂(001) and o-Al₁₃Co₄(100) surfaces.

Whatever the oxidation temperature (from 100 to 923 K) and oxygen partial pressure (from 10⁻⁸ to 10⁻⁷ mbar) only aluminium is oxidized, while copper and cobalt remain in the metallic state. We found that the oxidation mechanism of γ -Al₄Cu₉(110) is driven by aluminium segregation at the surface, whereas the oxidation mechanism of Al₉Co₂(001) and o-Al₁₃Co₄(100) is related to the amount of oxygen adsorbed on the surface.

For the three CMA surfaces, RT oxidation at saturation in oxygen yields a uniform disordered aluminium oxide film. For γ -Al₄Cu₉(110) surface, subsequent annealing of this disordered oxide layer at 923 K leads to the formation of crystalline aluminium oxide islands which exhibit a peculiar rectangular structure called sixton. This sixton structure is similar to that previously reported for ultrathin alumina films grown on various metallic substrates, as for instance NiAl(110) and Ni(111) [2]. Its unit cell comprises 92 atoms arranged in an interfacial Al₂₄O₂₈ plane and a surface Al₁₆O₂₄ plane [3-4]. For both Al-Co surfaces, the aluminium oxide film grown at RT dissolved upon subsequent annealing before any ordering occurred, owing to oxygen diffusion

into the bulk.

We found that the sixton structure can occur on $\text{Al}_9\text{Co}_2(001)$ after oxidation at higher temperature (773 K); however the oxide film is poorly ordered. For the $o\text{-Al}_{13}\text{Co}_4(100)$ surface, no oxidation conditions could be found to form a well-ordered oxide film. The formation of the sixton oxide structure depends on the ability of aluminium to segregate at the surface, which is related to the nature of the intermetallic bonds inside the crystal and, in particular, their covalence degree. Given their strong covalent character, $\text{Al}_9\text{Co}_2(001)$ and $o\text{-Al}_{13}\text{Co}_4(100)$ exhibit a lower aluminium mobility than $\gamma\text{-Al}_4\text{Cu}_9(110)$, which hampers the formation of the sixton structure.

STM and photoemission study of vacancies and hydroxyls at the SrTiO₃(110)-(4×1) surface

T13 Surface Science

#SS-7-Or-7

Z. Wang, X. Hao, S. Gerhold, M. Schmid, U. Diebold.

Vienna University of Technology - Vienna (Austria).

The surfaces and interfaces of SrTiO₃ have attracted intense interest in diverse fields ranging from solid-state physics to surface chemistry and oxide electronics. In all these applications the structural and electronic surface properties are vital of importance, yet perovskite surfaces are notoriously complex and hard to control. We report an STM and synchrotron radiation photoemission spectroscopy study of SrTiO₃(110) surface. This polar surface tends to form a homologues series of (n×1) (n = 4~6) reconstructions, which can be reversibly tuned by changing surface chemical composition through depositing Sr or Ti metals followed by annealing.¹ The (n×1) reconstructions are well explained by models consisting of tetrahedrally coordinated TiO₄ layers.² The commonly observed (4×1) reconstruction is arranged in distorted six- and ten-membered rings. Such an arrangement breaks the mirror symmetry of surface along the [1-10] direction, and two degenerate anti-parallel (4×1) domains are formed. Vacancy clusters of (Ti₂O₃)²⁻ and (Ti₄O₅)⁶⁻ type are present at domain boundaries. The relative ratio of these domain boundaries can be tuned judiciously by adjusting the oxygen pressure during annealing.

Oxygen vacancies (V_O) can be created by exposure to synchrotron radiation, and are accompanied by the evolution of an in-gap state at a binding energy of 1.3 eV. A similar in-gap state is also observed after exposing the surface to atomic hydrogen. Core-level and valence band photoemission spectroscopy studies of water adsorption on the surface indicate that water doesn't dissociate on the clean surface, while it can dissociate on the surface with V_O. V_O and hydroxyl species (OH) on the surface are identified by STM. OH pairs form on the surface after dosing water at room temperature, indicating water dissociation at the V_O on the surface (see Fig. 1). While water doesn't adsorb and dissociate on the surface upon further dosing water.

Density functional theory calculations are performed on the surfaces with V_O , OH and water. The energy barrier for water dissociation on clean surface and V_O is 0.9 and 1.5 eV, respectively, supporting that V_O boosts water dissociation on the surface. This work was supported by the Austrian Science Fund (FWF project F45).

Water reacts dissociatively on the Si (001)-2x1 surface, preserving the dimerization. Monohydrides and silanols are present on the surface, together with a low (10^{-2} ML) surface concentration of isolated dangling bonds (IDBs). Recent STM experiments we have carried out emphasize the impact of Si doping on the areal density and on the charge state of the surface dangling bond (negative on n^+ substrate [1] and neutral on lightly p doped substrate). The charge state of IDBs as a function of the doping found here is similar to that of H-Si (001) terminated surface [2]. Therefore by analogy with the case of the H terminated surface, radical chain reactions (via H jumps) between isolated dangling bonds and pi-bonded molecules are expected [3]. However radical reactions via OH jumps, together with direct reactions with silanols and monohydrides must be also envisaged. We present here a study on the chemical reactivity on the water-covered Si (001) surface exposed to alkenes, carboxylic acids and aldehydes, using synchrotron x-ray photoemission. While, alkenes likely react via a radical mechanism (H jump) [4], carboxylic acid grafting consumes surface OH and an ester is formed. The reaction of aldehydes is discussed in terms of the formation of ethers or (hemi-)acetals. Compared with classic organic reactions (esterification, acetal formation) which are slow/reversible, the grafting of aldehydes/carboxylic acids is efficient on the water-covered Si (001)-2x1. This class of high selectivity reactions is an interesting method for the grafting of organic molecules on Si (001), especially for polyfunctional molecules, which generally adopt multiple bonding configurations on the clean Si (001) surface.

Investigation of fluorinated fullerene C₆₀F₁₈ sub-monolayer film was carried out by using Near Edge X-ray Absorption Fine Structure (NEXAFS) and X-ray Photoelectron Spectroscopy (XPS) techniques. C₆₀F₁₈ molecules having asymmetric type structure and high dipole moment about 10 D (shown by arrow in figure, with F atoms in bottom part of a C₆₀-type cage) were deposited in situ in high vacuum about 10⁻¹⁰ mbar by powder evaporation from Knudsen cell at 150°C on Ni (100) substrate. Angular dependence of NEXAFS spectra obtained for C1s (285 eV) and F1s (690 eV) absorption edges by using synchrotron radiation at RGBL-PGM beamline, BESSY II storage ring, was established. This indicates the presence of an ordered structure of C₆₀F₁₈ film on Ni surface. Theoretical calculation by using the Density Functional Theory (DFT) allowed to identify the 1s→π* and 1s→σ* spectral peaks, and thus to make conclusion that dipole moment of deposited C₆₀F₁₈ molecules is orthogonal to the substrate surface. Moreover, analysis of NEXAFS spectra fine structure shows that molecules are deposited with F atoms touching the substrate. NEXAFS spectra have demonstrated that thermal annealing of C₆₀F₁₈ film at 150°C leads to growth of molecular ordered surface structure. This ordered structure is preserved while heating at least up to 250°C.

XPS spectra of C₆₀F₁₈/Ni(100) system have shown the valence band adsorption state composed from admixture of Ni3d metallic state and F2p band belonging to fluorofullerenes, together with evident Ni2p core levels. This indicates the island-type self-assembling of C₆₀F₁₈ film formation on metal substrate. Note that similar island-type structure of C₆₀F₁₈ film deposited on graphite HOPG substrate was previously observed by using atomic force microscopy, showing 15-20 nm height islands with mean lateral dimension of 60-80 nm.

Thus, there seems to be outlined a possibility to make island-type nanostructures based on $C_{60}F_{18}$ molecules to obtain nanoscale electric fields.

Organic charge-transfer (CT) complexes are molecular compounds mixing two species with different electron affinities: an electron donor (D) and an electron acceptor (A). Charge transfer processes between D–A complexes and metallic electrodes are at the heart of novel organic optoelectronic devices such as solar cells [1]. In contrast with the existing exhaustive study of the bulk properties of CT solids, very little is known about the thin-film behaviour. The transition from bulk D-A complexes to ultra-thin films of monolayer thickness deposited on metals introduces a new phenomenology related to the organic–inorganic interface [2]. Effects like hybridization, CT with the surface and molecular level alignment become factors that may govern the electronic transport. Hence, the adsorption of an ultra-thin D–A layer on a metal opens a new field of research for the potential application of CT complexes as devices in the nanoscale.

Simultaneous characterization of the interdependent structural and electronic properties is required for a thorough understanding of the D-A complexes under study [3]. Here, by combining both Scanning Tunnelling Microscopy and X-ray Photoelectron Spectroscopy in situ, we can study the delicate balance that exists between intermolecular and molecule–substrate interactions, as well as the hybridization, and the charge transfer taking place in model D–A assemblies at metal-organic interfaces.

By controlling the stoichiometry between tetrathiafulvalene (TTF, electron-donor) and tetracyanoethylene (TCNE, electron-acceptor), we can tune both the structural and the electronic properties of a donor-acceptor system on Ag(111). We show that this

system exhibits various structural phases two of which are shown in Fig: 1, depending on the stoichiometry. Each phase leads to different levels of charge transfer. Interestingly enough, the charge-transfer does not seem to follow a monotonic behavior with the D:A ratio. These results demonstrate that atomistic studies on the growth of organic thin films under ultrahigh vacuum conditions can lead to the kind of accurate control needed in order to optimize device characteristics.

One way to introduce a band gap into the electronic structure of graphene is to cut graphene into nanometer-wide ribbons, termed graphene nanoribbons (GNRs). In this top-down approach, however, the lack of control over the edge roughness and edge passivation of the GNRs severely limits the capability to produce GNRs with reliable electronic transport properties. Recently, a bottom-up approach has been developed that enables the fabrication of GNRs with atomically precise edges via thermally induced polymerization and subsequent partial cyclodehydrogenation of suitable precursor molecules on a metal surface[1]. The electronic structure of one specific armchair-type GNR with a width of 7 carbon dimer lines (7-AGNR, Figure 1) has since been studied by scanning tunneling spectroscopy and angle-resolved photoemission spectroscopy and the predicted band gap of 2.3 eV on the metal substrate has been confirmed experimentally[2]. Picking up one terminus of such a GNR with the tip of a scanning tunneling microscope (STM) has further enabled controlled electronic transport measurements on individual GNRs[3].

While the cyclodehydrogenation step of the synthesis has been studied in great detail[4], less is known about the polymerization step, which determines the length of the GNRs. This presentation focusses on the atomic structure found at the termini of 7-AGNRs obtained via the bottom-up approach[1]. The short zigzag edge at the termini of 7-AGNRs gives rise to a localized mid-gap state with a characteristic signature in STM. By combining STM experiments with STM simulations based on large-scale density functional theory calculations (Figure 1), we demonstrate that the termini are passivated by hydrogen[5].

Our findings further suggest that hydrogen may be poisoning the polymerization

reaction. Minimizing premature dehydrogenation during the polymerization step could therefore be a way to grow GNRs with lengths significantly exceeding the 30 nm reported so far. Possible routes will be discussed.

Discussion of the density functional theory methods applied for solving complex surface structures based on the example of $c(8\times 2)/(4\times 2)$ InAs (001)

T13 Surface Science

#SS-15-Or-2

J. Kolodziej, G. Goryl, D. Toton.

Uniwersytet Jagiellonski - Krakow (Poland).

The surface structure of InAs (001) reconstructed $c(8\times 2)/(4\times 2)$ is studied experimentally using scanning probe microscopies (SPM) as well as theoretically by an ab initio density functional theory (DFT) calculations. Based on the experimental results it is found that the structure belongs to a so called ζ -family [1,2] but it fluctuates at room temperature (RT). Because of the fluctuations the surface structure appear regular at RT, while at cryogenic temperatures it freezes to show disorder and a few different local features (Fig. 1a,1b). By DFT calculations many metastable surface structures are identified on the studied surface. Numerical scanning tunneling microscopy (STM) images of these structures are obtained using their DFT density of states and the Tersoff-Hamman approximation (Fig 2). By comparison to the experimental STM images it is found that all features observed on the real surface have their theoretical counterparts. However, certain theoretical structures are not observed in reality even though their energies are the lowest among all the metastable structures found.

Taking into account this as well as the fact that earlier total energy DFT studies [3-5] failed to reach the right solution for the ground state of the structure under study we indicate that the concluding about complex surface structures based on the global DFT energy minimum is rather unsure. On the other hand the mere existence of the DFT energy minima (i.e. local minima) for the structures corresponding to experimentally observed features is usually predicted correctly by the DFT methods. We acknowledge financial support by Polish NCN under the contract 2011/03/B/ST3/02070.

We have studied the adsorption behavior and dehalogenation properties of the hexaiodo-substituted cyclohexa-m-phenylene (CHP) on corrugated hexagonal boron nitride (h-BN) on Rh(111). Well-defined monolayers of h-BN are produced by thermal decomposition of borazine ((HBNH)₃) on transition metal surfaces in a self-limiting process. Spatially heterogeneous interaction with the underlying substrate can result in strongly corrugated superstructures, e.g. on Rh(111) a regular pattern of depressions with 3.22nm periodicity is formed. Areas of weakly bonded h-BN ("wires") separate strongly bonded "pore" regions that exhibit a diameter of 1.5nm [1]. Single CHP molecules adsorb within those pores and are aligned along the [12] direction of the h-BN lattice (cf. Figure left). The dehalogenation of the CHP is the first step to induce the aryl-aryl coupling leading to the formation of porous graphene [2, 3]. Contrary to the case on metals, where complete thermal dehalogenation can be achieved close to room temperature, the h-BN substrate requires higher temperatures and imposes a distinct abstraction sequence on the molecule. Following the dehalogenation process experimentally by scanning tunneling microscopy and spectroscopy and theoretically by DFT calculations we gain detailed insights to the catalytic properties of h-BN with regard to the site and orientation specific adsorption, the dehalogenation sequence and the CHP radical binding to the h-BN. Thus we can discuss the particular challenges that need to be faced in the *in situ* growth of graphene nanostructures on the insulator h-BN.

Complex metallic alloys like quasicrystals and approximants are considered as low cost alternative materials for heterogeneous catalysis [1]. The specific reactivity relies on the so-called site isolation concept in which the catalytic performance of a material is determined by small and well separated atomic ensembles containing an active transition metal element at the crystal surface.

The Al₁₃Fe₄ intermetallic compound has been identified recently as one such promising candidate for heterogeneous hydrogenation catalysis [2]. In this work, we investigate the structure of the Al₁₃Fe₄(010) surface using both experimental methods under ultra-high vacuum (scanning tunneling microscopy, low energy electron diffraction, photoemission) and *ab initio* calculations. The results indicate that the topmost surface layers correspond to incomplete puckered planes present in the bulk crystal structure. The main building block of the corrugated termination consists of two adjacent pentagons of Al atoms, each centered by a protruding Fe atom. These motifs are interconnected via additional Al atoms referred as “glue” atoms which partially desorb above 873 K. The surface structure of lower atomic density compared to the complete bulk puckered plane is explained by a strong Fe-Al-Fe covalent polar interaction that preserves intact at the surface the clusters present in the bulk structure (Fig. 1).

The proposed surface model identifies well separated atomic ensembles in line with the site isolation concept [3]. In conclusion, the surface structure of Al₁₃Fe₄(010) is

discussed in relation with that of the structurally close $\text{Al}_{13}\text{Co}_4(100)$ surface [4], both compounds being approximants to the decagonal phase.

The understanding of the interactions between biomolecules and metal/oxide surfaces is mandatory for all those applications in which this interaction wants to be either exploited (biomaterials, nanoelectronics, hybrid material design) or avoided (fouling, hygiene). The huge experimental effort in this field was however so far insufficient for a complete understanding of the complex bio-molecule/surface interactions at the molecular level. Model experiments and computations are thus mandatory.

Amino acids (AA) are protagonists of fundamental studies, since they are the basic constituents of peptides and proteins and are simple enough to bring information on the chemical interaction of some biological functions with the surface. When deposited from the gas phase, AA self-assemble on metal surfaces most often in the zwitterionic form, while anionic adsorption was sometimes detected.

We report here on the interaction of (S)-Glutamic Acid (Glu) with LMI Ag surfaces at $250\text{ K} < T < 400\text{ K}$, investigated by experimental and theoretical methods. Glu molecules self-assemble in different geometries, depending on substrate and deposition temperature, and adsorb always in the non-zwitterionic form [1-4], at variance with what expected for analogy with other AA adsorbed on Ag(111) [5]. On Ag(100) four different structures are identified [2]. For the “squares” and the “flowers” (coexisting at $T=350\text{ K}$ – see figure) a carefully combined STM, HREELS, XPS and DFT analysis allowed to unravel the details of the self-assembled layer and the driving mechanisms of the self-assembly process. The “square” geometry consists of neutral Glu molecules, while the “flower” one is made by 50% of neutral units and 50% of anions (forming the tetramers). The Glu-Ag(100) interaction is due to weak van der Waals forces in the former case and to chemisorption when deprotonation occurs. The role of H-bonds, involving mainly carboxyl groups, is

fundamental for both structures. For the “square” geometry the formation of OCOH—OCO—OCO—OCO—OCO—OCO—OCO— cycles at the vertex of the squares is the driving mechanism for self-assembly. This cycle also explains the formation of individual “tetramers”, whereas the whole “flower” structure occurs via a key-slot mechanism between the lateral NH₂ moiety and carboxylic groups of the flat molecules. An empirical model based on statistical analysis of high resolution STM images is proposed for the other layers.

Cr segregation at the Fe-Cr alloy surface studied by Mössbauer spectroscopy

T13 Surface Science

#SS-P1-10

R. Idczak, R. Konieczny, J. Chojcna.

Institute of Experimental Physics, University of Wrocław, pl. M. Borna 9 - Wrocław (Poland).

In the last few years, there was much interest of mechanical, thermodynamic and magnetic properties of Fe-Cr alloys, in particular many works concerned enthalpy of solution, enthalpy of mixing and short-range order parameter (SRO) of this system at low Cr concentration [1, 2]. Motivation for these studies is fact, that high-chromium ferritic/martensitic steels, containing up to 15 at. % of Cr, are candidate materials for advanced fission reactors (Generation IV), accelerator-driven systems using spallation neutron sources and fusion reactors. These types of steels are able to perform reliably for long time under high irradiation levels (total dose of 50 to 200 displacements per atom (dpa)) and at high temperatures (up to 900 K). Moreover, high-chromium steels are known for their excellent corrosion resistant properties. These properties originate from the formation of a stable surface Cr oxide film, which prevents further oxidation of an alloy deep into the bulk. On the atomic scale, the necessary supply of Cr atoms to the surface should be provided by a segregation of Cr atoms toward the surface. The problem here comes from the existing controversy in both experimental data and theoretical results [3-5]. The disagreement between various studies concern chromium surface segregation remains unresolved. Taking the above into account we decided to measure Cr segregation at the $Fe_{1-x}Cr_x$ alloy surface with x in the range $0.01 \leq x \leq 0.15$ by Mössbauer spectroscopy. This unique experimental technique allows to take data simultaneously from the surface by conversion electron Mössbauer spectroscopy (CEMS) and from the bulk by transmission Mössbauer spectroscopy (TMS). The observed differences between surface and bulk data should give the answer about segregation process in Fe-Cr alloys. Such comparison between obtained from the surface and the bulk Mössbauer spectra for Fe-Cr alloy were presented in Fig. 1. Our results suggest that Cr atoms segregate to the surface of the Fe-Cr alloy.

A promising approach for the further miniaturization in semiconductor device physics is the functionalization of inorganic semiconductor surfaces by organic molecules [1].

In this context, we have investigated the reaction of the common organic solvent tetrahydrofuran (THF) on Si(001) by means of scanning tunneling microscopy (STM) and X-ray photoelectron spectroscopy (XPS). Despite its inert behavior in solvent based organic chemistry, an unexpectedly rich surface chemistry of THF was observed on Si(001). Entirely different adsorption geometries were identified at low temperature and at room temperature. Furthermore, a complex reorganization occurs at elevated surface temperatures.

At low surface temperature of 50 K, the STM measurements indicate an adsorption geometry with the THF molecule localized at the lower Si dimer atom. In the XP spectra an energetic shift of the O(1s) peak to higher binding energies is observed for this configuration when compared with the THF multilayer signal. Thus a dative bonding between a free electron pair of the oxygen atom and the empty dangling bond surface state is suggested. At surface temperatures above 220 K, an irreversible rearrangement of the THF molecules is observed both in the XP spectra and STM images. The resulting configurations bridge two dimers of adjacent dimer rows as clearly indicated in the STM images. For temperatures higher than 700 K, the STM and XPS data point to the decomposition of the molecule into silicon carbide and silicon oxide structures.

In addition to thermal excitation, the conversion between the dative-bonded configuration and the stable room-temperature configuration can also be induced locally by the tunneling tip at low temperature. Based on detailed investigations of the voltage and current dependence, this effect was attributed to a direct electronic excitation induced by electrons which tunnel into an unoccupied molecular orbital.

Interaction of water with ZrO₂ ultrathin film-from UHV to elevated pressure

T13 Surface Science

#SS-12-Or-13

H. Li, C. Weilach, G. Rupprechter.

Institute of Materials Chemistry, Vienna University of Technology - Vienna (Austria).

Introduction

ZrO₂ is known as an excellent support in the methane steam reforming. Particularly, the interaction of water and ZrO₂ is of great importance, as the hydroxyl group might influence the sintering of supported Ni, or participate in the reforming reaction [1]. In order to conduct fundamental studies on ZrO₂ using a surface science approach, thin film model catalysts have been prepared and their interaction with water have been studied both under UHV and at elevated pressure.

Experimental

The ultrathin ZrO₂ film was prepared following a route proposed by Schmid and coworkers [2]. The structure and the chemical composition of the film were characterized by Low Energy Electron Diffraction (LEED) and high resolution X-ray Photoelectron Spectroscopy (XPS), respectively. Thereafter, the film was exposed to 10 L water at 100 K for monolayer water studies, and to high pressure water in the range from 10⁻⁶ mbar to 10⁻¹ mbar at 300 K for in-situ studies. Temperature Programmed Desorption (TPD) was used to investigate the dissociation of water upon heating, and XPS was used to study the hydroxylation of the film. Besides, defective films prepared by soft sputtering of the pristine film were also studied.

Results

LEED and XPS showed the formation of a well-structured ZrO₂ film. In case of the monolayer water studies, TPD showed a D₂ desorption peak between 200 K and 400 K. And on the defective film, XPS showed the development of a shoulder, as

compared to the single O 1s peak obtained from the pristine film, as shown in Fig.1. For the high pressure studies, TPD gave a broad D₂ desorption peak between 350 K and 650 K. In Fig.2, XPS showed that the above mentioned shoulder developed into a separated peak, which might be attributed to hydroxyl groups.

Surface-confined metal organic architectures have recently been studied for alkali and transition metals in 2D.^[1] However, the field of lanthanides on surfaces remains largely unexplored. Here we present, via scanning tunneling microscopy (STM), a distinctive supramolecular chemistry coordination between cerium atoms and dicyanitrile-oligophenyl linkers (p-NC-Phn-CN-p (n=3,4)) on Ag (111).^[2,3] Our observations reveal the expression of distinct five-fold coordination nodes, which are flexible and thus useful for intricate periodic surface-confined molecular architectures.

By carefully tuning the concentration and the stoichiometric ratio of rare-earth metal centers and molecular linkers, the peculiar five-fold coordination results in a 2D hierarchic metal-organic assembly based on dodecameric units. For an increase in the cerium supply, a fully reticulated 2D metal-organic network evolves, whereby all linkers are connected to both sides to Ce centers, following a design pattern interpreted as a molecular Archimedean snub square tessellation of the surface.^[4]

Thus, our study introduces the first implementation of the f-block elements^[5] in a 2D metallosupramolecular assembly, revealing the versatility of surface-confined lanthanide-based chemistry to engineer complex networks and intricate surface tessellations with particular metal-organic motifs.

The direct formic acid fuel cell (DFAFC) [1, 2, 3], operating at temperatures below 90°C, is a promising source of electric power for a range of applications. Catalysts based on metal nanoparticles/conducting polymer/ graphene are important material for using in DFAFC. Because graphene is also applied in many other applications there are manufactures for its preparation now. The graphene materials from different manufactures were subjected to oxidation in ozone, to oxidation in electron pink plasma and to reduction in H₂ atmosphere at higher temperature. Surface properties of these samples were characterized by X-ray photoelectron spectroscopy (XPS) and Reflection Electron Energy Loss Spectroscopy (REELS). The XPS is applied for determination of surface composition and a content of C bonding, whereas REELS, informing on the energy loss processes of the excited electrons during their transport to the surface, for structural characterisation. The REELS spectroscopy provides information from the energy and intensity of the quasi-elastic peak and inelastic π and $\pi+\sigma$ energy loss peaks, where the $\pi+\sigma$ energy loss peak can be separated into C sp² and C sp³ surface and bulk components. Obtained experimental data show great influence of surface properties (composition, content of the C sp² and C sp³ bonds and carbon-oxygen groups) on used chemical processes. Results help to improve preparation procedures of graphene layers.

Although the structure of a single atom thick, free-standing honeycomb structure of Si atoms is predicted to be stable in a low-buckled configuration [1] instead of a planar geometry like graphene, their calculated band structures are quite similar, as the linear crossing of π bands at Fermi level gives rise to Dirac cones at the K and K' points of the Brillouin zone [1]. Silicene, the so-called Si-counterpart of graphene, has been recently discovered in epitaxial forms [2-4] and it is now the object of an exponentially increasing interest as an emerging allotrope of Si and for applications in high-speed electronic devices.

We demonstrated that a large scale silicene sheet can form spontaneously on the clean (0001) surface of zirconium diboride (ZrB₂) thin films epitaxially grown on Si(111) by ultrahigh vacuum-chemical vapor epitaxy (UHV-CVE). Annealing under UHV condition induces the segregation of Si atoms on the Zr-terminated ZrB₂(0001) surface in the form of a uniform epitaxial ($\sqrt{3}\times\sqrt{3}$)-reconstructed silicene sheet [4]. The study by photoelectron spectroscopy using a surface-sensitive radiation pointed out that among the 6 atoms of the unit-cell, two are sitting on hollow sites of the Zr surface, three near bridges sites and one on top of a Zr atom [4]. The silicene nature of this atom-thick silicon sheet is demonstrated by the presence of a parabolic π -electronic band centered at the K point of the Brillouin zone, as resolved by angle-resolved ultraviolet photoelectron spectroscopy. According to our first principles calculations, the band gap opening is primarily a result of the specifically imprinted buckling rather than the electronic coupling with the diboride layer [4].

The silicene sheet is textured into stripe domains regularly separated by linear boundaries. By means of a scanning tunneling microscopy investigation at low temperature (LT), which suppress the thermally-activated hopping of the domain

boundaries, we determined that this large-scale ordering results from repeated rotations of the silicene orientation by 180° . The Si atoms on top of a Zr atom alternate between the two sublattices of silicene. As a consequence of the creation of the domains, the position of the Si atoms at the boundaries deviates from the honeycomb structure of the domain center.

LT-scanning tunneling spectroscopy carried out at the center of the domain evidences the semiconducting nature of the silicene sheet epitaxied on ZrB₂(0001). Moreover, the mapping of the local density of states gives precious insights on the microscopic origin of the electronic bands. In particular, it shows that the orbitals of on-top Si atoms contribute predominantly to the π bands in agreement with the sp²-like coordination of those Si atoms, as established by density functional theory calculations. Finally, the consequence of the slightly different coordination of the Si atoms at the boundaries on their electronic properties will be also addressed.

SS-P3-18

Characterization of ZnO polar surfaces irradiated under Ar-ion beam

T13 Surface Science

#SS-P3-18

M. Krawczyk, W. Lisowski, K. Nikiforov, J.W. Sobczak, A. Jablonski.

**Institute of Physical Chemistry, Polish Academy of Sciences - 01-224
Warszawa (Poland).**

Two polar surfaces of the wurtzite-type ZnO crystal, the Zn-terminated ZnO(0001) and the O-terminated ZnO(000-1) surface planes, have attracted increasing interest. The question arises, how argon ion-beam interaction affects surface morphology and elemental composition in the surface region of both polar ZnO crystals. In order to address this issue, we performed combination of X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM) and atomic force microscopy (AFM) studies. The results were compared for two single-crystalline ZnO with polar (0001) and (000-1) surfaces irradiated with Ar ions of energy 0.5-5 keV at the incidence angle of 55° with respect to the surface normal. XPS spectra were recorded on the PHI 5000 VersaProbe™ scanning ESCA Microprobe using monochromatic Al K_α radiation. SEM images were obtained with FEI Nova NanoSEM 450 Scanning Electron Microscope, and AFM images were acquired in non-contact (FM) mode with UHV-350 AFM/STM microscope (RHK Technology). The atomic concentration of zinc and oxygen were evaluated using the multiline program [1], where the integrated area of XPS peaks associated with the Zn 2s, Zn 2p_{3/2}, Zn 2p_{1/2}, Zn 3s, Zn 3p, Zn 3d and O1s core levels was used for accurate analysis. Figure 1 displays the ion-energy dependence of the O/Zn at. concentration ratio of the irradiated polar surfaces for the 5 min sputter time. The resulting O/Zn values for the sputter-cleaned Zn-polar and O-polar surfaces were found to be 0.76 and 0.66, respectively, as a result of ion-beam induced loss of oxygen from the surface [2]. SEM and AFM images showed that both ion-irradiated polar surfaces were more defected than the corresponding clean surfaces. The annealing of Ar⁺ ion-beam etched surfaces led to formation of smooth surface with uniform steps [3], and partial removing of surface defects caused by ion-irradiation. In conclusion, our studies on low-energy Ar-ion irradiated polar surfaces of ZnO would be beneficial to use these highly resistive materials under appropriate conditions.

²Dipartimento di Energia, Politecnico di Milano - Milano (Italy).

We present a scanning tunneling microscopy and spectroscopy (STM-STs) investigation of the structural and electronic properties of titanium oxide nanostructures on Au(111). Gold-supported Ti and TiO_x nanoislands represent both a model system for the investigation of oxide nanostructures and promising systems for applications in catalysis and photocatalysis [1,2]. However detailed STM-STs studies of the morphology, local structure and electronic properties of TiO_x on Au(111) are lacking; only recently Wu et al. [3] have shown, in the regime of partial surface coverage, the presence of atomically ordered structures that differ from typical bulk structures [3].

Ti was deposited by e-beam evaporation, leading to preferential nucleation at the elbows of the herringbone Au reconstruction [4] and, in comparison to other metals, retarded coalescence, out-of-elbow disordered growth, intermixing with Au and interlayer diffusion; the electronic properties of Ti islands have been investigated by STS measurements.

For different Ti initial coverage in the 0.1 ML-1.5 ML range, TiO_x nanostructures were obtained by subsequent exposure to O₂ (~ 500 L) followed by annealing in vacuum at 850 K, leading to a ~ 25% decrease in the equivalent total coverage. At low coverage (< 0.5 MLeq) the Au(111) reconstruction is distorted and two different phases are observed, named *pinwheel* (constituting the first layer, fig.1) and *triangular*, always observed on top of the pinwheel. We interpret the structure of the pinwheel phase as a Moiré pattern characterized by a ($\sqrt{133} \times \sqrt{133}$)R17.5° reconstruction, which is different from the model discussed in [3]. At higher coverage (0.5-1.5 MLeq) coalescence of pinwheel islands occurs and other

TiO_x phases are observed whose structure and orientation have been identified via atomic resolution STM imaging and LEED: in the first layer the pinwheel and the *honeycomb* phase, characterized by hexagonal symmetry and (2×2) reconstruction; in higher layers the triangular phase and a *row* phase, not reported before, characterized by 20-40 nm wide islands whose surface presents a periodic series of atomic rows with variable apparent height (Fig.1), and which may be related to one of the bulk phase surfaces of TiO₂. Finally, STS measurements on the different TiO_x nanostructures will be discussed, indicating the presence of a gap in the electron LDOS around Fermi level.

The electronic ground state of the Si(111)7x7 surface, many times discussed, is still unclear.

Its room temperature metallic nature, apparently in line with past band structure calculations, has been reported as dwindling upon cooling, but never really investigated down to helium temperatures. Through a careful low temperature STS study, a small but unmistakable insulating gap is shown to open up below 20 K.

To clarify the nature of that insulating state, we undertook spin-polarized electronic structure calculations which, while density-functional based, are able gauge the strength of electron correlations, including the possibility of Mott type ground states. Results indicate that the ground state of Si(111)7x7 has a multiplicity of competing magnetic phases, including a ferromagnetic state.

By comparing theory and experiment, we discuss possible origins of the observed insulating ground state, especially those involving, along with magnetism, a small symmetry-breaking distortion taking place among the outer Si atoms surrounding the structural DAS vacancy.

The possibility to obtain systems where the magnetic or catalytic atoms are well separated and arranged in regular arrays is allowed at the nanoscale by using molecular self assembly of π -conjugated molecules containing metal ions.

Porphyrins are a class of such molecules with a planar macrocycle that can accept metal ions of different kind at the center (metalation), thus forming metallo-porphyrins.

There are several ways to metalize porphyrins by wet-chemistry [1]. Even more interesting is the metalation of porphyrins in ultra high vacuum (UHV) by evaporation of metal on H₂-porphyrin self-assembled on surfaces [2-6], since this method allows to obtain metallo-porphyrins that typically are not stable as single-molecules thanks to the action of the support surface, which stabilizes the valence state of the evaporated metal [5,6]. A risk, however, is the formation of metal clusters in addition to metallo-porphyrins due to the reduced mobility of some metals adatoms or to an excessive metal ions deposition.

Here, using synchrotron radiation spectroscopy, we show a new method of porphyrin

metalation in UHV without the metal evaporation. Depositing one monolayer of H₂-tetraphenyl-porphyrins (H₂-TPP) on Fe, Ni and Al substrates, a substrate adatom binds directly to the macrocycle and metalates the porphyrins, forming Fe-TPP, Ni-TPP and Al-TPP, respectively. Metalation in a similar manner was obtained on Cu surfaces by other research groups [7-9]. Energetics obtained by density functional theory calculations confirms the possibility of such a kind of metalation. The redox reaction happens at room temperature for Fe and Ni substrates [10], while it requires heating at 400 K for the Al substrate. Moreover, the interaction with Al is so strong that just above 400 K the molecule starts to decompose forming Al-N alloy.

Time domain mapping of short voltage pulses with plasmonic light

T13 Surface Science

#SS/NST-1-Or-5

M. Etzkorn ¹, C. Große ¹, K. Kuhnke ¹, S. Loth ², K. Kern ¹.

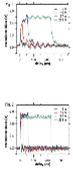

¹Max Planck Institute for Solid State Research - Stuttgart (Germany), ²Center for Free-Electron Laser Science - Hamburg (Germany).

Time-resolved STM measurements using electronic pulses enable the study of local dynamics in the nanosecond-regime and below [1]. One necessary prerequisite for such measurements are defined pulse profiles of the transient bias voltage $V(t)$ at the tunnel junction. Due to high frequency limitations of the wiring and impedance mismatches in the experiments (in particular for UHV, low temperature set-ups), well defined pulses fed into the STM will deviate from perfectness when they reach the tunnel junction. Here we introduce a new concept that enables a direct, non-invasive, and quantitative mapping of $V(t)$ in the junction using STM-induced light emission via tip-induced plasmons. This method takes advantage of two effects: 1) The number of photons emitted from a tunnel junction is a bijective function of the voltage. 2) Both, plasmon decay and photon detection are fast (< 1 ns) compared to the time scale of the variation of $V(t)$. By redundant measurements of the autocorrelation using an all-electronic pump-probe scheme, we proof that this method indeed measures the correct pulse shapes. Using this new optical read-out we have extracted the transient bias signal in our system for rectangular pulses fed into the bias line of the STM (see Fig. 1). Significant deviations from the feed-in pulses are observed, demonstrating the importance of a possibility to determine $V(t)$. We can assign the deviations to the low-pass filtering and resonances within the cable. Moreover, using this method, we determine the transfer function of our set-up and show, how this function can be used to construct the intended pulse shape in the junction. Fig. 2 shows optimized square pulses which are generated from applied bias time pattern that correct for the imperfections in the bias signal line. This leads for instance to an improvement in the falling edge width from ≈ 50 ns to < 5 ns.

Bulk Molybdenum Tips for Scanning Tunneling Microscopy and Spectroscopy

T13 Surface Science

#SS/NST-1-Or-8

P. Carrozzo ¹, C. Casari ², M. Passoni ¹, C.E. Bottani ², A. Li Bassi ².

¹Dipartimento di Energia, Politecnico di Milano - Milano (Italy), ²Dipartimento di Energia, Politecnico di Milano; CNST - Center for Nano Science and Technology @PoliMi, Istituto Italiano di Tecnologia - Milano (Italy).

We present a method for the preparation of bulk molybdenum tips for Scanning Tunneling Microscopy and Spectroscopy (STM-STS) and we show their potential in performing high quality and high resolution imaging and local spectroscopic measurements.

STM is a very powerful tool to investigate the morphological, structural and electronic properties of surfaces and nanostructures with extremely high resolution down to the atomic scale. STM-STS measurements in UHV can be performed with mechanically cut Pt/Ir tips or, more commonly, with chemically etched tips, typically made of W, even though other metals are sometimes employed (e.g. Au) [1]. Magnetic tips are instead adopted for spin polarized (SP) measurements, either by fabricating bulk tips (e.g. Cr [2]) or coating W tips. In this framework, thanks to its inertness and ease of handling, Mo represents a good alternative, but up to now Mo tips have not been used for STM measurements. We have fabricated Mo tips by developing an optimized procedure for electrochemical etching a 99.99% Mo wire in a NaOH solution, exploring conditions such as NaOH concentration and applied bias. Mo tips are characterized by a regular shape at the micron scale and a sharp tip apex with a radius of curvature of about 50 nm, as shown by scanning electron microscopy images (fig.1), and high quality tips can be routinely obtained with a high success rate. We tested Mo tips by performing atomically resolved STM measurements on single crystal surfaces in UHV. Mo tips permit to obtain very high quality images of the Au(111) superstructure and STS measurements show the Au Shockley peak at -0.47 eV. Imaging and local STS measurements of the Si(111)-7×7 surface were also performed, and atomic resolution was achieved, showing in particular the rest atoms of the Si(111)-7×7 reconstruction at negative bias (below -1.5 V, fig.1), contrary to

what normally happens with conventional W tip [3]. A comparative analysis of STS data acquired with different tips (W, Cr and Mo) can be used to gain information on the dependence on the tip density of states. Finally Mo tips have been successfully employed for original measurements of surface nanostructures, namely structural investigation via atomic resolution imaging of peculiar TiO_x ordered phases grown on Au(111).

The method used for the fabrication of Mo tips is versatile and we show that it can be extended to other metals, e.g. cobalt.

Synergistic effect of metal and metal-oxide nanostructures on ethanol reforming over non-noble metal based model catalysts

T13 Surface Science

#SS-14-Or-1

Widespread utilization of hydrogen as energy carrier requires the solution of issues connected to its sustainable generation and safe distribution. Since our current energy infrastructure is well prepared for handling liquid fuels, a very compelling utilization strategy can be based on on-site hydrogen generation by catalytic conversion of hydrogen-containing compounds such as ethanol. Economically viable approaches, however, require sophisticated yet robust and cheap reforming catalysts. Until recently, noble or near-noble metal-based systems seemed to offer the best choice for ethanol reformers. Apart from efforts for reducing the noble metal content, recent experiments indicate that good results can be obtained on multicomponent catalysts built around the members of the iron group. Ni emerges as a key ingredient for these catalysts, but since a delicate balance between different surface functionalities is needed for suppression of unwanted side reactions, doping with further metal or oxide components is unavoidable. Because of the required complexity, a detailed understanding of the interplay between the constituents of the active surface is a prerequisite for successful design of a noble metal free ethanol reforming catalyst.

Accordingly, a comparative multi-technical study of Ni-based, Co and Ce-containing catalysts on MgAl₂O₄ support was carried out. While the Ni- and especially the Ni-Co containing catalysts suffered from extensive coke formation, addition of Ce in the form of a somewhat reduced oxide successfully eliminated this side process. Catalytic tests revealed a strong synergism between Ni and Co, as the desired

conversions, such as water-gas-shift reaction and direct steam reforming of acetaldehyde, are dominating in the bimetallic system leading to high hydrogen yield. Structural and electron spectroscopic studies indicated considerable exchange of Mg cations to Ni or Co, leading to the formation of transition metal doped spinel support. Since Co turned out to preferentially occupy the exchangeable Mg sites, in the bimetallic case considerably larger fraction of Ni could be reduced to metallic state than in the monometallic case. The easier transformation of ethanol to acetaldehyde and the direct steam reforming of acetaldehyde evidenced by catalytic tests and DRIFT measurements were therefore traced to the increased metallic character of Ni, together with charge transfer processes at the interface between the Ni particles and the semiconducting support.

In order to further elucidate the background of the Ni-Co interplay in ethanol steam reforming, model catalysts were developed by depositing mono- and bimetallic layers onto epitaxial CeO_2 films grown on CaF_2 -buffered Si(111). In this approach relevant structural parameters such as chemical identity, amount or oxidation state of the active metals can be relatively independently controlled, thus allowing the separation of their influence on the adsorption and initial transformations of ethanol molecules. Results of electron spectroscopic and in situ vibrational spectroscopic measurements emphasized the key role of the finely balanced interaction of the constituents in the working mechanism of noble metal free ethanol reforming catalysts.

Resonant soft X-ray reflectivity (RSoXR) is a quantitative tool to study the interplay between electronic properties, geometry and morphology of a wide class of ultrathin films and layered system with sensitivity to the depth distribution of chemical species and buried interfaces. Element- and bond-specific information, beyond the total electron density distributions, can be obtained by scanning the photon energy through specific absorption edges and playing with the polarization and incidence angle of the impinging field.

For the first time to our knowledge, we applied polarized-light resonant soft X-ray reflectivity (P-RSoXR) at the carbon K-edge to study morphology and ordering of an organic anisotropic self-assembled layer on Au(111). In particular, we studied the 1,4 benzenedimethanethiols (BDMT)/Au(111) system. In recent years we gained detailed knowledge on the formation of BDMT SAMs on well-defined gold surfaces, exploiting both in vacuum and in-liquid deposition, thanks to an in-depth investigation by spectroscopic ellipsometry (SE), reflection-absorption IR spectroscopy (RAIRS), electrochemistry, photoemission and X-ray absorption (XAS).^(1,2) We were able to elaborate a protocol for obtaining well-organized SAMs of BDMT molecules in a standing up configuration, with a sulfur headgroup bonded to the substrate and the other SH unbound terminal pointing upright. This method was used to prepare the

BDMT films.

P-RSoXR data at the carbon K-edge were taken at the BEAR beamline at ELETTRA in grazing incidence of linear polarized light, from s- to p- scattering geometries.

To interpret the P-RSoXR data we followed an approach based on the calculation from the first principles (through DFT) of the film optical constants. We calculated the anisotropic optical cross sections of the molecule, the corresponding polarizability, we modeled the molecular arrangement and we constructed the corresponding anisotropic dielectric tensor of the film. We finally simulated the propagation of light inside the vacuum/BDMT/Au system as a function of the incidence geometry, obtaining a simulated reflectivity to be fitted to the experiment.

This method permitted us to exploit the sensitivity of P-RSoXR to derive quantitative information on the layer anisotropy, molecular orientation and thickness of self-assembled monolayers (SAMs) at surfaces simultaneously.

In the present contribution we demonstrate the validity of this approach which – we believe - opens interesting possibilities in the study of a wide class of organic thin films. The method transfers to soft-X range the knowledge gained in the years in the field of visible (ellipsometry included) and infrared spectroscopy of thin anisotropic films. Moreover, it offers a tool of quantitative investigation in those cases where electron spectroscopy cannot be employed because of the presence of nonconductive materials, poor vacuum or materials buried at distances from surfaces higher than the electron free collision path.

Scalability and process-induced disorder problems often appear when producing semiconducting–metallic graphene networks. We present here an all graphene nanostructure with a one-dimensional metallic–semiconducting–metallic junction. Our technique relies on graphene grown on patterned SiC steps [1], without chemical functionalization or finite-size patterning.

We have studied these nanostructures by photoemission, that successfully allowed us to observe the ideal dispersion in flat epitaxial graphene on SiC [2,3]. The bottom-up growth procedure promotes graphene strips along the slopes. At the edge of these graphene strips, a semiconductor, is bonded to metallic graphene. This semiconductor is only a few nanometers wide (a few graphene lattice constants), a level of precision beyond modern lithographic limits. Moreover, the properties are preserved across micrometric distances as observed by averaging the properties of the ribbons in the observation area. The band gap is greater than 500 meV in an otherwise metallic graphene ribbon (fig. 1) [4].

Analysis of organic films deposited by a RF CCP discharge in a N₂ CH₄ mixture

T13 Surface Science

#SS-5-Or-5

N. Carrasco ¹, F. Jomard ², J. Vigneron ³, A. Etcheberry ³, G. Cernogora ¹.

¹LATMOS - Guyancourt (France), ²GEMAC - Versailles (France), ³ILV - Versailles (France).

In Titan's atmosphere, the largest Saturn's satellite, solid organic aerosols are formed by the dissociation of N₂ and CH₄. In order to simulate the chemistry involved in the Titan's atmosphere, a low pressure (0.9mbar) RF CCP discharge is used. The experimental device is described in [1]. Gas mixtures of N₂ and CH₄ mixture (from 1 to 10% of CH₄) are injected continuously. The plasma discharge in N₂-CH₄ gas mixtures leads to the production of analogues of Titan's atmospheric aerosols: both as grains in the volume [2] and as thin films on the surface of the reactor [3]. SiO₂ substrates of 1cm diameter and 1 mm thickness are placed on the grounded electrode of the discharge. Organic films are deposited during 2 hours in order to have films thickness less than 1 μm. After the two hours, samples are recovered at ambient air for ex-situ analysis. Two complementary analyses are performed to analyse the thin film chemical composition: XPS and SIMS.

XPS surface and profile analysis are performed with a high resolution XPS probe. The relative amounts of C, N, O and Si are measured from the first down to the 300 nm along the film depth-profile. It is observed that below 60 nm the amounts of C and N remain constant. No Si is observed in the studied layer, and O is negligible below 60 nm. The relative amount C/N is measured as function of the injected CH₄ amount. It is shown that the ratio C/N decreases from 0.4 to 0.1 when the CH₄ amount increases from 1 to 10%. These C/N ratios are lower than those measured in the solid grains produced in the volume of the discharge [2].

In order to check the uniformity of the organic layer, SIMS analysis is performed after XPS studies using an IMS-4F (CAMECA) [4]. The H, C, O and Si secondary ions are measured during the SIMS depth profile. After a few tens of sputtering, the all the ions signals are constant. The organic layer composition is homogeneous. The limit

of the organic film is detected after 600 to 2000 s of etching, by a rapid increase of O and Si signals, corresponding to the SiO₂ substrate. By measuring the depth of the sputtering crater, it is possible to determine the true thickness of the organic film. Absolute elemental analysis measurements are not an easy task with SIMS. However, the evolution of the ratio H/C in arbitrary units is deduced from the ratio of the corresponding ions signals. It is shown that this ratio remains the same, about 0.1, whatever the injected CH₄ amount. For powders, Sciamma O'Brien et al. (2010) have shown that this ratio increases with the amount of injected CH₄. These results show that important differences exist between the chemical compositions of organic materials produced as powders or films in the same experimental conditions.

Adsorption and self-assembly of functionalized [5]helicene molecules on insulating ionic surfaces

T13 Surface Science

#SS-14-Or-2

B. Hoff ¹, M. Gingras ¹, R. Peresutti ¹, G. Felix ¹, C.R. Henry ¹, A.S. Foster ², C. Barth ¹.

¹CINaM-CNRS Campus de Luminy Case 913 13288 Marseille Cedex 9 - Marseille (France), ²COMP Centre of Excellence, Aalto University School of Science, Department of Applied Physics, Finland - Marseille (France).

In recent years organic thin films on insulating surfaces have become very important since they have the advantage of electronically decoupling molecules from the support, unlike metal surfaces. This leads to new phenomena of adsorption and self-assembly, which detailed mechanisms are studied on the model surfaces of ionic alkali halides by noncontact atomic force microscopy (nc-AFM) and Kelvin probe force microscopy (KPFM) [1].

The current tentative picture for the adsorption of molecules on ionic insulating surfaces in general considers a non-site specific van der Waals interaction between the molecule and the surface, but also an electrostatic interaction between the ionic lattice of the surface and functional groups of the molecule, which contain a partial charge or exhibit a local dipole. Although such two contributions explain to some extent experimental observations, many important questions remain still open – the current tentative model needs urgent further confirmation.

In this contribution we focus on functionalized pentahelicene molecules, which are deposited in ultrahigh vacuum (UHV) onto the (001) surfaces of different pure and Cd²⁺ doped alkali halide (Suzuki surface) crystals [2]. The local structure of the films and their dipole distribution are studied by UHV nc-AFM and KPFM, respectively, and DFT theory. The helicene molecules carry either one or two bromine atoms (MonoBromo, DiBromo) or one or two cyano groups (MonoCyano, DiCyano) (Figure (a)). We show that the adsorption as well as the self-assembly of the molecules strongly depend on the number of functional groups, the type of group (dipole) and the ionic lattice of the surface. For instance, in Figure (b) the nanostructured (001) Suzuki Surface, which exhibits Suzuki regions (containing all the Cd²⁺ ions) and

pure NaCl regions, is covered by one monolayer of DiCyano. Self assembly only occurs in the pure NaCl regions, and in the Suzuki regions a rather amorphous structure is found.

We explain that in particular the electrostatic interaction of the functional groups with the ionic lattice plays a major role in the adsorption, where adsorption geometries ('charge matching') and dipole strengths are of key importance. They all may have an impact onto intermolecular interactions determining if self-assembly via π - π stacking of the helicene molecules is possible or not.

Electron Spectroscopy Studies of Adsorbed Chiral Molecules on Magnetic and Non-Magnetic Surfaces

T13 Surface Science

#SS-11-Or-4

J. De Miguel ¹, F.J. Luque ¹, I.A. Kowalik ², M. Niño ³, R. Miranda ¹, D. Arvanitis ⁴.

¹Univ. Autónoma - Madrid (Spain), ²Inst. Physics, Polish Acad. Sci. - Warsaw (Poland), ³IMDEA-Nanociencia - Madrid (Spain), ⁴Uppsala Univ. - Uppsala (Sweden).

Recently, layers of chiral molecules have been shown to scatter electrons differently depending on their spin [1,2]. These experiments prompt questions about the relationship of molecular chirality with spin and the influence that the magnetisation of the substrate can have on the adsorption of chiral molecular films.

Ultra-thin films of the chiral enantiomers (R,R)-(+)- and (S,S)-(-)-1,2-Diphenyl-1,2-ethanediol (DPED, see the inset in Figure 1) have been studied using absorption of circularly polarized x rays (XAS) at the carbon K edge and valence band photoemission. The substrates used were a single-crystal Cu(100) surface and ferromagnetic Co(100) films epitaxially grown on it. The measurements were performed at the I1011 and I3 beamlines of synchrotron MAX IV (Lund, Sweden), as well as in our home lab in Madrid.

Figure 1 shows a representative XAS spectrum acquired on a DPED film grown on Cu(100). The different features in it have been identified and assigned to specific electronic transitions. The sharp peak at ~284 eV corresponds to the π^* resonance of the C unsaturated bonds. The set of peaks appearing behind this one between 285 and 290 eV have also π -type character and are assigned to the C–H bonds in the molecules, whereas the broader features at higher energies correspond to σ -type C–C bonds [3].

Pairs of spectra were acquired using circularly polarized radiation with opposite helicity ($\sigma+$, $\sigma-$) and compared by taking their intensity ratio. The results of these measurements are displayed in Figure 2. Several clearly dichroic features can be observed coincident with the C–C and C–H π orbitals showing opposite signs for the two enantiomers.

The films of chiral DPED have also been grown on ferromagnetic Co(100) films; their effect on the atomic magnetic moments of the Co atoms will also be discussed.

The molybdenum hexacarbonyl $\text{Mo}(\text{CO})_6$ physisorbs as entire molecules on most noble metals, metal oxides and relatively inert surfaces at liquid-nitrogen temperatures and desorbs upon thermal heating close to 200 K. In the case of copper surface, the temperature programmed desorption measurements established a more complex behaviour [1]. Under heating, decomposition of the adsorbed molecules occurs via several steps over a temperature range from 170 to 480 K. The dissociation channel competes favourably with desorption.

Molybdenum hexacarbonyl has been deposited on copper substrates at low temperature and studied by scanning tunneling microscopy (STM), X-ray photoelectron spectroscopy (XPS) and periodic density functional theory (DFT) calculations. The adsorbed molecules form a dense hexagonal monolayer on both Cu(111) and Cu(100) surfaces [2]. The molecules arrangement and orientation on the surface are confirmed by DFT calculations including van-der-Waals interaction. Under heating, dissociation products adsorb on the surface and generate well-defined monolayers. Dense superstructures with particular domain orientation, depending on the surface symmetry, are observed by STM on Cu(111) and Cu(001). XPS spectra analysis indicates that the superstructures are formed by $\text{Mo}(\text{CO})_x$ ($x < 6$) fragments, where the number of CO groups depends on the substrate temperature. Experimental results are considered in comparison with theoretical calculations of $\text{Mo}(\text{CO})_x$ fragments dissociation on copper surfaces. DFT results confirm the predominance of dissociation channels over desorption: in particular on Cu(001), the first dissociation of $\text{Mo}(\text{CO})_6$ is widely favored with an exothermicity close to 2 eV. Following dissociation steps are also preferred compared to desorption with low endothermicities around 1 eV while adsorption energies cost between 3 and 4 eV.

Q. Fu, R. Mu, L. Jin, Y. Zhang, X. Bao.

Dalian Institute of Chemical Physics, the Chinese Academy of Sciences - Dalian (China).

We show that an extended two-dimensional (2D) nanospace forms between graphene sheets and solid surfaces, where guest atoms or molecules can be accommodated at the interfaces and chemical reactions may be performed therein (Figure 1). It has been demonstrated that O, Pb, Ni, and Si atoms can diffuse underneath graphene at elevated temperatures, decoupling the graphene layers from the Ru(0001) substrate [1, 2]. Even at room temperature, the intercalation of CO molecules at graphene/Pt(111) interfaces was also observed. The 2D nanospace presents as an extended confined environment, which exhibits nano-confinement effect on the chemical reactions on the solid surface. In-situ low energy electron microscopy (LEEM)/photoemission electron microscopy (PEEM), ambient pressure X-ray photoelectron spectroscopy (AP-XPS), polarization-modulation infrared reflection absorption spectroscopy (PM-IRAS), and density functional theory (DFT) calculations reveal the nano-confinement effect from the graphene cover, which destabilizes adsorption of CO on Pt(111) surfaces and promotes the catalytic CO oxidation confined under graphene cover [3]. CO intercalation and CO oxidation under BN cover has also been explored and a similar confinement of the BN cover on surface chemistry was observed.

Structural and Magnetic properties of Cobalt nanoparticles on graphene/SiC(0001)

T13 Surface Science

#NST/SS-P2-05

L. De Lima, A. De Siervo, R. Landers.

State University of Campinas - UNICAMP - Campinas (Brazil).

Fabrication of monodispersed and uniform-sized nanoclusters on substrates is currently a challenging subject that has received great interest. Monodispersed metal nanoclusters on insulating or semiconducting substrates have a wide range of applications in heterogeneous catalysts [1], as well as prototypes for magnetic medias with ultrahigh-density recording [2]. A promising route to fabricate nanostructures arrays is the self-assembly of atoms and molecules induced by surface nanotemplates (atomically well-defined surfaces) that are naturally or artificially patterned at the nanoscale [3]. In this work, cobalt nanoparticles were grown on graphene/SiC(0001). The graphene was obtained by heating a SiC(0001) surface to temperatures of about 1150°C in ultra-high vacuum and Co was directly deposited on this surface at room temperature by electron-beam evaporation and various sessions of evaporation were done with different deposition rates and times, monitored by X-Ray Photoelectron Spectroscopy (XPS) and Scanning Tunneling Microscopy (STM). Basically, the cobalt clusters prefer to form on the defects sites, in the border between different regions of the substrate. XPS shows that the cobalt peak agrees with metallic cobalt, which indicates that there is no cobalt silicide/carbide formation. The magnetic properties of nanoparticles were investigated with X-Ray Magnetic Circular Dichroism (XMCD) at PGM beamline of Brazilian National Laboratory of Synchrotron Light. The XMCD results (L_{2,3} edge at 20K) show a enhancement of the orbital moment with a apparent in-plane anisotropy and no contribution of magnetic dipole operator, indicating that the spin density are spherically symmetric. These results were obtained with the application of sum rules [4].

Atomic and electronic structure of the InAs (001) surface

T13 Surface Science

#SS-17-Or-7

N. Tomaszewska, J. Kolodziej.

Faculty of Physics, Astronomy, and Applied Computer Science, Jagiellonian University - Kraków (Poland).

The (001) surface of InAs displays multitude of stoichiometry dependent, complex reconstructions. In the present paper we show studies of this surface for two different reconstructions, using angle-resolved photoemission spectroscopy (ARPES), low-energy electron diffraction (LEED), and scanning tunnelling microscopy (STM). Standard preparation procedure of the In-rich surface InAs(001) by ion sputtering and heating at 400-550°C is used which leads to the $c(8 \times 2)/(4 \times 2)$ reconstruction. This reconstruction may be transformed to the As-rich (2×4) reconstruction by exposing the surface to As_2 molecular flux and thermal annealing. Prepared surface structures are verified by LEED and their electronic structure is studied along main crystallographic directions, as well as on the Fermi surface, by ARPES. As for today no detailed research of the InAs(001) electronic band structure has been carried out. Atomic structure of InAs(001) $c(8 \times 2)/(4 \times 2)$ was described by Kumpf et al. [1], and recently in detail by G.Goryl et al. [2]. The As-rich (2×4) structure was discussed by W. Barvosa-Carter et al. [3]. Both structures are rather complex, containing many atoms in their unit cells and consequently they support many electronic bands. We give preliminary discussion of these bands and we track the origin of few individual bands. We also discuss the surface electronic state localized near Fermi surface close to J' points in the reciprocal space. As we show, this state makes it possible to use STM for imaging of the In sublattice applying extremely low bias voltages. We think that the state arises due to broken translational symmetry at the surface, i.e. it is the Shockley state.

Interfaces of thin film, Studied by SPR Technique

T13 Surface Science

#SS-P3-28

K. Ayadi.

IOMP UFAS - Setif (Algeria).

Abstract: An experimental procedure has been devised to study the diffusion of impurities throughout thin films using the surface plasmon resonance technique. When such a film is in contact with two dielectrics having different indices the surface plasmons, at two interfaces of a metallic film can be optically excited simultaneously, by attenuated total reflection (ATR). The plasmons are totally decoupled.. Experimental results of the diffusion of gold through thin silver films are presented using the experimental procedure outlined above.

Keywords : Surface plasmon, attenuated total reflexion, diffusion

Résumé:

Le dispositif expérimental conçu est destiné à exciter optiquement les plasmons de surface aux deux interfaces d'une couche métallique en contact avec deux diélectriques d'indices différents. Les plasmons sont totalement découplés, ce qui nous permet d'accéder séparément aux propriétés de chaque interface. Un tel dispositif peut servir à étudier la diffusion d'une impureté à travers la couche, dans ce travail, nous avons procédé à l'étude de la diffusion entre deux couches d'argent et d'or, cette étude a permis également d'apprécier la vitesse de diffusion a travers la couche d'argent.

Mots clés : Plasmon de surface, diffusion.

INTRODUCTION.

In the visible and near infrared spectrum, materials such as alkyls and noble metals behave as free electron materials. Their electronic optical properties can be particularly reached by exciting the surface plasmons with ATR at the interface of these elements and a dielectric such as vacuum. The surface plasmons are very sensible to the interface properties, as it was reported in several works realised on systems like gold, silver, aluminium and alloys [1-5].

When surface plasmons are decoupled, the properties of the two interfaces become separately accessible and thus the study of the impurities diffusion process is possible. In this paper, the technique is described in details and applied to the diffusion of gold throughout thin silver films.

RESULTS

Fig 2 : $R_p(\alpha)$ at the external interface

Fig 3 : $R_p(\alpha)$ at the internal interface

Figure 2 and 3 : Reflection factor of the system Prism/MgF₂/Ag

Serie 1 : $\lambda = 630$ nm , Serie 2 : $\lambda = 590$ nm , Serie 3 : $\lambda = 550$ nm

Serie 4 : $\lambda = 510$ nm , Serie 5 : $\lambda = 470$ nm

This preliminary study shows that the surface plasmons can be excited separately at two interfaces of a thin metallic film. The resonance curves are completely decoupled due to the judicious experimental set up. This constitutes a powerful and non-destructive probe that may be used to study the diffusion process of impurities through thin films.

IMDEA Nanociencia - Madrid (Spain).

Monolayer graphene (MLG) supported on metallic substrates is a widely studied subject nowadays, among other things because of the interesting moiré patterns arising from the lattice mismatch between graphene and the metal. However, interaction with the metal often leads to the suppression of many interesting effects, like the inter- or intra-valley scattering processes present in the case of non-metallic substrates [1]. A possible way to decouple MLG from the substrate is the intercalation of an atomic layer of a different element between them [2-5], and indeed it has been recently shown that MLG/Si/Ru(0001) do present inter-valley scattering [6]. Here we study the MLG/Pb/Ir(111) system and show that, under certain growth conditions, lead enters through graphene-free patches and intercalates between graphene and iridium preserving the original 9.3×9.3 incommensurated moiré structure [7]. As structure for the Pb inter-layer, we propose a rectangular lattice (close to Pb(110)) commensurated with graphene. Our measurements also suggest that lead decouples graphene from the metallic substrate and breaks its sub-lattice symmetry, allowing to observe both inter- and intra-valley scattering processes [8] not present in the absence of Pb.

Randomness destroys translational invariance resulting in exponential spatial localization of wave functions through quantum interference. This effect — known as Anderson localization — is a universal property of waves, which has been observed directly in light and matter. In electron systems, Anderson localization has been studied mostly indirectly in transport experiments through metal-insulator transitions or conductance fluctuations. This complicates theoretical descriptions as, e. g., calculating the conductance remains a challenging task despite highly sophisticated models. Using the BiPb/Ag(111) mixed surface alloy, we go beyond averaged quantities both in theory and experiment. We measure simultaneously chemical composition and local electronic structure linking experiment and theory on the most fundamental level: we demonstrate the atomically resolved observation of spatial wave function localization for a mixed surface alloy — a purely two-dimensional electron system in a static disordered potential. We then use the chemical composition as the structural input for the “original” real space Anderson tight-binding model which allows us to directly compare the locally resolved wave functions in experiment and theory with remarkable agreement.

The (101) surface is the dominant face exposed on TiO₂ anatase nanoparticles and has been theoretically shown to be the thermodynamically low-energy surface.¹ In spite of the importance of TiO₂ catalysis very few studies have been performed on the anatase TiO₂(101) single crystal surface.²⁻⁴ Fundamental studies on the role of TiO₂ surface structure on adsorption, dissociation, and desorption of formic acid has been performed on rutile single crystals and it was shown that surface structure plays an important role in observed chemistry.⁵ In this investigation we have characterized the interaction of formic acid with anatase TiO₂(101) surfaces using temperature programmed desorption, x-ray photoelectron spectroscopy (XPS), and low energy electron diffraction. Formic acid is found to dissociate on the anatase TiO₂(101) surface on adsorption at low temperature, and undergoes decomposition upon desorption. Using deuterated formic acid and co-dosing with water allows us further elucidate the surface reaction mechanisms. These results will be compared to prior data that has been obtained for rutile single crystal surfaces.

We demonstrate the recent investigations of graphene on cubic SiC(001) substrates. The quality of graphene and number of monolayers on large area of substrate depend on preparation technology, which was proved by a number of experimental techniques (μ -LEED, LEEM, PEEM, ARPES etc). The overlayers show atomic and electronic structure typical for free-standing graphene. We believe, that very soon the method can represent a real step towards graphene-based electronic technologies.

A study of the magnetic, magneto-impedance, thermal and structural properties for the amorphous alloys $\text{Fe}_{73.5-x}\text{Cr}_x\text{Nb}_3\text{Cu}_1\text{Si}_{13.5}\text{B}_9$ with $x = 0, 2, 4, 6, 8$ and 10 is presented. These alloys were prepared in form of ribbons by a melt spinning technique and their structural state was checked using X-ray diffraction with $\text{CuK}\alpha$ radiation. The temperature (T) and the magnetic field (H) dependences of the magnetization were measured using temperature cycling (H fixed) and field cycling (T fixed) with a Vibrating Sample Magnetometer (VSM)-VersaLab Quantum Design, Inc. In the temperature cycling measurements, the sample in its ferromagnetic state is first heated from room temperature to a certain temperature in presence of magnetic field. Then the sample is cooled from the paramagnetic state to room temperature. The temperature and applied field were varied in the ranges $300 \leq T \leq 900$ K and $0 < H \leq 1$ kOe, respectively. In the heating procedure, the magnetization curves exhibit a Hopkinson-type weak anomaly at a certain temperature T_{Ho} just below the amorphous Curie temperature $T_{\text{Curie,am}}$ with increasing temperature and fall basically to zero before that sample reaches its crystallization temperature. It was also found that the magnetization is irreversible below an irreversible temperature $T_i(H)$ with respect to the heating-cooling procedures. The complex impedance in these ribbons was measured for applied dc magnetic fields from -80 to 80 Oe at room temperature, via the so-called four-probe technique. Here we emphasize the presence of a “three-peak behavior” in magneto-impedance curves. The thermal characterization was carried out using differential scanning calorimetry DSC (TA DSC-Q100) and thermogravimetric analysis TGA (TA TGA-Q500). Particular attention is also given to observation of crystallization kinetics via DSC, TGA, and magnetization. A (H, T) phase diagram that contains T_{Ho} , $T_{\text{Curie,am}}$, and $T_i(H)$ for each of the ribbons under study is presented and discussed.

The extraordinary electronic properties of graphene makes it one of the most promising candidate materials for future nanoelectronic devices [1]. Additionally, its elastic behavior has recently been determined by indentation experiments on large free-standing monolayer samples and continuum mechanics modelling [2,3]. However, it is unclear up to what extent such features are preserved when the dimensions of the graphene sheet reach the atomic scale. Graphene samples of such dimensions can be produced by growing a graphene monolayer on Ru(0001). In this system, ripples of about a hundred atoms are formed, due to the lattice mismatch between the carbon monolayer and the metallic substrate [4-7]. In this contribution, large scale Density Functional Theory simulations of the indentation of such ripples are used to unravel that Non-Contact Atomic Force Microscopy (NC-AFM) experiments, performed on monolayer graphene/Ru(0001) samples under ultra-high vacuum conditions, are indeed probing the reversible deformation of this corrugated structure. These results prove that the elastic behavior of graphene is preserved at the nanoscale.

Scanning Tunneling Microscopy (STM) and Noncontact Atomic Force Microscopy (NC-AFM) provide atomic-scale information on surface structures and related physical properties in the atomic scale. There has been an excellent study on the classification of atoms through force spectroscopy by Prof. Morita's group [1]. However, it is still difficult to obtain elemental information directly without supports from other surface science techniques. Previously, we reported development of NC-AFM combined with the synchrotron radiation X-ray, named "**X-ray Aided Non-contact Atomic force Microscopy (XANAM)**" [2] as a chemically sensitive NC-AFM. According to the text book on NC-AFM, a chemical bonding arises between a tip-apex and a surface during imaging at the atomic level. Strength of the chemical bonding force may depend on the electron density of bonding and anti-bonding states. Thus, a hypothesis was proposed as follows; if the electron density of states of the chemical bonding was resonant with the inner core level of electrons through X-ray irradiation, changes in the interaction force relevant to chemical information should appear. However, piezo-electric cantilever, a kind of self-detection cantilever, was used in the previous measurements [2]. A sharp tip was difficult to obtain, because the tip was made of piezo thin films fabricated by semiconductor process, though the self-detection cantilever has a merit of reducing complexity for optical beam alignments.

Therefore, **we have modified the cantilever system into a qplus sensor type [3] in order to improve the quality of XANAM measurements.** Adopting the qplus sensor has another merit of adding the functionality for electric current measurement. We carried out simultaneous measurements of dependency of electric current on distance between a W-tip and a gold film, as well as for frequency shift and amplitude

of the qlus sensor (Fig. 1). These measurements were conducted under X-ray irradiation with various energy ranges. In the presentation, we would discuss about data on the dependency of the force spectroscopy and the bias spectroscopy on X-ray energies. This work is majorly supported by several Grants from the JSPS, the MEXT and the NEDO. The experiments were carried out under the approval of Photon Factory Advisory Committee (ex. PAC: Proposal No. 2009G567, 2012G099).

³University of Tokyo - Kashiwa (Japan).

Since the Au(111) surface state was found to be spin split to an unexpectedly large extent in 1996, the Rashba spin splitting on the surfaces of heavy elements were studied intensively. In 2007, the Ag surfaces covered with a Bi monolayer [1] or a Ag₂Bi surface alloy [2] were found to exhibit giant Rashba spin splitting, which indicated a possibility of the Rashba effect on light-element semiconductors such as Si and Ge. We have been searching for Rashba spin-split surface states on semiconductors [3-8], which has a lot of implications to semiconductor spintronics. For instance, surface spin accumulation due to the spin Hall effect would be exploited to realize direct spin injection into semiconductors.

Here we discuss on three distinct types of Rashba spin-split surface states. First one is a Rashba spin-split *metallic* surface state that was first identified on a semiconductor surface [5]. The surface state exhibits a free-electron-like dispersion with a spin splitting of 200 meV at E_F . The surface exhibits a high 2D electrical conductivity, implying that the surface can serve as a standard material for surface spin transport studies. Secondly, we show the surface states found at the Γ point on A/Ge(111) (A =Bi, Br) [6,7]. These states originate from bulk electronic states but become surface states (resonances) due to the truncation of the crystal at the surface. The surface states are Rashba spin-polarized as evidenced by spin-resolved photoemission. Surprisingly, the first-principles calculation indicates that the spin polarization is induced by the spin-orbit coupling at subsurface Ge atoms. The conclusion is supported by the observation of a significant spin polarization on Ge(111) covered with Br, which has an atomic number very close to Ge. Third example is a surface state on Tl/Ge(111)-(1x1) [8], which has six valley-type electron pockets at K points within the surface Brillouin zone. Due to peculiar symmetrical reasons, the electrons are completely spin-polarized toward the surface normal, with the neighboring electron pockets polarized to the opposite directions (outward/inward).

Thus the surface serves as a unique 2D metal with coupled spin-valley degrees of freedom.

Scanning Tunneling Microscopy Studies of Orientations and Electronic Structures of C₆₀ Molecules

T13 Surface Science

#SS-1-Or-9

Z. Qin, C. Liu, J. Chen, G. Cao.

Wuhan Institute of Physics and Mathematics, Chinese Academy of Sciences -
Wuhan (China).

C₆₀-based compounds and/or assembly have stimulated much physical and technical interest for their unique electronic properties and physical significances in the field of electron amplifiers, molecular sensors, quantum computers, etc [1], which motivates a considerable amount of studies of the structures and/or self-assembly of C₆₀ molecules on various surfaces. The physical behaviors and/or properties of C₆₀-metal system depend on the nature of the chemical bond that is related to the orientations of the C₆₀ cage with respect to the substrate, on their geometric adsorption structures, and on the partial filling of the lowest unoccupied molecular orbital (LUMO) which is influenced by the charge transfer from the substrate metal. Here, we present a scanning tunneling microscopy/spectroscopy (STM/STS) study of the molecular orientations and nucleation behaviors of C₆₀ molecules on Pt(111) as well as their electronic properties. The chemical bond related molecular orientations as well as the localized geometrical C₆₀/Pt(111) assembled structures and their evolutions are well studied. Moreover, by inserting epitaxial layer between the C₆₀ molecules and the metal substrate, the metallic substrate states are effectively decoupled and the interaction of the C₆₀ molecules with the epitaxial layer becomes weaker. Due to the inhomogeneous distribution of the work function inside the epitaxial layer the degree of charge transfer between the C₆₀ molecules and the Pt(111) is periodically modulated, which results in the formation of the dim-bright STM contrast of C₆₀ molecules.

Transition metal catalyzed reactions have played an important role in synthetic and process chemistry. The homogeneous catalyst surely causes effective reaction; however, a lot of efforts and energy are required for reusing the catalyst. From this viewpoint, development of the easily treatable heterogeneous catalyst is strongly desired for reducing the waste of expensive rare metal. Although the polymer supported catalyst has been developed, it cannot tolerate under severe conditions such as high temperature and it is restricted to use in organic solvents. On the other hand, Pd acetate (Pd(OAc)₂) molecules immobilized on the S-terminated GaAs(001) has high catalytic activity and stability for Heck reaction [1]. However, the GaAs substrates including toxic As, it is not suitable for mass productions. To solve this problem, a new type catalyst was reported recently [2], which transition metals were supported on the S-modified Au(111). In order to develop more effective catalysts, it is essential to understand the function of the Pd catalyst of the S-modified Au(111). Therefore, in this study, we tried to find the stable structure of Pd catalyst on the S-modified Au(111) by DFT calculations using the program package VASP [3]. After some experimentation, it showed that the SO₄ might be adsorbed to the Au(111) substrate after piranha treatment [2]. Our calculation found that the stable position of SO₄ is fcc site on Au(111). The binding energy of SO₄ on Au(111) is very strong. After taking a particulate model into consideration, it assumes that the nano cluster surface would be planar in the particulates of about 3-5 nm, and aims at examining the reactivity of the surfaces Pd and SO₄. For this reason, we also calculated the stable position of SO₄ on Pd(111). Our calculation assumed that there is activity in the portion of the edge of a nanoparticle, and researched the correlation between SO₄ and Pd atom on Pd(111) surface. Figure 1 shows the most stable structure of SO₄/Pd-Pd(111) in energy. The electric charge of the surface of Pd shifts to +2 direction when SO₄ adsorbs.

Organic spintronics has attracted growing attention not only because its fundamental interest but also the potential industrial applications. In addition, with organic tailored functionality and enduring spin coherence, organic spintronics offers a new and tantalizing approach toward multifunctional devices. Recently, the interface of ferromagnetic-organic hybrid structures is found to critically influence the efficiency of spin injection and transport in devices. A fundamental understanding of how interfacial properties engineer the surface spin polarization is important to facilitate the spin injection, transport, and the design of the local spin polarization in organic spintronics.

We imitated the interfacial regimes of organic-ferromagnetic heterostructure in a spin-valve structure to investigate how the interfacial hybrid state affects the spin injection/detection. To understand the efficient spin injection at organic-ferromagnetic contact for organic spintronics, we have implemented donor-acceptor pair via a strong organic acceptor on contact with ferromagnetic metal. The electronic structures and magnetic couplings are examined by utilizing various synchrotron-based spectroscopy and microscopy techniques. Our results reveal that the tailored interface by donor-acceptor pair is not only capable of tuning energy levels with a surface dipole layer but also expresses a spin-polarized organic layer and a remarkably enhanced magnetic anisotropy of the ferromagnetic film. The novel magnetic properties are contributed from strong magnetic coupling caused by the molecular restructuring of charge-transfer complex.

Phase Transition of Oxide Growth on Si(111)7×7 Studied by Real-time Photoelectron Spectroscopy and Theoretical Calculations

T13 Surface Science

#SS-14-Or-4

J. Tang¹, K. Nishimoto¹, S. Ogawa¹, A. Yoshigoe², S. Ishidzuka³, D. Watanabe¹, Y. Teraoka², Y. Takakuwa¹.

¹Tohoku University - Sendai (Japan), ²Japan Atomic Energy Agency - Sayo (Japan), ³Nagaoka University of Technology - Nagaoka (Japan).

The initial oxidation kinetics on Si(001) with O₂ shows a drastic phase transition from Langmuir-type adsorption to two-dimensional (2D) oxide island growth, where etching of Si surfaces with SiO desorption takes place at the same time of oxide growth, depending on the O₂ pressure and substrate temperature¹⁻³. The oxygen uptake curves in the phase transition conditions interpreted by a dual oxide species (DOS) model with movable and steadily bonded oxygen atoms². Although surface migration is negligibly short in Langmuir-type adsorption on Si(001) based on the DOS model, we have recently reported that surface migration of oxygen species, probably metastable oxygen molecule O₂^{*}, affects significantly the oxidation kinetics in Langmuir-type adsorption on Si(111)7×7⁴. In this study, to clarify the influence of O₂^{*} on the phase transition, the initial oxidation kinetics were investigated by real-time photoelectron spectroscopy using He resonance line (21.22 eV) and synchrotron radiation (710 eV) at SPring-8, and theoretical calculations.

In Fig. 1, the O 2p uptakes taken in situ during continuous O₂ supply (solid lines) indicate that Langmuir-type adsorption is in progress due to the curve fitting analysis based on the DOS model. When O₂ gas was stopped at about 50% of the surface oxide coverage θ_{oxide} , however, it is obvious that the O 2p uptakes (broken lines) has almost no decrease and slightly decreased at 590°C and 610°C, respectively, while it steeply decreased at 640°C and eventually no oxide remained on Si(111) after 5000 s. The findings suggest that oxide can be decomposed through SiO desorption even at the temperatures in Langmuir-type adsorption region, which is quite different from that on Si(001). Namely it is difficult to define the phase transition of oxide growth on

Si(111) on the basis of the DOS model. Furthermore, O 2p intensities decrease at slower rate when O₂ supply was stopped at the larger θ_{oxide} . The observed changes of decomposition rate are ascribed to those of oxygen adsorption states depending on θ_{oxide} by the curve fitting analysis of O 1s photoelectron spectra and theoretical calculation of O 1s binding energies. Based on the results, a surface reaction model of the phase transition of oxide growth on Si(111)7×7 in which the role of O₂^{*} is taken into account is proposed.

Epitaxial Silicene - tunable hybridization with the substrate and weak interactions with epitaxial organic overlayers

T13 Surface Science

#NST/SS-1-Or-3

R. Friedlein, F. Bussolotti (#), A. Fleurence, Y. Yamada-Takamura.

Japan Advanced Institute of Science and Technology - Nomi, Ishikawa (Japan).

The electronic and structural properties of epitaxial silicene formed on $\text{ZrB}_2(0001)$ thin films grown on $\text{Si}(111)$ wafers upon adsorption of either potassium atoms and anthracene and pentacene molecules have been studied using photoelectron spectroscopy and electron diffraction. For pristine silicene, a particular, atomic-scale buckling leads to the opening of a direct band gap at the Γ point, while ZrB_2 -related surface states are not affected. This is consistent with only a minor degree of hybridization between Si- and Zr-derived states. The electronic interactions at the interface can be tuned by electron donation from adsorbed potassium atoms, upon which hybridization is progressively switched on.

In oligoacene monolayers, molecules grow with the long molecular axis aligned parallel to the surface. The further growth of pentacene multilayers is strongly temperature-dependent and characterized by a competition of flat and standing configurations. In anthracene films at about 140 K, molecules are found to grow in a point-on-line commensurate relationship between the bulk-like bc-plane of anthracene and silicene. At 293 K, anthracene molecules do still adsorb which indicates that the interactions involved are stronger than those on the graphite (0001) surface and enhanced by the atomic-site specific charge distribution associated with the buckling of silicene.

The results indicate that the charge-density modulation associated with the atomic-scale buckling of silicene render the interactions with organic adsorbates as compared to graphene, which allows for specific epitaxial conditions for the growth of overlayers. On the other hand, the results also confirm that silicene is strikingly

different from other Si surfaces for which the presence of dangling bonds leads to chemisorption of organic adsorbates.

SS-P3-11

FTIR spectroscopy of water clusters adsorbed on solid neon surface

T13 Surface Science

#SS-P3-11

Y. Shimazaki, S. Takekuma, K. Yamakawa, I. Arakawa.

Gakushuin University - Tokyo (Japan).

Water clusters have been investigated for several decades in terms of their structure, dynamics, and interaction between hydrogen bonds in the cluster. Experimentally, water clusters have been generated in the gas phase, on helium droplet, and by matrix isolation mainly with the use of rare gas solids [1, 2, 3]. In addition, there was also a successful investigation to observe the clusters adsorbed directly on Pt(111) surface [4]. In the previous study we investigated the photoinduced desorption of water clusters on solid neon surface [5]. From Photostimulated Desorption Time of Flight Mass Spectrometry (PSD-TOF-MS) we found that the clusters of $(\text{H}_2\text{O})_n$ with $n=2\sim 12$ were generated on the surface. Furthermore, it was revealed that the size distribution of the clusters strongly depends on the coverage in the submonolayer region. In the present study we performed non-destructive measurement of water clusters adsorbed on solid neon surface using the technique of Fourier Transform Infrared Spectroscopy (FTIRS).

The experimental apparatus consists of a vacuum chamber with a liquid helium cryostat, a FTIR spectrometer, and a compartment of a liquid nitrogen cooled MCT detector. After baking at 393K for 24 hours the base pressure of 1×10^{-8} Pa was achieved. The substrate was the gold film which was vacuum-evaporated on the oxygen-free copper holder mechanically fixed on the cryostat. The incident angle of p-polarized infrared light on the substrate was 80° . The solid neon was grown on the substrate at 6 K with the thickness of 300 atomic layers. Then, coverage of water on neon surface was gradually increased from 0.05 to 1.0.

The Infrared spectra of water clusters adsorbed on solid neon surface are shown in Fig. 1. The broad peak from 3000 cm^{-1} to 3700 cm^{-1} was due to the formation of amorphous ice. On the other hand, the adsorption peaks of 3542 cm^{-1} , 3384 cm^{-1} , 3345 cm^{-1} , and 3224 cm^{-1} were attributed to the vibrations of hydrogen bonded OH in the clusters of trimer, tetramer, pentamer, and hexamer, respectively. In the presentation we will discuss the dependency of the cluster size distribution on the amount of adsorption of water, and will compare the result with the one obtained by PSD-TOF-MS.

Photochemical Assembly of Diazonium Molecular Monolayer on Hydrogen-Terminated Si(111)

T13 Surface Science

#SS-P3-04

K. Shimosaka, T. Ichii, H. Sugimura.

Department of Materials Science and Engineering, Kyoto University - Kyoto (Japan).

[Introduction]

A self-assembled monolayer (SAM) covalently bonded to a Si substrate is promising for molecular electronics. It is well known that organic molecules terminated with a vinyl, hydroxyl or aldehyde group are attached to a hydrogen-terminated Si (Si-H) substrate by replacing its surface H atoms with the organic molecules. Further extension of this process is crucially required in order to modify the bonding structure of SAMs, because it would heavily affect electron-transfer properties between the molecules and the Si substrate. Diazonium molecules, which electrochemically react with Si-H and to form a SAM[1], are candidates. Here we report on a photochemical approach to form a SAM from diazonium molecules without applying an external electrode potential.

[Experimental]

Two types of Si (111) wafer (Phosphorus doped n-type and boron doped p-type) were used for the present experiments. 4-nitrobenzene diazonium tetrafluoroborate (NBD-BF₄) was used as a precursor molecule. 10 mM dimethyl sulfoxide solution of NBD-BF₄ was put in a quartz vessel. Si-H was immersed into the solution and irradiated with visible-light (200 mWcm⁻²) for 4 hours. As schematically illustrated in Fig. 1 NBD molecules photochemically immobilized on the substrate.

[Results and discussion]

X-ray photoelectron spectroscopy (XPS) N 1s spectra of the NBD monolayer on Si (111) was shown in Fig.2. In Fig.2, both spectra have two large peak contributions around 406 eV of binding energy and at about 400 eV, attributed to NO₂ and NH₂ groups, respectively. These results imply that NBD molecules are certainly

immobilized on the Si substrate and a part of the NO₂ group reduced to NH₂ groups. The N 1s peak intensity of the p-type sample is higher than that of the n-type sample. On the p-type Si surface, photo-generated electrons remained more stably than the n-type Si surface. Such electrons more readily reduce NBD molecules to promote the immobilization reaction.

The evolution of electronic and structural properties of topological insulator surfaces upon deposition of various adsorbates is of significant interest currently [1-5]. Typically, the Dirac state survives upon such an adsorption, however, additional Rashba-split two-dimensional electron gas states arise at the surface, as was shown for Bi₂Se₃ exposed to molecules [1], alkali [2], noble [3, 4] and magnetic [5] metal atoms. Meanwhile, structural investigations of the impurity deposited Bi₂Se₃ surface revealed partial [2] or almost complete [3, 4] disappearance of adatoms at room and higher temperatures. The authors of these works claimed that majority of the adatoms intercalates below the surface, presumably into the van der Waals gaps of the Bi₂Se₃ crystal, however the mechanism of such an intercalation has not been investigated yet. To study this mechanism we consider the case of the silver atoms deposited on the Bi₂Se₃ surface. Two possible intercalation mechanisms are examined: penetration from the terrace under the step and penetration via interstitials and/or vacancies of the surface quintuple layer block. It is shown that the former mechanism is strongly preferred over the latter one due to significant energy gain appearing at the step. According to performed estimations, the room temperature diffusion length of silver atoms reaches ten microns within a couple of minutes both on the surface and within the van der Waals gap, which essentially exceeds a typical distance between steps. These results shed light on the mechanism of intercalation of metal atoms deposited on the Bi₂Se₃ surface.

NST/SS-1-Or-4

DFT calculation for adatom adsorption on single layer h-BN

T13 Surface Science

#NST/SS-1-Or-4

A. Ishii, T. Torobu, K. Nakada.

Tottori University - Tottori (Japan).

Two-dimensional (2D) materials with a layered structure such as graphene, hexagonal boron nitride (h-BN) and molybdenum disulfide (MoS₂) have been attracting attention. Similar to graphene, h-BN, MoS₂ has a hexagonal crystal structure. h-BN is known as a very good electrical insulator with good thermal conductivity and stability.

Recently, single layer h-BN will be focused attentions to be substrates of new nano structure devices using its two-dimensional feature. It has been widely used in vacuum technology and also been employed in electronics, nuclear energy, x-ray lithography, lubrication, etc [1-2]. As specific device application, the h-BN substrate is used as graphene field-effect transistors (GFETs) [3]. Thus, the single layer h-BN will be focused attentions to be substrates of new nano structure devices using its two-dimensional feature. For functionalizing of single layer h-BN or construction of nano structures on graphene, it is necessary to investigate the binding of materials on single layer h-BN. However, in general, the mechanism of the growth of the three dimensional materials or nano structures on the two-dimensional material is not yet understood.

For the first step, it is significant to investigate the adsorption of atoms on single layer h-BN. Therefore, in this work, we investigate stabilities and electronic structures of adatom of almost every atomic species to understand the three dimensional material on single layer h-BN which is a typical two-dimensional material. We actually calculated by a method like the calculation of the atomic adsorption on the graphene [4]. The aim of this research discusses with stability of the adatom in h-BN by analysis from the electronic structure using the first-principle calculation technique.

The results will be very helpful to plan the construction of nano structures on single layer h-BN.

SS-11-Or-6

The properties of organic monolayers on Al(111) enhancing surface inertness

T13 Surface Science

#SS-11-Or-6

T. Yamada, R. Sato, M. Kawai.

RIKEN - Saitama (Japan).

We conducted surface-scientific investigation for a series of organic thiol adsorbates and carboxylic adsorbates on clean surfaces of single-crystalline aluminum (111) for our purpose of passivating metallic Al towards air oxidation. We studied the monolayer structures, thermal and electron-beam alterations, and the ability to block oxidation by ambient O₂, by means of X-ray photoelectron spectroscopy (XPS), X-ray absorption spectroscopy (XAS), vibrational analysis by high-resolution electron energy loss spectroscopy (HREELS), electron diffraction, and scanning probe methods. Clean Al(111) readily accepts alkanethiols, aromatic thiols and fluoroalkane thiols to form stable monolayers at room temperature. The hydrocarbon parts of thiols were proven to be intact after adsorption by the electron spectroscopies for *n*-C_{*n*}H_{2*n*+1}SH adsorbates and 4-biphenylthiol (4BPT). The SH species was not detected vibrationally, indicating that S is anchoring the hydrocarbon part on Al. Irradiation of electron beam (~ 100 eV) introduced a substantial amount of unsaturated C-C bonds with a nearly complete loss of C-H bonds from the monolayer, both from alkane and aromatic thiols. A quasi-graphitic monolayer is anticipated to be formed by electron irradiation. The electron-bombarded monolayers of this type exhibited a substantial robustness towards oxidation in ambient O₂. [1,2] Figure 1 shows the thickness of oxide layer on clean and monolayer-covered, and electron-bombarded Al(111) measured by XPS after an exposure to 0.1 MPa of O₂. Linear fluoroalkane thiols, *n*-C_{*n*}F_{2*n*+1}C₂H₄SH (*n*=4,8) also form monolayers at room temperature with a full coverage smaller than the alkanethiols. When the adsorption process was made at substrate temperatures higher than 100°C, the uptake of carbon exceeded the monolayer amount of the precursor molecule, and substantial loss of F from the adlayer was observed. The adlayer seemed to be composed of polymerized fluorohydrocarbon, and exhibited a substantial strength against oxidation. We also tested a series of carboxylic acids (C_{*n*}F_{2*n*+1}COOH (*n*=1,2,3) and CH₃COOH), referring to preceding researches [3]. Intact monolayers of these compounds exhibited a fair robustness against oxidation. Passivation of metallic Al surface with ultimately thin - monolayer - organic compounds is essential in utilizing the favorable electronic,

thermal and mechanical properties of Al in nanotechnology, in the forms of thin layers and nanoparticles.

Surface photoreactions of water and hydrocarbons have been investigated for decades because of their importance in the area of planetary physics [1]. Although water clusters have drawn much attention in recent years, surface photochemical reaction involving water clusters has not been sufficiently studied yet. In the previous study, we investigated photoreaction of water clusters and methane coadsorbed on rare gas solid. It was revealed from Photostimulated Desorption Time of Flight Mass Spectrometry (PSD-TOF-MS) that the compounds which are not simple combination of water and methane were produced [2]. In the present study, using the technique of Fourier Transform Infrared Spectroscopy (FTIR), we aimed to identify products of photochemical reaction of water and methane, which includes a monomer, clusters, and ice on solid neon surface.

The experimental set up consists of a vacuum chamber with a liquid helium cryostat, a FTIR spectrometer and an external MCT detector cooled by liquid nitrogen. The chamber was evacuated to the ultra high vacuum condition (1×10^{-8} Pa) after baking at 373 K for 24 hours. We adopted the Au film as the substrate, which was vacuum-deposited on the oxygen-free copper holder mechanically connected to the cryostat. The temperature was monitored by a chromel-alumel thermocouple set on the holder. The incident angle of p-polarized infrared light was 80°. Solid neon with 100 atomic layers was prepared on the substrate at 6 K. Then, water vapor was introduced to the chamber from one gas line, followed by the exposure of methane from another gas line. After the coadsorption state of water and methane on solid neon surface was achieved, we irradiated the sample with a laser plasma vacuum-ultraviolet light (the wavelength was ranged from 12 to 108 nm and the photon number was 2×10^{13} per minute). The infrared spectra were measured before and after irradiation.

From the spectrum after irradiation, it was revealed that CO, CO₂, CH₃OH were generated. The integral intensities of their absorption peaks increased as the

irradiation time became longer. However, increasing rate of the integral intensity of the peak due to CH₃OH was suppressed with time (Fig.1). In the presentation, we will discuss it in terms of the photoreaction mechanism, as well as result of photo reaction of water clusters and methane.

We have already developed a novel high brightness and high spin-polarized low energy electron microscope (SPLEEM) [1-3]. Our developed SPLEEM can make us the dynamic observation of the magnetic domain images possible. However the size of the spin-polarized electron gun is large and we have started to develop a new compact spin-polarized electron gun with a new idea. Two devices are necessary to operate 3-dimensional spin direction; a spin manipulator which changes the out-of-plane spin direction and a spin rotator which can change the in-plane spin direction. We have proposed a multi-pole Wien filter which enables 3-dimensional spin operation with one device. Fig. 1 shows a drawing of the developing 3D multi-pole spin manipulator which has 8 poles and the magnetic and electric field in the multi-poles Wien filter. Uniform field can be obtained at the center part of the Wien filter with 8 poles and 12 poles, however 4 poles filter gives non-uniform field even at the center. In the present development 8 poles Wien filter has been adopted. The results of magnetic domain images and asymmetries of Co(4ML)/W(110) vs. polar and azimuthal angles with one device have been obtained, which will be shown in the presentation.

We report on a quantum mirage formation in molecular systems, manganese-phthalocyanine (MnPc) based organic nanostructures, created by removing H atoms using a low-temperature scanning tunneling microscope. Based on experimental observation and scattering theory, we find out that the observed local density of states (LDOS) around the molecular lobes is a quantum mirage of the Kondo effect at the molecular center. Chemical bonds between unpaired carbon atoms and the Au substrate are selectively formed as scattering centers, by which the two-dimensional electron states on the surface are scattered, and the intervention of electron waves leads to the aforementioned LDOS away from the center. Furthermore, with applying external magnetic field on the artificially-controlled molecular structure, through Zeeman splitting of the Kondo peaks at different atomic sites of a dehydrogenated MnPc molecule, Landé g factors of the molecular structure have been spatially mapped. This finding opens up a new opportunity for controlling quantum scattering and intervention using artificially-controlled molecular structures.

Template-directed Assembly of Functional Molecules on Epitaxial Graphene on Ru(0001)

T13 Surface Science

#NST/SS-2-Or-9

H. Guo.

Institute of Physics, Chinese academy of Sciences - Beijing (China).

Recently, the graphene monolayers have been found to adopt a superstructure - moiré pattern - on Ru(0001). By using scanning tunneling microscopy/spectroscopy, the selective adsorption and formation of ordered molecular arrays of FePc and pentacene molecules can be realized on the graphene/Ru(0001) templates. With in-depth investigations of the molecular adsorption and assembly processes we reveal the existence lateral electric dipoles in the epitaxial graphene monolayers and the capability of the dipoles in directing and driving the molecular adsorption and assembly. When increasing the molecular coverage, we observed the formation of regular Kagome lattices that duplicate the lattice of the moiré pattern of monolayer graphene. Furthermore, we demonstrate the graphene grown epitaxially on Ru(0001) can be used as a buffer layer to study the intrinsic electronic properties of adsorbed molecules. The intrinsic molecular orbitals of C₆₀, pentacene and perylene-3,4,9,10-tetracarboxylic dianhydride (PTCDA) molecules were imaged by scanning tunneling microscope (STM). High resolution STM images of the molecules reveal that the graphene layer decouples the individual molecules electronically from the metallic substrate, which is also verified by density functional theory calculations. It has great advantages compared to other buffer layers, for instance, thin organic films, NaCl, and oxides. The epitaxial graphene layer on Ru(0001) is of both fundamental and technological importance for investigating molecular interaction and structures on solid surface.

Self-Ordered Vicinal-Surface-Like Nanosteps at the Thin Metal-Film/Substrate Interface: new surface structures

T13 Surface Science

#SS-2-Or-5

B. Pokroy, C. Saguy, S. Boroukhin.

Technion - Israel Institute of Technology - Haifa (Israel).

We report on the self-formation of periodic atomic and nano steps at the interface between the metal thin film and the underlying supporting substrate[1] (Figure1), revealed by the template stripping method [2] (Figure 2). Such vicinal-like and atomic stepped surfaces of metals and semiconductors exhibit well-arranged, periodic atomic steps and have numerous applications in microelectronics, catalysis, direction of nanowire arrays, patterning of quantum dots and magnetic domains, and many more. In contrast to classical vicinal surfaces which are produced by the expensive and tedious procedure in which single crystals of a desired material are cut at a small angle to the low surface energy plane followed by surface sputtering and annealing under ultrahigh vacuum for imaging, our surfaces form on polycrystalline materials, at almost room temperature, and at atmospheric environments and have no need of any other procedure in order to image. We also demonstrate how the step periodicity can be easily controlled and explain the mechanism of formation. We also present new atomic structures on these surfaces that have never been observed previously using standard vicinal surfaces.

XPS for Characterization of Working Devices

T13 Surface Science

#NST/SS-1-Or-6

S. Suzer.

Bilkent University, Chemistry Department - Ankara (Turkey).

XPS measurements were performed while 3 different devices were under operation. This is achieved by imposing both static and pulsed electrical and optical stresses to devices for their operations:

i- For operating a device, consisting of large area Graphene on a Quartz substrate and between two metal electrodes, a potential was applied to one of the electrodes while the other one was grounded. By following the variations in the binding energy of C1s, the potential drop was monitored, which exhibited a uniform resistive shift for the pristine graphene but was not very uniform after its oxidation, due to formation of cracks and faults. Surprisingly, the O1s peak of the quartz substrate followed the same pattern as the C1s of graphene.

ii- For operating a Si-Diode, both forward and reverse bias were applied across the p-n Junction, and the variations in the position of the Si2p peak were recorded. This enabled us to identify and separate n- and p- domains from each other.

iii- For operating a GaN-Photodiode, the device was subjected to light illumination, in addition to forward and reverse bias applications. This approach enabled us, to detect both dopant dependent (n- or p-) as well as photoresistance changes in the Ga3d peak positions, again reflecting on uniform and defective domains.

Details of the experimental set-up, as well as utilization towards performance measurements and characterization of defects affecting will be presented.

Supramolecular recognition is a useful tool to realize highly organized and periodic structures at the nanometer scale [1]. Additional spontaneous chiral ordering can be obtained from self-assembly giving rise to new possible applications for these functionalized surfaces [2-3]. However, chiral precursors are not always needed to develop chiral assembled structures on surfaces, as in the case of organizational chirality.

In this work we investigated the self-assembly of achiral triphenylamine derivatives which feature cyano functionalities for the formation of intermolecular non-covalent bonds based on dipolar coupling. As substrate a (111)-oriented Au surface was used and the experiments were carried out with scanning tunneling microscopy (STM) at 77K. We observed the coexistence of two phases, both arranging into chiral porous networks. Homo-chiral domains extend for hundreds of nanometers and, in some cases, even over Au step edges. The structural models, the intermolecular interactions as well as the influence of the substrate on the assembly will be discussed for both two phases. Furthermore, we compare the results with theoretical calculations. Also the effect of post-annealing onto the assembly was investigated: a transformation of one phase into the other occurs together with a global improvement in the quality of the porous network. Such molecular chiral porous networks are of great interest for many applications as in opto-electronic devices, sensors and for catalysis.

CeO_{2-x} surfaces as reducible oxide model systems

T13 Surface Science

#SS-7-Or-5

P. Luches ¹, F. Pagliuca ², F. Boscherini ³, V. Grillo ¹, S. Valeri ².

¹S3, Istituto Nanoscienze, CNR - Modena (Italy), ²Dip. di Scienze Fisiche, Matematiche e Informatiche, Università di Modena e Reggio Emilia and S3, Istituto Nanoscienze - CNR - Modena (Italy), ³Dipartimento di Fisica e Astronomia, - Bologna (Italy).

The optimization of materials allowing for an accurate and reliable control of reversible reduction/oxidation processes, i.e. of their reducibility, is a challenging topic for a number of relevant applications of these systems, such as catalysis and energy conversion.

The use of model systems in this context allows for the application of advanced surface science techniques, which can give a detailed atomic scale picture of the investigated process and of the relevant factors which can influence the reducibility of the materials under study.

In this context we present and discuss the results obtained on thin epitaxial films of cerium oxide grown on a Pt(111) substrate. The films grow with a flat surface morphology and a high crystal quality [1]. The epitaxial structure of the layers has been analyzed by X-ray adsorption fine structure measurements on the Ce-L₃ edge [2] and by HR-TEM cross sections. The modifications of the stoichiometry of the films have been studied by angle-resolved X-ray photoemission spectroscopy.

The analysis of the obtained results shows that the concentration of Ce³⁺ ions in the films can be reversibly modified by thermal treatments in UHV and in O₂ atmosphere. The final degree of reduction of the films has been found to depend on several factors, such as annealing time and temperature, and initial degree of oxidation. The effect of the proximity with the Pt surface has also been investigated by comparing films of different thickness. The critical temperature for reversible reduction shows an increase with film thickness. The reduction process is more relevant in the surface layers than in the deeper ones. The film surface shows remarkable changes after a significant reduction, with the appearance of a different contrast in the STM images and of a reconstruction in the LEED patterns (Fig.1). The large scale film morphology instead remains unaltered (Fig.1 c,d). The original stoichiometry, surface morphology

and structure of the films can be reversed back to the original one by heat treatments in O₂.

Electronic states of double-layer graphene with various rotated stacking angles

T13 Surface Science

#NST/SS-P1-18

K. Kakitani, H. Kaji.

Department of Electrical and Electronic Engineering, Okayama University of Science - Okayama (Japan).

Graphite or small numbers of layers of graphene with unconventional stacking are expected to show characteristic electronic and optical properties for future electronic devices. Recently experimental results show that one can produce the rotated double-layer graphene with various rotation angles as polycrystalline. For example, Kim et al. perform a Raman spectroscopy study for such double-layer graphene consist with domains having randomly rotated stacking angles. [1] Their experimental results suggest that the two graphene layers keep their electronic structure as a single graphene layer in spite of their unconventional stacking. They succeed to obtain spectra for each single rotation angle double-layer graphene, however, their samples are polycrystalline and consist with small domains. The electronic structure of the whole polycrystalline sample is not clear. In this paper, we investigate the electronic structure of the double-layer graphene with various rotated stacking angles for both the single crystalline and polycrystalline.

We perform the first principles calculation for the rotated double-layer graphene having several rotation angle coexisting with the translational symmetry and construct a tight-binding model. The first principles calculation results shows the rotated double-layer graphenes are insensitive to the displacement parallel to the layers. We also perform the tight-binding model calculations to obtain the electronic states of polycrystalline double layer. For the polycrystalline with random rotation angles, the wave number is not a good quantum number. The superstructures of periodic structures with rotated stacking vary from the rotation angles. We superimpose the density of states projected into the 1×1 reciprocal space (RDOS) for the systems with various rotation angles to obtain the dispersion relation comparable with the angle resolved photoemission measurements. The calculated RDOS shows the similar characteristics of the simple superposition of the graphene layers.

Institute of Experimental Physics, University of Wrocław, pl. M. Borna 9, 50-204 - Wrocław (Poland).

Gallium nitride is a wide band - gap semiconductor. It is characterized by having high thermal stability, large breakdown electric field, good mobility and thermal conductivity. Recently, gallium nitride has attracted interest due to its wide applications for light emitters and detectors, high frequency field effect transistors or high power microwaves devices [1, 2]. One of the important requirement for these systems is more reliable and thermally stable Schottky contacts on n-type GaN. A good example is ZrN/Zr/GaN structure, where the Zr/GaN interface has proper thermal stability [3, 4]. That kind of the nitride - based semiconductor devices consist of many layers of various materials, so it is important to understand the chemical composition and surface reconstruction itself as well as the reconstruction of adsorption layers.

In this work, the result of the growth of Zr on the GaN surface were studied. The samples used were 10 μm thick n-GaN (Si-doped) and p-GaN (Mg-doped) deposited on Al_2O_3 substrates (producer: Technologies and Devices International, An Oxford Instruments Company). Thin Zr layers were deposited at room temperature and subsequent annealed at high temperature between 600 $^\circ\text{C}$ – 1100 $^\circ\text{C}$. Observed changes in the chemical composition, bonding environment and reconstruction of the surface layer, caused by additive Zr adsorption and applied annealing process are presented and discussed. In experiment were used the X-ray photoelectron spectroscopy (XPS), low-energy electron diffraction (LEED) and Auger Electron Spectroscopy (AES). This techniques allowed to investigate the chemical composition, bonding environment and surface reconstruction. All measurement were performed at room temperatures under the pressure below $4 \times 10^{-10} \text{Tr}$.

Helium Atom Scattering Measurements of the Surface Structure and Dynamics of Sb(111)

T13 Surface Science

#SS-3-Or-9

M. Mayrhofer-Reinhartshuber, A. Tamtögl, P. Kraus, M. Polanz, W.E. Ernst.

Institute of Experimental Physics, Graz University of Technology - Graz (Austria).

As one of the essential components in the recently discovered group of topological insulators [1], the semimetal antimony (Sb) is an attractive candidate for studying the properties of its surface. Quite recently the surface phonon dispersion curve of Sb(111) as well as the influences of electron-phonon interaction were calculated using density functional perturbation theory [2]. However, there has been a shortage of experimental data for comparison and verification of the models used. Hence, for a comprehensive understanding of topological insulators measurements on antimony are long overdue.

As a surface sensitive technique, Helium Atom Scattering (HAS) allows to investigate elastic as well as inelastic phenomena associated with structure and dynamics of the electronic corrugation slightly above the Sb(111) surface.

Therefore we investigated the surface of an Sb(111) single crystal using HAS measurements. Elastic scans show sharp diffraction peaks which match well with the predicted positions calculated from the already known surface structure. The analysis of resonance features in-between the purely elastic diffraction peaks (see Figure 1) led to three bound states. Based on the bound state energies, a helium-surface interaction potential of pure van der Waals character was determined.

The surface phonon dispersion curve was obtained by analyzing signals from inelastically scattered helium atoms in time-of-flight spectra. The Rayleigh mode is in good agreement with simulations based on ab-initio calculations. Phonon modes localized in the second bilayer result in oscillations of the electronic corrugation at the surface and therefore detectable signals. The possibility to measure these subsurface modes with HAS is a consequence of the electron-phonon coupling. The

phonon dispersion of Bi(111) [3, 4] shows similar modes. Thus, this may be a general property of semimetal surfaces.

Thermodynamic Criteria of Nanophase Stabilization in Metal Melts

T13 Surface Science

#SS-2-Or-13

Y. Minaev.

Prof., D.Sci., Academician - Moscow (Russian Federation).

Keywords: Disperse systems. Thin Films. Thermodynamic Criteria. Advanced Alloys Modification.

Abstract. The thermodynamic analysis of stability conditions was carried out for a disperse

heterophase systems obtained by a method of the nanosize solid phases (NSP) injected into

For a thermodynamic criterion (K) of stability it was selected the specific variation of a free

energy of the process of a disperse system degradation (referred to the unit of a surface of

phases contact change)[1, 2] for three particles in melt; $K_3 = \sigma_L^2 - \sigma^{av}$. The analysis was

carried out in view of formation of thick and thin elastic wetting films of metal with a tension

$\sigma^L = 2\sigma^{av} + \Pi L$ (here σ^{av} - an interfacial tension on the boundary NSP - metal) and disjoining

pressure Π on the contact boundary of a particles of disperse phase (after Derjaguin definition). Accepting according Derjaguin the additivity of an operation of surface and

capillary forces[3], those are in equilibrium with a tension σ_2^L of a thin film in a place of a

tangency between particles and, taking into account equation for σ^L , we obtain:

liquid alloys. The material NSP with higher melting temperature than at an alloy fulfills a role

of a phase for a metal dispersion strengthening. In the present work it was solved the problem

of possibility of evaluation for these purposes of NSP materials.

$$\sigma_2^L = 2\sigma_2^{\alpha\gamma} + \Pi(L) L = P_c L_0 + 2\sigma^{\alpha\gamma} \cos\theta^{\alpha\gamma} = 2\sigma^{\gamma} \cos\theta^{\alpha\gamma} + 2\sigma^{\alpha\gamma} \cos\theta^{\alpha\gamma} \quad (1)$$

Known relations $P_c = \sigma^{\gamma}/R_c$, $R_c = L_0/2\cos\theta^{\alpha\gamma}$ for capillary pressure of a meniscus in a narrow

clearance L_0 on a perimeter of a tangency of particles here are used. From (Eq.1) the expression $\Pi(L)$ through experimentally measured parameters was obtained:

$$\Pi L = 2 \cos\theta^{\alpha\gamma} (\sigma^{\gamma} + \sigma^{\alpha\gamma}) - 2\sigma_2^{\alpha\gamma}$$

. For the considered process with substituting σ_2^L from (Eq.1) to K_3 , we can write for constant temperature for two and three particles: $K_2 = 2\cos\theta^{\alpha\gamma} (\sigma^{\gamma} + \sigma^{\alpha\gamma}) - (2/3)\sigma^{\alpha\gamma}$;

$K_3 = 2\cos\theta^{\alpha\gamma} (\sigma^{\gamma} + \sigma^{\alpha\gamma}) - \sigma^{\alpha\gamma}$. Here K_2 and K_3 are the new criteria which can be used for

performance of equilibrium conditions, stability and direction of the aggregation process. The

process of a NSP aggregation (by join of three particles) is impossible, if $K_3 \geq 0$. The inequality

will be transformed to the thermodynamic conditions of the steady suspension NSP formation

in liquid metals with use K_3 :

$$\cos\theta^{\alpha\gamma} \geq 1/2(1 + \sigma^{\gamma}/\sigma^{\alpha\gamma}) \text{ and if } \sigma^{\gamma} \leq \sigma^{\alpha\gamma}, \cos\theta^{\alpha\gamma} \geq 1/4 \text{ or } 75^\circ \geq \theta^{\alpha\gamma} \geq 0 \quad (2)$$

In case formation of elastic thin films it is equivalent to a condition of formation of final boundary angles less than 75° on a material, prepared from NSP.

On a basis of own experimental data the evaluation of some compounds series of metals IV -

VI groups of a periodic system were carried out for justified of possibility of using as exogenous modifiers of a nickel alloys. The example of dispersion hardening was reduced for

high-temperature strength nickel alloy for aircraft turbine.

The obtained method evaluation of high temperature disperse systems is accessible for use to

wide group of scientists and engineers worked in material science

The creation of 1D and 2D polymers directly on a metallic surface from organic monomers is one of the most important topics in molecular nanotechnology [1] because these materials can be seen as a promising alternative to conventional silicon-based materials for a wide range of applications. The rapid progress of the bottom-up approach in nanotechnology has opened up new pathways to build up various 1D and 2D novel architectures on surfaces from starting molecular building blocks. However, the lack of mechanical stability of these nanostructures stabilized by relatively weak and reversible non-covalent interactions can be regarded as a major challenge for implementing such structures in practical applications. In this talk, we introduce an efficient approach to overcome this obstacle.

Herein, organic monomers with different protecting groups were synthesized. They were adsorbed on metallic surfaces under UHV conditions and subsequently, investigations were carried out with STM and XPS before and after annealing the samples [2]. The protecting group can be split off during the annealing step and the de-protected monomers are connected to one another by covalent bonds. By tuning the design of the organic monomers (number of legs, molecular core, controllability over both the reactivity and the size of the polymeric structure are achieved.

We present a detailed ab initio study of the electronic structure and magnetic order of one Fe monolayer on the Ir(001) surface covered by adsorbed oxygen and hydrogen. Results will be compared with a clean Fe/Ir(001) limit which has been intensively studied recently [1-3] and a strong tendency to the antiferromagnetic order and a complex magnetic structure were indicated. We show that the adsorption of oxygen (and also of the hydrogen) leads to the p(2x1) antiferromagnetic order. This result was obtained by two complementary approaches, namely using the total energy evaluations for limited number of magnetic configurations and by a disordered local moment analysis. Finally, based on the calculated magnetic ground states, we also estimate theoretically the spin-polarized scanning tunneling images using a simple Tersoff-Hamann model.

The following main conclusions can be drawn:

- (i) Oxygen adsorbs on the Fe/Ir(001) onto the four-fold hollow sites and influences the atomic geometry of the system more strongly as compared to hydrogen in bridge positions. The interlayer relaxations are presented and compared with clean surface limit.
- (ii) The adsorbate-iron hybridizations broaden density of states features as compared to the case without adsorbate. This change of the electronic structure manifests itself in corresponding modifications of exchange interactions and the STM images.
- (iii) The magnetic stability is strongly influenced by oxygen adsorption, and we predict the antiferromagnetic p(2x1) state as a magnetic ground state for one monolayer oxygen coverage.

- (iv) The $p(2 \times 1)$ -ordering is weakened by decreasing oxygen coverage and changes into complex magnetic ground state for the oxygen free case.
- (v) The coverage by one monolayer of hydrogen leads also to a weak stabilization of the antiferromagnetic $p(2 \times 1)$ order.

Dihydrotetraazapentacene (DHTAP, $C_{18}N_4H_{12}$) layers can be used as organic semiconductors with a high potential in electronic and optoelectronic applications such as photovoltaic cells or flexible displays. The charge carrier mobility in these potential devices is of a prime importance in order to realize and optimize them. In crystalline organic materials, this mobility is controlled by the structure of the thin film: the molecular orientation and the electronic coupling between molecules. For this reason the growth of dihydrotetraazapentacene DHTAP on Au(111) at different temperatures has been studied by STM at 77K. DHTAP is a molecule that is nearly planar in gas phase and that can be evaporated in ultrahigh vacuum at temperatures of about 510K. The molecule adopts a lying down adsorption geometry on the Au(111) surface with the molecular plane parallel to the surface. For surface temperatures of about 170K during deposition molecular rows of DHTAP can be found with an intermolecular distance of about 0,75nm. If one increases the temperature of the surface during the deposition above 210K the increased surface mobility of the molecules leads to the formation of distinct ordered regions on the surface. Initially small molecular aggregates can be found on the elbows of the Au(111) herringbone reconstruction and molecular wires form on the fcc domains of the reconstruction. At higher coverage the fcc domains are further decorated and finally a nucleation on the hcp domains can be found. At monolayer coverage both the fcc and the hcp domains are covered with molecular wires formed by the absorbed DHTAP. The intermolecular distance remains at about 0,75nm and the molecules are linked by hydrogen bonds. The noise present in the STM images suggests that even at 77K the molecules rest quite mobile. This fact is corroborated by the evolution of the STM images with time, which clearly show the displacement of the molecules. The second and the third layer grow in perfect registry with the first layer (see fig. 1). Upon annealing of the monolayer or the multilayer at room temperature no evolution of the morphology of the DHTAP layers has been found.

STS measurement have shown that the HOMO-LUMO gap of the molecule, which is 2.93eV in gas phase, is slightly diminished upon adsorption to about 2.6eV for the DHTAP molecules in the second layer.

Figure 1 : A DHATP layer on Au(111). The second layer is in perfect registry with the first layer.

In the first part of our presentation we will report on the low-temperature growth of gallium nitride (GaN) ultrathin films on silicon wafers covered with the native oxide by physical vapour deposition of Ga atoms assisted with a low energy (50 eV) nitrogen ion beam bombardment. This has been carried out using a special atom-ion beam source developed in our group [1]. We have studied the morphology and elemental composition of these layers by atomic force microscopy (AFM) and X-ray photoelectron spectroscopy (XPS) as a function of substrate temperature (RT-300°C). The growth occurred at much lower temperatures than in conventional GaN deposition technologies (e.g. MOCVD, 1000°C). In the second part, we will present the results on a simple hybrid method for the selective growth of GaN nanostructures on a pre-patterned native silicon oxide substrate. The patterning was performed by a Ga focused ion beam (FIB) to create nucleation centers in form of an array of pits and grooves. Using ion –beam assisted physical vapour deposition described above an assembled growth of GaN single crystals at the nucleation sites was achieved at 300°C (Fig. 1). The characterization of these crystals was performed using SEM and AFM related techniques (including EFM and SKFM).

Surface treated nano and pigmentary TiO₂ for various applications

T13 Surface Science

#SS-P3-19

N. Veronovski, D. Verhovšek, M. Lešnik.

Cinkarna, Metallurgical and Chemical Industry, Celje, Inc. - Celje (Slovenia).

Titanium dioxide (TiO₂) is produced in two major commercial forms worldwide; the pigment and the nano grade. In general, incorporation of UV absorbers like TiO₂ (nano)particles in rutile crystal structure is of potential interest as an ultraviolet (UV) blocking material in personal care products, paints, coatings and plastics because of its excellent UV light absorption properties. Although TiO₂ is an effective UV absorber, it requires special surface treatments to suppress its inherent photoactivity. The most common surface treatments are silica (SiO₂), alumina (Al₂O₃) and zirconia (ZrO₂). The TiO₂ final properties can be strongly influenced by the conditions during surface treatment. Thus the aim of this research was to determine optimum treatment conditions, which yield homogeneous coatings of desired morphology, which entirely cover the TiO₂ surface. The structure of the surface treated TiO₂ (nano)particles was characterized using various techniques, such as scanning electron microscopy (SEM), and transmission electron microscopy (TEM). One of the most significant properties of an insoluble oxide like TiO₂ and SiO₂ is the isoelectric point (IET). Surface treatment of TiO₂ resulted in the shift of IET. With intention to determine their applicable value, surface treated TiO₂ (nano)particles were subsequently incorporated into various matrixes.

SS-14-Or-6

The O/Cu(110) nanostructured surface reactivity toward H₂S

T13 Surface Science

#SS-14-Or-6

C. Poulain, F. Wiame, V. Maurice, P. Marcus.

LPCS (CNRS and Chimie Paristech) - Paris (France).

Due to the need to find alternative ways to create smaller systems in the microelectronics industry, self-organized growth of nanostructures on metallic surfaces attracts much interest [1]. Among such surfaces, the O/Cu(110) nanostructure consists of O-induced (2x1) reconstructed stripes periodically aligned in the [001] direction and alternating with bare Cu stripes [2]. It is an ideal playground to study the relationship between structure and reactivity at the nanometer scale since periodicity and stripes width are easily tunable by the mean of oxygen exposure [3,4]. Despite an extensive study of the O/Cu(110) nanostructured surface for the last two decades [5], very few is known about its reactivity. It is however a key factor in understanding and controlling its self-organisation by studying the influence of its structural parameters.

After a presentation of the reaction mechanisms occurring on the surface within H₂S exposure, we will present an investigation of the periodicity (L) and oxidized stripes width ($\omega_{\text{Cu-O}}$) roles in the reaction. Four radically different nanostructures have been elaborated to do so. Scanning tunnelling microscopy data showing a critical dependence of the local configuration for the sample reactivity will be presented. Auger electron spectroscopy data will show the role of the structure on the reaction kinetics.

Results show that the reaction leads to the formation of sulphur c-(2x2) islands preferentially on oxidized stripes and that this is favoured on nanostructures with greater $\omega_{\text{Cu-O}}$ (Fig. 1). Sulphur c-(2x2) islands are also found at oxidized stripes edges, at Cu-O rows extremities. The reaction mechanism also involves the detachment of Cu-O row segments from these edges. The segmented rows diffuse on the oxygen-free areas due to short-range repulsion with the oxidized stripes. It is also shown that the periodicity influences the reactivity through the oxidized stripes

edges density ($2/L$), hence demonstrating the chemical, as well as the physical dependence of the reaction.

Sensitivity of calculated electronic and magnetic properties on “molecule-surface” systems with van der Waals corrected Density Functional Theory

T13 Surface Science

#SS-1-Or-10

H. Tang.

CEMES/CNRS - Toulouse (France).

Due to the non local nature of the van der Waals (vdW) force, this dispersive interaction could not to be considered within the local density approximation of classical Density Functional Theory (DFT). Since the mid of 90s, increasing efforts have been put on the vdW correction in the framework of DFT. However, in spite of the improvements recently introduced through different approaches (DFT+D, vdW-DF, TS-vdW, etc ...) [1], the calculated electronic and magnetic properties of a “molecule-surface” system in real case (when the molecule and the substrate are not used to valid a vdW correction method) could be easily affected by the accuracy of vdW correction. In this presentation, a detailed analysis on the variation of the optimized structure, adsorption energy, density of states, work function, partial charge, spin multiplicity and magnetic moment for a couple of molecules (FeTPP/FeTPP and “Ru-535” dye on gold, etc ...) will be discussed as a function of vdW interaction description. This comparative analysis will show the importance of preliminary verification of vdW correction as well as experimental results used to validate simulation results.

Defects, such as atomic steps and kinks, play an important role as active sites in many catalytic reactions. One way of studying these defects' role in a catalytic process is by using vicinal surfaces with a high density of periodic steps, and monitor how their surface structures are affected by the reaction conditions. In this contribution we have studied Rh(553) under realistic CO oxidation conditions using in situ surface X-ray diffraction (SXRD) and mass spectrometry.

From a previous study we know that exposure to O₂ leads to major rearrangements of the Rh(553) surface. At intermediate O₂ pressures (about 10⁻⁵ mbar) the surface facets into (331) and larger (111) facets, while (111) and equivalent (11-1) facets are formed together with the surface oxide at about 10⁻³ mbar [1]. In the present study we show that this faceting behavior applies also in a mixture of CO and O₂ during high catalytic activity. In mixtures that are slightly oxygen rich we find a combination of (331) and (111) facets, and under more oxygen rich conditions we find the surface oxide being formed on the (111) facets. In addition we found faceting into (110) and (111) facets in a CO rich mixture.

It has also been suggested that steps are involved in spontaneous activity oscillations [2]. One of the aims in this study was to find conditions where these oscillations are present and look for changes in the facet structure. Following the recipe from previous experiments, we applied reaction gas mixtures with high O₂ partial pressure and high activity, and then stepped down in O₂ partial pressure to approach the conditions where CO reclaims the surface and kills the reaction. In the beginning of the experiment, this resulted in spontaneous oscillations with a period of about 5 min. After the investigation of the faceting behavior shown above, we were not able to initiate the oscillations again. From the experiments we also found that the

surface is highly active even in CO excess, strongly contradicting our previous results. Our present interpretation is that the steps have become more perfect, due to the extensive exposure to reaction gases, and that the steps are less prone to CO poisoning than a flat surface.

Surface phonon dispersion and the role of glide symmetry on the hydrogen-terminated Si(110)-(1×1) surface

T13 Surface Science

#SS-10-Or-4

S. Matsushita ¹, K. Matsui ¹, H. Kato ¹, T. Yamada ², S. Suto ¹.

¹Department of Physics, Graduate School of Science, Tohoku University - Sendai 980-8578 (Japan), ²RIKEN - Hirosawa, Wako, Saitama 351-0198 (Japan).

We report the surface phonon dispersion curves mapped over the 1st and 2nd surface Brillouin zones (SBZ) of the rectangular unit cell of hydrogen-terminated Si(110)-(1×1) [H:Si(110)] surface by means of high-resolution electron energy loss spectroscopy (HREELS). Generally, it is always possible to select the wave vector of phonons in the 1st Brillouin zone using the reduced zone scheme. In the theory, Prince [1] discussed aspects of band structure, dispersion and degeneracy, as well as selection rules valid in a variety of electron spectroscopies for specific space groups containing the glide symmetry operation as an essential symmetry operation. To confirm the theory, several experiments were performed on the adsorption systems of C/Ni(100), CO/Ni(110) and CO/Pb(110) but, so far, there is no systematic investigation on the role of the glide symmetry operation.

We successfully prepared a well-ordered and ultra-clean H:Si(110) surface by etching a Si(110) wafer in 40% aqueous solution of NH₄F [2,3]. The surface has a two dimensional space group of *p2mg* with two glide planes along the [1-10] direction, i.e., Γ -X direction in reciprocal space. The surface order was verified by LEED. The cleanliness and the phonon dispersion were measured by HREELS [4]. The surface phonon modes were observed exclusively in the 1st and 2nd SBZ, strictly classified into even and odd local modes, respectively. The dipole and impact scattering selection rules on the surface where mirror planes, two-fold rotation axis and glide planes exists, hold quite well and made it possible to assign the phonon modes. For example, when we measured the phonon dispersion curves from 1st to 2nd SBZ along the Γ -X direction, the peak at 25.4 meV suddenly appeared at the X (edge of the 1st SBZ) and existed in the 2nd SBZ. According to the selection rule for the glide symmetry operation, we assigned this peak to C₁₁ mode, which is

exclusively odd-symmetric for the glide plane. We followed the notation of the phonon modes proposed by Gräschtus [5], who calculated phonon dispersion curve of H:Si(110) without considering the glide plane. The even modes of RW, C_s, B₀ and S_s modes are observed in only the 1st SBZ, and the odd modes of RW, C_{t1}, B_i and S_a modes are observed only in the 2nd SBZ along the Γ -X direction. On the other hand, along the Γ -X' direction (perpendicular to the Γ -X direction), all the observed phonon modes were mapped in the 1st SBZ, because there is no glide plane. Furthermore, it is found that the phonon of Si-H bending and stretching mode on H:Si(110) surface was highly anisotropic for the directions of Γ -X and Γ -X'. We observed the two pairs of Davydov splitting peaks of the bending (B₀ and B_i) and stretching (S_s and S_a) modes. We found sizable dispersion of the four modes along the Γ -X direction, but no dispersion along the Γ -X' direction. This indicates that there is no effective physical interaction to pass the vibrational motions in a unit cell to the [001]-neighboring unit cells on the topmost surface.

SS-15-Or-3

Maximum aspect ratio of a coherent nanowire at equilibrium

T13 Surface Science

#SS-15-Or-3

G. Boussinot.

Max Planck Institut für Eisenforschung - Duesseldorf (Germany).

Nanostructures elongated perpendicular to their supporting substrate have attracted attention owing to their ability to sustain the coherency at the interface with the misfitting substrate. Although the morphology of nanocrystals can depend on the history of the production process, for example for a catalyst-assisted growth, it may be estimated by an energy minimizing procedure that provides the equilibrium state. Here [1] simple qualitative scaling arguments are used to derive the equilibrium aspect ratio of an elongated coherent cylindrical nanowire depending on its volume V . It is found to scale as $(V/d^3)^{1/4} \gg 1$ where d is the elasto-capillary length that arises from the competition between surface energy and bulk elastic energy.

Using the usual law for the critical radius of a nanowire (below which coherency is maintained whatever its height perpendicular to the substrate), the maximum aspect ratio of a coherent nanowire at equilibrium is found to increase linearly with the lattice misfit with the substrate. This demonstrates that coherent nanowires with large aspect ratios exist at equilibrium for large misfits.

In addition, it can be shown that when the height of the coherent crystal is limited to a size $L \gg d$, a possible equilibrium state for $V \gg L^2 d$ consists of an assembly of non-interacting nanowires.

NST/SS-P1-19

Cu intercalation to graphene sheets grown on SiC(0001)

T13 Surface Science

#NST/SS-P1-19

K. Yagyu, H. Tomokage, T. Tajiri, A. Kohno, T. Suzuki.

Fukuoka University - Fukuoka (Japan).

It is well known that graphene sheets are grown above 1200°C on SiC(0001) surface in the consequence of the desorption of Si atoms. A specific linear dispersion at K point is, however, unobserved on the first graphene sheet, “Zero layer”, made by this heating process, because of sp^3 -type interactions between the substrate. I. Gierz et al. reported that Au deposition on the zero layer followed by annealing produces a single graphene sheet as a result of Au intercalation under the graphene sheet [1]. In our study, Cu is used instead of Au for a practical electronic device.

First of all, the zero layer was grown on the 4H-SiC(0001) surface after the annealing of the substrate at 1200°C. Cu atom was deposited on the zero layer with the amount of 12 Å at room temperature followed by the annealing, which is called “post-annealing”, at 500-800°C. The obtained surface was analyzed by scanning tunneling microscopy (STM) and x-ray photoemission spectroscopy (XPS).

After the deposition of Cu atoms, the zero layer was covered by three dimensional Cu islands at room temperature. The substrate was unchanged below 500°C of post-annealing. Above 600°C to 700°C, the surface was drastically changed. Cu islands vanished and the graphene lattice was observed by STM, thus the topmost surface is considered to be a single graphene. Moreover the graphene sheet is corrugated with the period of $(6\sqrt{3}\times 6\sqrt{3})R30^\circ$ (Fig. 1). Low energy electron diffraction pattern of the surface shows 6 satellite spots around a (10) spot, which assists the corrugation found in the STM image. After the post-annealing at 600-700°C, although Cu islands vanished from the surface, Cu was obviously detected by XPS. Therefore Cu is considered to be intercalated under the graphene sheet during the post-annealing, which is similar to the case of Au deposition [1]. C 1s core-level spectra were obtained before and after the post-annealing. In the C 1s spectra, a signal which shows the 1st layer evolved after the post-annealing. Therefore it is concluded that

the sp^3 interaction between a graphene sheet of zero layer and the substrate disappeared because of the Cu intercalation.

The $(6\sqrt{3}\times 6\sqrt{3})R30^\circ$ corrugation disappeared after the post-annealing at 800°C . Instead of the corrugations, zero layer with many defects and triangular structure appeared.

In conclusion, we found that a single graphene sheet is also obtained by the Cu deposition instead of Au; however it was achieved at 600°C , 200°C lower temperature than the Au case of 800°C .

[1] I. Gierz et al.: Phys. Rev. B 81 (2010) 23408

Figure 1. STM image of post-annealed sample shows a lattice of graphene with a $(6\sqrt{3}\times 6\sqrt{3})R30^\circ$ corrugation. This sample was annealed at 700°C for 15 min after the Cu deposition.

SS-16-Or-6

Stress evolution during Si surface reconstruction

T13 Surface Science

#SS-16-Or-6

H. Asaoka, Y. Uozumi, Y. Yokoyama, K. Yamaguchi.

JAEA - Tokai, Ibaraki (Japan).

The importance of surface stress as a factor in the surface reconstruction is beginning to be widely recognized in nanotechnology. The Si(111) 7×7 reconstructed surface is well known to be based on dangling bonds reduction and adatom formation. Complex arrangements of the surface atoms, such as adatoms, dimers, and stacking faults are formed on Si(111) 7×7. Calculations by Vanderbilt et al. [1] show that the Si(111) 7×7 surface significantly affects the surface stress by introducing both tensile and compressive stresses depending on the site. Such a surface energy plays a critical role in determining the growth mode of heteroepitaxial layers. For instance, the Ge surface morphology changes from a two-dimensional wetting layer to a three-dimensional nanodot due to trade-off between the surface and the elastic energies. Despite the aforementioned importance of the surface energy of Si, the experimental knowledge on the impacts of reconstruction on the Si surface has been quite limited.

We have focused on measurement of the surface stress during atomic hydrogen exposition on Si(111) 7×7 and Ge(111) 5×5 surfaces, and subsequent Ge deposition on Ge wetting layer growth on H-terminated surfaces. To obtain information on both the surface stress and the surface reconstruction simultaneously, we have combined surface-curvature and RHEED instrumentations in an identical UHV system.

At the beginning of the atomic H exposition on Si(111) 7×7 and Ge(111) 5×5 surfaces, distinct released stresses are observed corresponding to the formation of H-termination. After the above treatment, a complete transformation of the surface structure occurs from each reconstructed surface to the 1×1 one. Furthermore, when the first bilayer growth of Ge on H-terminated Si(111) 1×1, the stress gradient changes drastically with change of the surface structure from 1×1 to 5×5 (Fig.1) resulting from H desorption. The unique stress behavior reveals that the Si(111) 1×1 surface releases 1.6 N/m (=1.3 eV/(1×1 unit cell)), of the surface energy from the strong tensile Si(111)7×7 reconstruction. The released stress matches with the calculated stress [1], which corresponds to the difference of structure between H-terminated Si(111) 1×1 and Si(111) 7×7 surfaces. Simultaneous measurement of the

surface stress and the surface reconstruction reveals the value of the tensile stress in Si(111) 7×7 reconstructed surface comparing to reference H-terminated 1×1 surface.

The formation of the interface between water and a solid is a truly challenging fundamental problem. On many surfaces the formation of this interface or wetting layer is accompanied by water dissociation to hydroxyl (1). The formation of hydroxyl plays an important role in stabilizing the wetting layer but partial water dissociation adds to the complexity of the wetting processes.

We have studied water adsorption on single crystalline rutile TiO₂(110) at the Swedish synchrotron radiation facility MAX-lab (2-4). Based on an extensive set of O1s spectra, DFT calculations and Monte Carlo simulations we have been able to derive a mechanism for the adsorption of water and subsequent partitioning into H₂O and OH on stoichiometric TiO₂(110) at 210K, a temperature at which the uptake is limited to titanium surface sites. When the temperature is decreased, the OH rate of formation decreases leading to an increased H₂O/OH ratio. This is discussed in terms of having water stabilized on the oxygen sites, inducing a metastable overlayer structure. A comparison with a previous high pressure XPS study reveals that the wetting layer formed under near-ambient conditions may be a similar, metastable structure (5).

Finally, the issue of surface defects is addressed: Dissociation at bridging O vacancies quenches the dissociation on stoichiometric parts with a correlation close to one. Ti interstitials with a typical density of a few percent have negligible influence on the H₂O/OH ratio.

SS-15-Or-4

Unique surface structure formation on Ge covered Si(110) surface

T13 Surface Science

#SS-15-Or-4

Y. Yokoyama, Y. Uozumi, H. Asaoka.

JAEA - Tokai, Ibaraki (Japan).

The semiconductor devices using SiGe thin film or Ge nano dot structure on a Si surface has the superior features, e.g. high-speed operation, low power consumption and high temperature stability, compared with pure Si semiconductor devices [1]. Therefore, a lot of research and development have been performed toward application in various fields, such as a communication terminal and a semiconductor laser. However, in order to fabricate the high-performance device, well-ordered SiGe thin film and Ge nano dot structure are required. In this study, we aimed for new SiGe nano structure fabrication by using Si(110)-16×2 reconstructed structure.

First of all, to fabricate the single-domain of Si(110)-16×2 structure, dc flowing along the [-11-2] direction is used to heat the surface. The STM image obtained using this procedure is shown in Fig. 1. This image clearly shows that a single-domain structure is formed over the entire specimen with stripes that run along the dc direction. Next, we deposited a Ge by using graphite crucible. In the case of 1 ML Ge deposition at RT, although the surface is covered with small grain of Ge, the striped structure originating from 16×2 single-domain is still maintained. After annealing at 973 K for 240 min, the surface morphology changes from single-domain to double-domain as shown in Fig. 2. The important points here, the direction of these stripes are different from clean 16×2 structure. These stripes directions deviate approximately 7 degrees from $\langle 1\ 1\ 2 \rangle$ direction, therefore we have determined that the direction of these stripes are $\langle 5\ 5\ 13 \rangle$. Since the stable structure of clean Si(110) at 973 K is 16×2 structure that run along the $\langle 1\ 1\ 2 \rangle$ direction, we have considered that this structure is SiGe surface. Moreover, this structure also differs from the SiGe-Si(110) structure reported by Butz and Lüth [2]. This result suggests that a new SiGe reconstructed structure has been created on the Si(110) surface.

Institute of Experimental Physics, University of Wrocław - Wrocław (Poland).

Superstructure formation caused by metal films deposition on a semiconductors surface, and in particular metal/Si(111) interface, has been investigated for many years. An example of such a system is the Pb on Si(111). This system has attracted considerable interest, especially due to its properties (its insolubility in the bulk of Si) [1]. It has been studied by many groups using various techniques, in particular at low-temperatures but there are still open questions [2,3]. It is known that the preferred adsorption site of Pb atoms on Si(111) surface is very selective and depends on coverage, temperature and also sample annealing history.

In this work the behaviour of Pb adsorption on the clean Si(111) 7x7 surface and influence of annealing temperature were studied in detail by low energy electron spectroscopy (LEED), Auger emission spectroscopy (AES) and X-ray photoemission spectroscopy (XPS). In the experiment pure Pb (99,999%) was evaporated on the Si substrate at room temperature by the 'one-stage deposition' and subsequent annealed in the temperature range between 300 °C - 580 °C. For the samples, prepared in such a way, two kind of surface superstructures were observed

and $\sqrt{3} \times \sqrt{3} R30^\circ$ reconstructions. As an example, LEED images for about 1 ML of Pb coverage, after sample annealing at 300 °C ($\sqrt{3} \times \sqrt{3} R30^\circ$ reconstruction) (a) and after further annealing at 480 °C (3×3 and $\sqrt{3} \times \sqrt{3} R30^\circ$ reconstructions) (b) are shown in the Fig. 1. The obtained results suggest that the growth of Pb follows the Stranski-Krastanov mode and are consistent with the conclusion that Pb atoms occupy places mainly above the rest atoms and between the Si adatoms [4].

We adopt fringe counting from classical moiré interferometry on moiré patterns observed in scanning tunneling microscopy of strained thin films on single crystalline substrates. We analyze inhomogeneous strain distribution in islands of CeO₂(111) on Cu(111) and identify a generic source of strain in heteroepitaxy—a thickness-dependent lattice constant of the growing film. This observation is mediated by the ability of ceria to glide on the Cu substrate. The moiré technique we are describing has a potential of nanometer-scale resolution of inhomogeneous two dimensional strain in incommensurate layered systems, notably in supported graphene. [1]

Graphene has a large potential for applications within the field of nanotechnology, for example in transparent electrodes and transistors. For many of these applications it is essential to tune the electrical properties of the graphene layer by doping. One very efficient way to dope graphene is by intercalation of atoms or molecules under graphene. Intercalation is also interesting from a chemical point of view, since atoms or molecules confined between the substrate and the graphene layer might exhibit different properties than they would on the bare substrate. Intercalation of molecules or atoms under graphene has been demonstrated for a number of substrates. The majority of the previous studies prove that intercalation is possible, but lack an atomic level understanding. Here we present atomic scale studies of intercalation of two common gases, oxygen and CO, in the pressure interval from 10^{-8} to 0.1 mbar. Further, we plan to discuss examples of chemistry performed under the graphene layer. For oxygen exposed graphene we develop a coherent picture of temperature dependent oxygen intercalation.[1] Using X-ray photoemission spectroscopy (XPS) and scanning tunnelling microscopy (STM) we show that a perfect graphene layer forms an impenetrable barrier for the oxygen. In contrast, a partial graphene coverage on Ir(111) enables dissociative oxygen adsorption on the bare Ir and subsequent intercalation underneath graphene flakes at 355 K and above. We determine XPS and STM fingerprints for the intercalated oxygen structure and we unambiguously assign it to a p(2x1)-O structure similar to the one observed on clean Ir(111). The decoupling of the intercalated graphene film from the metal substrate is directly visualized through the inability to form well-ordered Pt cluster arrays on the

O-intercalated areas of graphene on Ir(111). Further, we have identified the rate limiting step for oxygen intercalation to be unlocking of the graphene edge and propose that this takes place through bond breaking between graphene edge bonds and the Ir substrate. We also reveal that oxygen energetically prefers to reside on the bare Ir(111).

Using a combination of high pressure XPS and STM we show that it is possible to

intercalate CO under graphene on Ir(111).[2] The ()R30° structure of the intercalated CO is identical to the structure formed on Ir(111) at high pressures. From DFT calculations the structural and electronic properties of CO-intercalated graphene are found to be similar to p-type doped freestanding graphene. Using STM and Pt-deposition we mark non-intercalated areas and find that they are always present as lines in the CO intercalated areas. They are predominantly formed in HCP and FCC areas due to the formation of weak chemical bonds in these areas upon re-lamination. Similar to wrinkle formation in graphene [3] we suggest that the network of non-intercalated lines is a way of releasing stress in the graphene layer.

SS-2-Or-6

Formation of In/Pd(111) surface alloys at low-coverage

T13 Surface Science

#SS-2-Or-6

G. Mcguirk¹, J. Ledieu¹, É. Gaudry¹, M. Armbrüster², M.C. De Weerd¹, V. Fournée¹.

¹Institut Jean Lamour, UMR 7198 CNRS, Université de Lorraine - Ecole Des Mines, Parc De Saurupt, Nancy Cedex (France), ²Max-Planck-Institut für Chemische Physik fester Stoffe - Nöthnitzer Str. 40, Dresden (dated: October 12, 2012) (Germany).

The high catalytic activity towards methanol steam reforming (MSR) of Pd/ZnO, Pd/In₂O₃ and Pd/Ga₂O₃ has been ascribed to the formation of PdZn, PdIn and PdGa alloys. One way to better understand these systems is to form surface alloys and this has been extensively studied in the case of the Pd-Zn by depositing Zn on Pd(111) under ultra-high vacuum conditions. It has been shown that deposition of 0.5 to 2 ML of Zn on Pd(111) at 300 K leads to the formation of (2 × 1) Pd-Zn domains occurring along three equivalent <110> substrate directions, resulting in an apparent (2 × 2) LEED pattern [1]. In addition to the (2 × 2) phases reported in several other bimetallic systems, a second surface reconstruction of (√3 × √3)R30° ordering has been identified in many systems [2]. The In/Pd(111) system exhibits both phases [3], but correlations to surface alloy phases is still lacking.

Here, we report on these different phases obtained after dosing 1 to 2 ML of In on Pd(111) followed by subsequent annealing up to 980 K. While diffuse (2 × 2) LEED patterns are observed at both coverages, the overall quality is slightly improved for 2 ML deposition. Corresponding XPS results suggest a partial coverage of stoichiometric PdIn after RT deposition of both layers. The evidence of PdIn formation is found by comparing Pd 3d core levels to those obtained for PdIn bulk samples. To analyze the resulting structure, the surface energies of the low index surfaces of PdIn have been evaluated by *ab initio* calculations along with the stabilization of In at the surface or buried in Pd(111) for different atomic concentrations.

Moreover, we have found that annealing the first layer to ~690 K results in a well-ordered $(\sqrt{3} \times \sqrt{3})R30^\circ$ phase with a surface lattice constant of 4.75 Å. This phase shows a slightly rumpled top-layer, characteristic of $(\sqrt{3} \times \sqrt{3})R30^\circ$ substitutional surface alloys found in other systems [2]. Annealing the second layer to the same temperature (± 10 K) leads to a surface of higher surface In concentration and a diffuse (1×1) LEED pattern. Annealing to higher temperatures (830 K) after 2 ML deposition yields In concentration comparable to those obtained for Pd(111) $(\sqrt{3} \times \sqrt{3})R30^\circ$ -In (after annealing ≈ 1 ML). However, the corresponding LEED patterns at this stage show a clear (1×1) phase without any indication of $(\sqrt{3} \times \sqrt{3})R30^\circ$ ordering. These results show that the surface reconstructions depend on the In diffusion processes, the latter being dependent on the annealing temperature and coverage.

In past decades, numerous experimental and theoretical studies have been devoted to understanding the interaction of H₂O with various metallic surfaces. The interaction between water molecules and the Au(111) surface is weaker than that of all the other close packed noble and transition metals, which could suggest that a wetting layer might not form on this substrate. Nevertheless, scanning probe studies have identified the formation of a first layer which serves as a precursor to the 3D growth of H₂O, a layer which was assumed to be amorphous at the temperature range probed by the experiments[1-2] in apparent contradiction with the $\sqrt{3}\times\sqrt{3}R30$ ordered pattern obtained in LEED measurements[3].

In this presentation we report helium atom scattering (HAS) measurements of the structure and dynamics of the first H₂O layer on Au(111). HAS is an extremely non-perturbative technique for studying surface structure and dynamics. It is sensitive to light atoms (e.g. the proton order in a water layer) and is capable of measuring the average structure on an atomic scale even in the presence of significant motion. Our measurements, performed at 110K, show a clear $\sqrt{3}\times\sqrt{3}R30$ helium diffraction pattern which continuously intensifies during the exposure to H₂O, suggesting the gradual formation of highly ordered H₂O islands which are commensurate with the underlying gold surface. Further multilayer growth results in a loss of the diffraction pattern and eventually an angular scattering distribution which is consistent with amorphous solid water phase expected at these temperatures. Additional information about the H₂O surface layer was obtained from inelastic helium-spin-echo measurements on this system[4]. Here we observed the appearance of an energy-loss mode associated with the H₂O surface layer. This

vibrational mode which seems dispersionless near the zone boundary exhibits avoided crossing behavior with the acoustic modes of the gold substrate. Complementary measurements of D₂O provide further insight into the origin of this mode.

SS-7-Or-11

Reactions of formate species on metal-deposited TiO₂(110) surface; effect of UV illumination

T13 Surface Science

#SS-7-Or-11

A. Farkas, F. Solymosi.

MTA-SZTE Reaction Kinetics and Surface Chemistry Research Group at the University of Szeged - Szeged (Hungary).

The interaction and reactions of formic acid, methanol and their dissociation products were studied on the clean, potassium-deposited and Rh-promoted TiO₂(110) surfaces by high resolution electron energy loss spectroscopy (HREELS), Auger-electron spectroscopy (AES), temperature-programmed desorption (TPD) and work function measurements (WF). Formic acid adsorbs molecularly on TiO₂(110) at 90K yielding strong losses at 1250, 1395, 1640, 1730 and 2975 cm⁻¹. The weakly adsorbed HCOOH desorbs below 300K, but a small extent of molecule remains on the surface and dissociates to formate and hydrogen. Formate species were identified in HREELS by the symmetric and asymmetric O-C-O stretching mode and C-H stretching mode at 1360, 1590 and 2950 cm⁻¹, respectively. TPD indicated that the main reaction products, CO₂ and H₂, desorbed around 590 K. This reaction very probably occurs on vacancies of the clean TiO₂ surface [1]. Dehydrogenation reaction is the favourable reaction route. Potassium deposition decreases the work function of the TiO₂(110) surface by ~3.3 eV at $\Theta_K \sim 0.9$ ML. Potassium as an electropositive additive enhances the rate of the dissociation and thus the concentration of reaction intermediates on the surface. Nevertheless the amount of the reaction products (CO₂, H₂) also increased with the potassium coverage (Td=550-600K). The dissociation of HCOOH is more pronounced, if we evaporated rhodium onto the TiO₂ surface. We observed a drastic change in the dissociation probability after ~1.5 ML rhodium deposition at RT followed by HCOOH adsorption at 90 K and annealing the surface to 300 K. The vibrations characteristics of formate dominated the HREEL spectra at this temperature; moreover a new adsorption feature appeared in the CO stretching region at ~2050 cm⁻¹. Illumination of the surface layer caused attenuation of the formate bands. We also followed the effect of illumination on the reaction of methanol adsorbed on

the potassium- and rhodium-deposited TiO₂(110) surface. Majority of the methanol molecules desorbed intact from the clean surface below RT. However a small fraction underwent dissociation to methoxy at and above 200K, as indicated by the appearance of the characteristic vibrations of methoxy at 1050, 1160, 1460, 2850 and 2960 cm⁻¹. On the potassium-covered surface its stability was enhanced and it was detectable by HREELS up to 300K. Interesting feature of the interaction of methanol with the Rh-deposited TiO₂ surface ($\Theta_{\text{Rh}} \sim 1$ ML) is that after UV illumination at 300 K we detected the generation of methyl formate. This observation supports our former catalytic results wherein we found that methyl formate is formed in the photoreaction of methanol [2].

Metastable oxygen molecule O_2^* , which appears during the initial oxidation on Si surfaces, has long lifetime of dissociation on Si(111)7×7 surface. Recently, we reported that the number of adsorbed oxygen atoms at the completion of Langmuir-type adsorption on Si(111) increases about three times with increasing temperature from RT to 600°C and that the strong temperature dependence of the saturation coverage is associated with O_2^* [1]. In this study, to clarify the role of O_2^* in the initial oxide growth, real-time photoelectron spectroscopy using He resonance line (21.22 eV) and synchrotron radiation (710 eV) at SPring-8 was employed to measure the time evolutions of oxygen uptake, work function ϕ and oxide adsorption states on partially oxidized Si(111) surface after O_2 supply was stopped.

As observed in Fig. 1, ϕ increases rapidly upon O_2 supply and then changes suddenly to a decrease, while O 2p uptake changes monotonically in a Langmuir-type adsorption manner. When O_2 supply was stopped at surface oxide coverage θ_{oxide} of 20%, ϕ does not increase but decreases although θ_{oxide} still continues to increase due to the residual O_2 gas. The observed decrease of ϕ is ascribed to the dissociation of O_2^* . Figure 2 shows the initial θ_{oxide} dependence of the correlations between ϕ and θ_{oxide} . Over the whole θ_{oxide} region, ϕ shows a significant decrease, suggesting that O_2^* is concerned with the oxide growth until Langmuir-type adsorption is completed. The decay curve of ϕ is fitted well with two exponential functions. Both of the estimated lifetimes increase with increasing θ_{oxide} up to 15%

and then is considerably shortened. This finding implies that O_2^* dissociation is caused more frequently on the Si surface with larger θ_{oxide} . The O_2^* dissociation kinetics is discussed based on the changes of the oxygen adsorption states.

Time-Dependent Density Functional Theory Calculation of Dielectric Function of Boron Nitride Nanostructures

T13 Surface Science

#NST/SS-P1-20

K. Watanabe, H. Goto, S. Hagiwara, J. Haruyama, C. Hu.

Tokyo University of Science - Tokyo (Japan).

Hexagonal boron nitride (h-BN), a structural analogue of graphite, has excellent mechanical and chemical stability together with a large electronic energy-band gap, and has been widely used in electronic devices. The BN sheet [1], just the analogue of graphene, has also attracted wide attention due to its useful properties such as a complementary 2D dielectric substrate for graphene electronics. The BN nanoribbons (BNNRs), which were recently produced under unwrapping multiwalled BN nanotubes, show semiconducting properties due to edge states and imperfections, and have width-dependent energy-band gaps [2] that can be tuned by transverse electric fields. Thus, the BN nanostructures are promising materials in optics and opto-electronics as functional semiconductors. However, compared with their carbon analogues, the study on optical properties of BN nanostructures is very few up to now.

The objective of the present study is to understand the dielectric properties of the BN nanostructures (3D h-BN, 2D BN sheet and 1D BNNR) by a first-principles electronic structure calculation, focusing on the dimensional dependence of dielectric functions. We use real-time time-dependent density functional theory (TDDFT) that incorporates vector potential for electric fields in the linear response regime to calculate the dielectric function. [3].

Our results have reproduced plasmon peaks in electron energy loss spectra (EELS) [4] of h-BN and the BN sheet observed in a very recent experiment [5]. We have found that the real part of the dielectric function becomes smooth as a function of energy when decreasing the dimension of the BN nanostructures. It further decreases with reduced ribbon widths and shows a tendency of approaching one. This property indicates that the screening effect of the Coulomb interaction is significantly reduced in low dimensional BN structures. The profiles of EELS spectra

become more similar to those of absorption spectra (imaginary part of dielectric function) for BN structures with lower dimension, especially for BNNRs. This means that the electronic excitations of low dimensional BN structures occur mostly through particle-hole excitations instead of plasmon excitations. We will discuss the above results of BN structures with the comparison of their carbon analogues in the presentation.

The electron orbital is a fundamental concept of science – it is central to physics, chemistry, and materials science. The possibility of resolving these orbitals directly is highly appealing. This has become possible with the invention of scanning probe microscopy techniques. Direct images of intra-atomic electronic structures have been obtained in recent atomic force microscopy [1,2] and scanning tunnelling microscopy (STM) experiments [3]. Here we present the results of distance dependent STM studies carried out with tungsten tips revealing sub-atomic electron orbital features at small tip-sample separations. The dependence of the STM contrast on the tunneling gap resistance suggests that the relative contribution of particular electron orbitals of the tip and surface atoms involved in tunneling can be controlled during precise distance dependent STM experiments. This is confirmed by STM studies with [001]-oriented single crystalline tungsten tips [4,5]. Electron microscopy images of the W[001] tips prove the formation of atomic scale pyramids at the apex. In our distance dependent STM experiments on a graphite (0001) surface (Fig. 1a,b) the carbon atoms were used to probe different *d*-orbitals of the tip's apex atom. The experimental data and density functional theory (DFT) calculations (Fig. 1c) prove that even localized W 5*d*-orbitals can be controllably probed with sub-Ångström lateral resolution at small bias voltages and tunnelling gaps of 2.0–3.0 Å. The sub-atomic features observed in experiments (Fig. 1b) reproduce the shapes of the 5*d*_z², 5*d*_{xz} and 5*d*_{xy} tungsten atomic orbitals. DFT calculations of both the fully relaxed (Fig. 1c) and constrained W[001] tip – graphite(0001) systems reveal that the transformation of the sub-atomic features is related to a substantial modification of

the orbital structure of the W atom at the tip apex due to a strong tip-surface interaction at small distances. Fluorescence spectroscopy of large π -conjugated molecules on surfaces

T13 Surface Science

#SS-11-Or-8

M. Sokolowski ¹, A. Paulheim ¹, C. Marquardt ¹, M. Müller ¹, A. Eisfeld ².

¹University of Bonn - Bonn (Germany), ²Max-Planck-Institut für Physik komplexer Systeme - Dresden (Germany).

Adsorption of large π -conjugated organic molecules on surfaces has become a topic of growing interest during last years under both fundamental and applied aspects, e.g., optoelectronic applications of molecular films. Although fluorescence (FL) spectroscopy of π -conjugated organic molecules is well-established for thin molecular films, for isolated or aggregated molecules on surfaces with coverages in the monolayer regime, this technique is not very common so far [1]. However, as we demonstrate, there are at least two interesting aspects concerning the combination of surface science experiments with FL spectroscopy. The first is related to the high signal-to-noise ratio and the very high spectral resolution of FL spectroscopy which allows performing experiments for ultimate low concentrations of molecules on surfaces down to the 10⁻⁵ monolayer range. The second aspect concerns the self-organization of molecules on surfaces. This enables one to prepare well-defined two-dimensional ordered molecular aggregates for which the intermolecular resonance interaction leads to interesting optical phenomena.

We report on these aspects on the basis of experiments performed for the well-studied model molecule PTCDA adsorbed on thin epitaxial films of KCl(100) on Ag(100) [2]. In the first set of experiments we have studied isolated molecules at very low coverages. The FL and FL excitation spectra are highly resolved and allow precise identification of the in-plane vibrational modes of the adsorbed PTCDA on KCl. Interestingly, there are additional low energy vibrational modes which are only explainable under the assumption of a distorted non-planar geometry of the adsorbed molecule, likely related to the electrostatic interaction of the anhydride groups with the surface cations [3]. Hence, information on the molecular geometry can be derived from the FL spectra here. Furthermore, we studied the thermal or optically induced diffusion of the PTCDA molecules from initially occupied terrace sites to energetically

more stable sites at step edges. This site change is visible as a line shift in the spectra [4].

In the second set of experiments, a complete ordered monolayer of PTCDA was prepared. It exhibits an interesting so-called brickwall structure with one molecule per unit cell [2]. As a consequence, the transition dipoles of all molecules are parallel and couple very effectively. This leads to a pronounced enhancement of the vibration-free optical transition (0-0 transition), known as "superradiance". The effect has been observed in self-organized so-called J-aggregates of dyes in solution so far. Here it is demonstrated for a strictly two-dimensional aggregate on a surface. However, the spectral lines shape is found to be broadened with respect that of isolated molecules. From a detailed theoretical modelling, we find that this is related to domain boundaries, possibly due to surface steps or growth defects, which limit the size of the aggregates.

SS-11-Or-9

Resolving the Interfacial Structure of Alkanethiol Self-Assembled Monolayers on Au(111)

T13 Surface Science

#SS-11-Or-9

Q. Guo ¹, F. Li ², J. Gao ¹.

¹University of Birmingham - Birmingham (United Kingdom), ²Tsinghua University - Beijing (China).

We have carried a systematic study of self-assembled monolayers (SAMs) of methyl-, ethyl-, and propyl-thiolate on Au(111) using scanning tunnelling microscopy (STM). High-resolution STM imaging reveals that the SAMs at saturation coverage form a common 3×4 structure at room temperature¹. The 3×4 phase consists of zig-zag rows of Au-atom-dithiolate unit, RS-Au-SR. Moving from propylthiolate to butylthiolate monolayer, transition from 3×4 to $(3\times 2\sqrt{3})$ -rect./ $c(4\times 2)$ occurs due to an increasing level of interactions among the alkane chains. 3×4 and $(3\times 2\sqrt{3})$ -rect. are two closely-related structures: one with zig-zag rows of RS-Au-SR; and the other with alternating zig-zag and zag-zig rows consisting of the same RS-Au-SR unit.

SAMs of methyl-, ethyl- and propyl-thiolate do not form either the $(3\times 2\sqrt{3})$ -rect./ $c(4\times 2)$ or the $\sqrt{3}\times\sqrt{3}$ -R30o structure at any coverage. The well-reported $\sqrt{3}\times\sqrt{3}$ -R30o phase for the longer chain alkylthiolate monolayers requires new interpretations. Our analysis shows that there is no pure $\sqrt{3}\times\sqrt{3}$ -R30o phase for any alkanethiol SAMs on Au(111) regardless the alkane chain length. The interfacial structure should always be 3×4 or $(3\times 2\sqrt{3})$ -rect.. As the chain length increases, the enhanced van der Waals interaction tends to keep the alkane chains at equal distances from each other, leading to the formation of a superficial $\sqrt{3}\times\sqrt{3}$ -R30o structure. Due to the flexibility of the alkane chains, a $(3\times 2\sqrt{3})$ -rect. structure at the interface is transformed gradually into a $\sqrt{3}\times\sqrt{3}$ -R30o-like structure at the surface.

One-dimensional (1D) electronic systems are well known as sources of intriguing physical phenomena such as non-Fermi liquid and Peierls type metal-insulator transition. In addition, the surface bands split into two due to the Rashba effect if the 1D systems are including heavy element atoms. For these peculiar phenomena of 1D electronic states, Pt-induced nanowires formed on Ge(001) surface (Pt/Ge(001)-NWs) is remarkable. The defect-less Pt/Ge(001)-NWs was firstly observed by Gürlu et al. with scanning tunneling microscopy (STM) [1]. After that, Houselt et al. reported that the surface periodicity of Pt/Ge(001)-NWs changes from a p(4x2) at room temperature to a p(4x4) below 80 K [2]. Recently, we experimentally proposed the atomic configuration of Pt/Ge(001)-NWs by means of reflection high-energy positron diffraction [3]. In the present study, we have investigated surface and electronic structures of Pt/Ge(001)-NWs by low energy electron diffraction (LEED), STM and angle-resolved photoelectron spectroscopy (ARPES).

The single-domain samples of Pt/Ge(001)-NWs were prepared on a vicinal Ge(001) surface. From LEED and STM, we have found the nanowires that line up parallel to the step edges. The ARPES measurements were performed at BL19A in KEK-PF and Cassiopée beamline in SOLEIL Synchrotron. We have observed four metallic bands associated with Pt/Ge(001)-NWs along the nanowire direction. The ARPES measurements also provide a constant energy map at the Fermi level. We found that the Fermi surface of one band consists of completely straight-line without

two-dimensional undulation. This suggests that the band is an ideal one-dimensional metallic state. On the other hand, the Fermi surfaces of the other bands exhibit weak two-dimensional undulations around the straight lines which a purely 1D Fermi surface would give, meaning some inter-chain interaction. We believe that the 1D metallic bands of Pt/Ge(001)-NWs are very suitable for the study of the peculiar physics in one-dimensional metals.

The pioneering discovery that brominated porphyrins undergo polymerization reactions upon annealing when adsorbed on a solid surface¹ has motivated extensive investigations over the last few years. The aim of a large part of such investigations has been to exploit other reactions which are known to work well in the solution phase to synthesize 2D polymers¹, graphene nanostructures², etc. Alongside these reactions, a number of intriguing reports on surface-based reactions with no solution-phase analog have appeared recently^{4,5}. In these cases, the surface must play a crucial role in the reaction mechanism. However, the atomistic details of how the surface changes the reactivity of the organic adsorbate in such dramatic ways are still not fully understood. Moreover, although purely electronic effects derived from charge-transfer between the adsorbate and the metal surface might be expected to affect the chemical reactivity of the adsorbed organic molecule, no previous study has tackled explicitly this issue.

In this communication we report on the thermally-induced chemical reactions of the organic electron acceptor 15,15,16,16-tetracyano-6,13-pentacene-*p*-quinodimethane (TCPQ) when adsorbed on Cu(100) studied by an in situ combination of Scanning Tunneling Microscopy (STM) and X-ray Photoelectron Spectroscopy (XPS) together with Density Functional Theory (DFT) calculations. We show that charge-transfer from the metal substrate to the organic adsorbate controls the molecular

conformation upon adsorption and, thereby, the strength and geometric availability of the different chemical groups to undergo chemical reactions. In particular, we will demonstrate that, upon annealing, two cyano groups are selectively eliminated from each molecule, a result that cannot be properly understood unless the role of the surface as a source of electrons is properly accounted for. Subsequent annealing leads to the formation of short oligomeric chains with pentacene and cyano groups in the repeating unit, which might be of interest for applications in organic electronics and photovoltaics.

Electron-phonon coupling (EPC) determines many relevant materials properties such as the lifetimes of excited electrons, BCS superconductivity, charge density waves, the Kohn anomalies in the phonon dispersion, etc. The information on EPC as currently derived from electron tunneling spectroscopy or heat capacity measurements is restricted to the single parameter λ averaged over all transitions across the Fermi surface and the phonon spectrum. However, a recent inelastic He atom scattering (HAS) analysis on ultrathin Pb films [1] demonstrated the surprising ability of HAS to provide information on the EPC strength for specific surface phonon modes (mode- λ spectroscopy). In this work we show that the extension of this analysis to corrugated semimetal surfaces is not trivial, due to the occurrence of bound-state resonance effects in the inelastic HAS intensities [2]. Unlike low-index metal surfaces which are perfectly flat, the semimetal Bi(111) surface exhibits a large corrugation [3] while supporting conducting electronic states at the surface [4]. Recent iHAS measurements on Bi(111) [5] revealed intense phonon features and comparatively strong EPC for certain modes. Using detailed information on the He-Bi(111) interaction potential obtained from elastic resonances, some of those intense features can be identified as resonantly enhanced. The complete procedure from measuring the relevant bound states to predicting possible resonance positions in the time-of-flight spectra using elastic and inelastic HAS will be presented and thoroughly discussed.

Surface science is continuously in search of new techniques to characterize the interface between a solid and its environment. During growth, the most refined characterization of the last layers of solid is often required as it sets the actual starting condition, whereas any real time information on the surface morphology and growth dynamics becomes most valuable. In both cases, the main challenge is to gain quantitative information on the terminating atomic layer, its structure, microscopic corrugation, mesoscopic morphology, charge transfer and type of terminating layer in composite materials, mosaicity, etc.

Electron diffraction techniques (LEED and RHEED) are well suited to resolve the lattice parameter of topmost layers, but are usually not sufficient for the unambiguous identification of the microscopic atomic structure. Moreover, the information related to the top layer is often blurred by contributions from underlying layers. Local description on the last atomic plan is best achieved by near field microscopic techniques (STM, AFM) but these are often too slow to be carried out in real time. We have developed a new technique based on diffraction of fast atoms at grazing incidence; it is named GIFAD for Grazing Incidence Fast Atom Diffraction.

The main advantages of GIFAD are:

- a superior surface sensitivity, the incident atom probes only the region lying at 2 to 5 Å above the last atomic plan
- the ability to provide simultaneously lattice parameter and microscopic surface corrugation (similar to that measured by AFM) averaged on a macroscopic level [1].
- the high sensitivity to mosaicity [2]
- its geometry being similar to that of RHEED, GIFAD is well suited for real time

monitoring of film growth

- this technique is truly non-invasive

The probing atoms, He with energies in the range 0.2 to 1 keV, are produced by neutralization of ions produced by a bright ion source. The diffraction pattern exhibits Bragg spots whose relative intensities can be analysed to extract the density profile of the valence electrons. Fig. 1 shows an example of such results obtained on a $c(2 \times 2)$ ZnSe(001) surface; the experimentally derived corrugation along the [100] direction points to the fact that maxima in the electron density do not necessarily sit on top of the atoms.

Other analytical properties of GIFAD will be presented and examples given in static as well as dynamical conditions.

Magnetic nanoparticles are important in many applications ranging from data storage to ferrofluids and to biomedicine. The ability to control simultaneously the size, shape and composition of the nanoparticles provides a great flexibility to tune their properties for their different bio-medical applications [1]. However, these particles are generally not bio-compatible and can be easily oxidized which alters their magnetic properties. A possible solution is to passivate the surface of magnetic nanoparticles with a chemically inert and biocompatible metal such as gold. The fabrication of cores-shell nanoparticles with a magnetic core and a gold shell has then become a promising route for biomedical applications [2]. Experimentalists of the MC2 group at CEMES (Toulouse) in collaboration with C. Langlois (INSA Lyon) have managed to grow Fe@Au core-shell nanoparticles of ~8-10 nm using phase vapor deposition techniques (Fig. 1). These particles take a very unusual morphology made of an iron nanocube encapsulated by gold truncated pyramids on every cube facet. Composition, size and shape of these nanoparticles show, however, some disparity, the growth mechanisms being difficult to control during growth by physical vapor deposition at high temperature. Furthermore, the influence of the coating on the electronic, structural and magnetic properties of the Fe core is not well known yet, neither its effect on the Fe oxydation properties. In this work, a Fe@Au nanoparticle was modeled by a simplified system in which the Fe core is represented by an infinite substrate, on which several atomic layers of gold are deposited. The Fe/Au interfaces, as they stand on the iron nanocube facets, have been studied using DFT calculations. We present results obtained from the detailed analysis of the structural, magnetic and electronic properties of these interfaces, as a function of the number of gold monolayers deposited on the Fe substrate.

We present a study of the molecular self-assembly of Zn(II) 5,10,15,20-tetra-(5-bromothien-2-yl)-porphyrin (ZnTBrThP) on the Ag(111) and Au(111) surfaces. These surfaces have been characterised by means of scanning tunnelling microscopy (STM), X-ray photoemission spectroscopy (XPS), valence band photoemission and x-ray absorption spectroscopy (XAS) from the submonolayer to multilayer regimes, in order to reveal the electronic properties and conformational behaviour of the molecules on these surfaces.

A pronounced substrate dependence is displayed in the self-assembly of the ZnTBrThP molecules on the Ag(111) and Au(111) $22 \times \sqrt{3}$ surfaces. The molecular assembly on the Ag(111) surface is consistent with metal-directed polymerisation, where linkage of the ZnTBrThP molecules is mediated by coordination to substrate atoms via the bromothienyl groups; the abstraction of Ag atoms is revealed in the formation of substrate vacancy islands. Weaker substrate bonding of the ZnTBrThP molecules on the Au(111) $22 \times \sqrt{3}$ surface permits a greater influence of direct intermolecular interaction in the self-assembled molecular overlayer. Here attractive dipole-dipole interactions between S and Br moieties of adjacent molecules stabilise the observed face-to-face alignment of the bromothienyl groups. When adsorbed on both surfaces, the ZnTBrThP molecules display a latent thermal lability, which results in the fragmentation of the bromothienyl groups upon annealing [1,2]. The elimination of the bromide moiety is common a feature on both Au(111) $22 \times \sqrt{3}$ and Ag(111) surfaces, however, in the latter case, the cleavage of the thienyl moiety is also observed.

Inhibition of the corrosion of aluminum: DFT studies of the adsorption of 8-hydroxyquinoline on Al(111) and Al₂O₃ surfaces

T13 Surface Science

#SS-P3-14

F. Chiter ¹, C. Lacaze-Dufaure ¹, H. Tang ².

¹CIRIMAT - Toulouse (France), ²CEMES - Toulouse (France).

Due to the high toxicity of chromates, the use of classical corrosion inhibitors for aluminum and aluminum alloys has been restricted in industrial applications. As a consequence, intense research efforts are being undertaken to find new environmentally friendly compounds. Experimentally it was shown that nitrogen-containing compounds are the most efficient corrosion inhibitors. Among these molecules, the 8-hydroxyquinoline (8-HQ) (figure-1) is particularly active in the prevention of the corrosion of aluminum and the 2024 alloy [1, 2]. We thus investigate the corrosion inhibition mechanisms of such molecules on pure Al and on Al₂O₃ surfaces by first principles calculations (periodic computations).

We first present a comparison of the stability of Al(111), γ -Al₂O₃(111), α -Al₂O₃(0001) and ultrathin alumina surfaces [3,4]. The interactions between the 8-HQ molecule and these surfaces are thus modeled and discussed, especially in term of adsorption sites and adsorption topology, calculated adsorption energies, stability of complexes formed by 8-HQ molecules with surface Al atoms. A detailed electronic structure analysis (charge transfer, density of states, work function, partial charge, etc ...) leads to the determination of the bonding.

Secondary electron intensity dependence on the layer structure

Attila Sulyok¹, Miklós Menyhárd¹ and Ludomir Zommer²

1 Research Centre for Natural Sciences, Budapest, Hungary

2 Institute of Physical Chemistry, Warsaw, Poland

The intensity of backscattered current depends on both the layer thickness and the atomic numbers. Thus, the alteration of layer thicknesses may result in a contrast in the secondary electron (SE) image. The old Seiler model described the SE intensity in those situation when a bulk material is covered by a thick layer of another material and an approximating formula was given for the contrast difference as a function of the overlayer thickness. The model cannot be applied to a target of a complex layered structure.

We will present experimental results demonstrating contrast changes because of altering layer thickness. The secondary electron intensity was continuously measured on specimen [3 x (nickel 40 nm / carbon 18 nm) on Si substrate during depth profiling. The actual depth was controlled by AES with simultaneous detection of Auger peaks (Ni and C).

Although there exist computer models for simulating the formation of SE images the reliability of them is not satisfactory. We developed a new Monte Carlo model based on tracking the electron trajectories. It includes the generation of secondary electrons and the main physical effects determining the backscattered SE intensity. BSE at 100 eV are calculated instead of the real SE at its low energies (10eV). Simulated intensity curves over Ni-C layer structure are interpreted and compared to measured results. The backscattering ratios provided by our model are within 10 % to the measured ratios. Both the simulated and the experimental curves demonstrate the complex behavior of SE intensity curves on a multilayer structure.

The backscattering on this Ni-C layer structure was also simulated by CASINO code.

We found higher deviation from the measured backscattering intensity ratios than that of our model.

Phase behavior of dimer adsorption model on honeycomb lattice at finite temperatures

T13 Surface Science

#SS-1-Or-11

V. Fefelov, S. Akimenko, V. Gorbunov, A. Myshlyavtsev, M. Myshlyavtseva, P. Stishenko.

Omsk state technical university - Omsk (Russian federation).

Dimer adsorption model is a very interesting model, because it allows identifying features of the phase behavior of adsorbed monolayers consisting of molecules with complex shape. Despite its simplicity the model takes into account the multisite adsorption, a different orientation of the molecules as relative to each other and relative to the surface, and also allows us to introduce specific lateral interactions. We have previously studied the phase behavior of the dimer adsorption model on lattices with different coordination numbers (honeycomb, square and triangular [1-3]). These studies have shown a strong dependence of the phase behavior of the adsorption monolayer on the coordination number of the lattice. In the case of square lattice one can observe only two ordered structures, in the case of triangular lattice – already three, but for honeycomb lattice in the ground state one can see devil's staircase of phase transitions (The term «devil's staircase» is usually used to describe the physical systems in which the amount of ordered structures in a finite range of phase space becomes formally infinite). It is interesting that the similar behavior of the adsorption monolayer occurs in real systems – the adsorption of trimesic acid on Au (111) [4]. Commonly, the devil's staircase appears as a result of the competition between long-range repulsive and short-range attractive interactions. Even the simplest models in which devil's staircase takes place include complex sets of interactions between particles. In the case of one-dimensional models it can be variable external field or long-range repulsive interactions, e.g. Frenkel-Kontorova model and one-dimensional Ising model; for three-dimensional models as a rule there are two or more competing interactions, e.g. well-known ANNNI model. However in our model there are only short-range repulsive lateral interactions. The main factor which leads to the appearance of infinite amount of ordered structures in our model is two competing

forms of adsorption. In [3] we studied the model of dimer adsorption on honeycomb lattice in the ground state. The aim of this work is to investigate of the phase behavior of the model at finite temperatures and answer the question: Is it possible devil's staircase phenomenon of phase transitions at nonzero temperatures? Model was studied by Monte Carlo method and transfer-matrix.

This study correlates the microstructure and Charpy impact test properties of a low carbon steel (0,038%) in different annealing conditions. Three heat treatments were applied. The volumetric fraction was measured and identified with optical microscopy, scanning electron microscopy (SEM) and, atomic force microscopy (AFM). The Charpy impact test results indicated that, when the temperature range was modified, the transition temperature was modified too, and the samples austenitized at 950°C absorbed more energy and the transition temperature decreased.

Copper-aluminum alloys are often used for aeronautical applications. In the presence of oxygen, aluminum can form an oxide surface layer, leading to high temperature resistant coatings with good resistance to oxidation and corrosion in aggressive environments. Moreover, copper-aluminum alloys exhibit good mechanical properties. The comprehension of copper deposition on Al and copper segregation in aluminum is thus of prime interest.

We performed periodic calculations in the framework of the density functional theory of copper adsorption on the Al(111) surface. On the perfect surface, several adsorption sites were studied and adsorption pathways normal to the surface for the Cu adsorption in bridge, hcp and fcc hollow sites were determined. An adsorption energy of 3.20 eV is calculated for the three considered sites. There is a large electronic transfer (around 1 electron) from the substrate to the ad-Cu in all cases. The adsorption of copper atoms is thus considered on surface vacancies and on the stepped surface. In both cases, the adsorption energy is increased. The population analysis shows again large charge transfers from the metallic surface to the Cu adatom.

University of Western Australia - Perth (Australia).

Electron spectroscopy enables the investigation of the characteristics of atoms, whether free and single, bound in molecules or in a wide variety of surface and thin films. Inelastic electron scattering offers a way to study momentum and energy transfer with strong correlation effects. Spin-polarised electron scattering opens a fundamental way to study topological effects and topological matter. The basic interactions have many and varied applications such as in magnetism, surface physics, topological insulators, quantum dot resonance fluorescence, cold atoms, the quantum Hall effect and magnon dynamics [1,2].

The present study identifies and expands the discussion of geometric phases from condensed matter to thin films [2], to molecules and to single atom phenomena [3] such as found on surfaces. The geometric phase is discussed from an experimental viewpoint to link concepts of vector potential, gauge transformations, electron correlations and the Pauli exclusion principle with the vector alignment and orientation of angular momentum and its transfer to radiated photons.

For single atoms of zinc and mercury, with two electrons in the outer valence orbits, observations indicate spin-polarized electron exchange excitation from a $1S_0$ to a $3S_1$ state [3]. During excitation, the parallel (aligned) electron spin is transported around a closed path to acquire a phase change of π radians which is observed directly as transferred alignment of observed radiated photon angular momentum to confirm coherent transfer in excitation and de-excitation processes.

Two examples of vortices are observed. (i) Straight vortex lines [4] are inferred for electron scattering ($e,2e$) momentum distributions from free atoms and surface scattering and are associated with a fixed value of z-component of angular momentum of a wave function and angular momentum conservation. The vortex line signifies a rotational orientation through an angle resembling a gauge degree of freedom and a gauge potential giving rise to a field strength related to a magnetic field with directional orientation of the vortex line. (ii) Vortex rings, formed by the superposition of electric field mixed wave functions with the same energy but different angular momenta, are inferred following the excitation of the electronic

$\Psi(200)$ and $\Psi(210)$ states of hydrogen atoms, with $\pi/2$ phase difference mixed by an external electric field. Coincidence detection of scattered energy-loss electrons with radiated photons shows oscillatory behaviour in the exchange Stokes parameter which changes phase as the electric field reverses and shows different lifetimes of the mixed parity 2S and 2P states.

In conclusion, the geometric phase arises from the breaking of time-reversal symmetry, and has been observed by measurements of the Stokes parameters for sums and differences of photon polarizations through the symmetry requirements of the wave function. The studies are indicating the development of ways to control the behaviour of a geometric phase.

A. De Siervo, L.H. De Lima, R. Landers.

Instituto de Física Gleb Wataghin, Universidade Estadual de Campinas - Campinas (Brazil).

Graphene on SiC(0001) is a promising platform for future integration of high performance electronic devices. Despite its fascinating characteristics, graphene has a feature that compromises its potential technological application: it is a zero gap semiconductor. Moreover, graphene on SiC is strongly coupled to Si layer underneath which reduces the electronic properties of graphene. It is then necessary to modify the electronic structure according to the application and this can be done with the functionalization of the graphene with atoms and molecules[1-3]. Using x-ray photoelectron spectroscopy (XPS) and Scanning Tunneling Microscopy (STM) we investigate the intercalation behavior of Co ultrathin films and particles on graphene/SiC. We found that ultrathin films of metallic Co and other metals, for instance W, as well as their oxides can intercalate below both, the sp³-hybridized carbon-rich interface layer, the so called buffer layer, and monolayer graphene. XPS shows that after growth, the metal is on the surface of the graphene/SiC and suffer oxidation when exposed to O₂. After heating to ~350C in ultra-high vacuum, there is a reduction of cobalt oxide and intercalation between graphene and buffer layer, as indicated by the STM images and XPS. After metal intercalation, graphene acts as a barrier to oxidation, preserving the metallic character of the material. This model was also applied to tungsten and XPS results confirm the hypothesis of intercalation and protection. Based on the experimental results we will also discuss about possible mechanisms of metal intercalation and protection.

Chemoselectivity in Hydrocarbon Conversion on Pd Model Catalysts

T13 Surface Science

#SS-18-Or-2

K. Dostert, C. O'Brien, A.A. Savara, W. Ludwig, S. Schauermann, H.J. Freund.

Fritz Haber Institute of the Max Planck Society - Berlin (Germany).

Recent progress in understanding the kinetics of the hydrogenation of simple unsaturated compounds on Pd [1-3] opened up opportunities to investigate the catalytic conversion of more complex systems. In this study, the kinetics of the hydrogenation of α,β -unsaturated carbonyls, which contain C=C and C=O bonds, on well-defined Pd/Fe₃O₄ model catalysts and Pd(111) is addressed by a combination of surface science techniques and molecular beam experiments.

Insight into the chemoselectivity of π (C=C) vs. π (C=O) hydrogenation were obtained on a microscopic scale by investigating several key steps: the adsorption process, the interaction of co-adsorbed reactants, and the kinetics of the conversion were addressed individually. The adsorption of isophorone on Pd(111) was investigated by synchrotron near-edge x-ray absorption fine structure (NEXAFS) and infrared reflection-absorption spectroscopy (IRAS) experiments. The results indicate different geometries of the C=C and C=O bonds with respect to the Pd(111) facet, especially when hydrogen is co-adsorbed. Furthermore, molecular beam experiments on the kinetics of the conversion of acrolein with hydrogen on Pd/Fe₃O₄ model catalyst show selective hydrogenation of the C=C bond. The activity of the catalyst was found to depend on the cluster size.

The combination of NEXAFS and IRAS experiments is shown to be a powerful tool, not only to obtain detailed information about the adsorption of isophorone on the Pd(111) facet, but also to monitor the interaction between the unsaturated π -bonds and hydrogen. The strong impact of hydrogen on the geometry of the C=C bond is in line with the results of molecular beam experiments, where selective hydrogenation of the C=C bond was observed.

The interaction of Co oxides with Graphite surfaces

T13 Surface Science

#NST/SS-1-Or-9

L. Soriano, D. Díaz-Fernández, J. Méndez, A. Gutiérrez.

Universidad Autónoma de Madrid - Madrid (Spain).

Since the appearance of the unique Carbon nanostructures like Carbon Nanotubes (CNT's) and Graphene, a lot of attention has been paid to their formation methods. In particular, the use of Co and Mo transition metals as catalysts has been reported in the literature [1]. Also, oxidized Graphene (GO) has been used to obtain Graphene sheets due to its hydrophilic properties which leads to the easy separation of GO [2]. In this work we have studied the interaction of Co with highly pyrolytic graphite (HOPG) surfaces in presence of oxygen.

Firstly, we have studied the growth of cobalt oxides on HOPG by thermal evaporation of metallic Cobalt in oxygen atmosphere (2×10^{-5} mb) at room temperature. A mixed Stransky-Kastanov like way of growth has been detected with the initial formation of a wetting layer 8 Å thick of CoO (Co^{2+}) and accumulation of CoO islands at the HOPG steps. Further deposition produces the formation of dendritic CoO islands on the terraces. These islands keep on growing up to coalescence forming a CoO thin film (Figure 1).

However the most interesting features appear when these films are submitted to thermal annealing at 400 °C for 1 h in an oxygen atmosphere (5×10^{-3} mb). Firstly, the former Cobalt oxide has been oxidized to Co_3O_4 ($\text{Co}^{2+,3+}$) forming islands of about 40 nm size. Attached to this Co_3O_4 islands, multiple concentric nano-rings (30-60 nm diameter) are observed (Figure 2b). Finally, nano-channels associated to the random path of Co_3O_4 islands have been formed due to the oxidation of the graphite surface. As a final result of this process, the graphite surface becomes oxidized with the formation of a buried CoO underlayer.

Plasmon resonances on low index flat surfaces of aluminium and silver

T13 Surface Science

#SS-2-Or-9

G. Raseev.

CNRS/Univ. Paris-Sud - Orsay (France).

The UV photoelectron spectra of plain metals and quantum wells display surface and volume plasmon resonances. For a p or transverse magnetic linearly polarized photon a theoretical model should use a transition operator with laser fields calculated for the actual system under study. In the vector potential from electron density-coupled integro-differential equations (VPED-CIDE) model [1] these laser fields are solution of the Ampere-Maxwell classical and material equations in the real space and the temporal gauge ($U=0$). The present work calculates the electron escaping probability from the power density absorption, the photoionization cross section both directly related to the PES, the reflectance, Feybelman's parameter $d(\text{perpendicular})$ and the induced by the laser electron density.

We study low index surfaces (001) and (111) aluminium [2] in the region 10-30 eV and of silver [3] in the region 3-10 eV. Our calculations favorably compare with the experimental angle and energy resolved photoelectron yield (AERP) spectrum of Levinson et al. [4] for Al(001) and of Barman et al. [5] for Al(111) surfaces. For Ag(001) and Ag(111) our theoretical spectra are in agreement with the AERP spectrum of Barman et al. [6]. Analysis in terms of the induced by the laser electron density and of the Feibelman's parameter $d(\text{perpendicular})$ permits to identify the nature of the plasmon resonances.

STM investigation of phenol adsorption on Cu(110)

T13 Surface Science

#SS-18-Or-3

Y. Kitaguchi, S. Habuka, T. Mitsui, S. Hatta, H. Okuyama, T. Aruga.

Department of Chemistry, Graduate School of Science, Kyoto University - Kyoto (Japan).

Phenol (C_6H_5OH) is a relatively simple π -conjugated molecule, and it has been used as a good model of a bifunctional molecule which has both an aromatic ring and an O-H group. We investigated the adsorption of phenol on Cu(110) at a single molecule limit using STM, and the assignments of adsorption states were conducted also using EELS. STM images recorded at 78 K revealed that phenol molecules are stabilized by forming a trimer (fig. 1a). The corresponding EELS showed a broad peak at ~ 400 meV arising from H-bonded O-H stretch while it showed no signature of free O-H bond, indicating that the trimer is in a cyclic configuration with any O-H bond involved in the H-bond. Such cyclic form of phenol trimer was also proposed to exist in gas phase as well as in the solid. The STM clearly shows four equivalent orientations for the cyclic trimer.

The EELS recorded after annealed to room temperature showed disappearance of the O-H stretch but the vibration modes of the aromatic ring were maintained. We assigned the thermal product as a phenoxy specie (C_6H_5O), as in the previous works [1, 2]. STM images show that the phenoxy species are arranged in one-dimensional chains along the [001] direction with a period of two atomic distance (0.7 nm) (fig. 1b) and form two-dimensional $c(2 \times 4)$ overlayer at saturation coverage [2]. The phenoxy specie is bonded to the short-bridge site via oxygen atom with the phenyl ring nearly parallel to the surface. It is shown that the STM can lift up the phenoxy ring and flip the molecule around the anchoring oxygen atom.

We also investigated the adsorption of benzenethiol (C_6H_5SH) on Cu(110) for the purpose of knowing the role of chalcogen atoms in the adsorption states, and it was revealed that a benzenethiol molecule is adsorbed as benzenethiolate (C_6H_5S) at 78 K and the benzenethiolate species are preferentially arranged along the [1-12] direction. Dipole-dipole interaction is suggested to be responsible for the preferential chain growth, while the chain direction is ruled by the steric repulsion between the chalcogen atom and the phenyl ring.

Owing to its peculiar electronic band structure, high carrier mobility and long spin diffusion length, graphene is a promising two-dimensional material for microelectronics and spintronics. Graphene also shows interesting magnetic properties when in contact with a ferromagnetic metal (FM). For instance, graphene carries a net magnetic moment when deposited on Fe/Ni(111) [1], and a 13 meV spin splitting can be induced in graphene due to proximity with a heavy element [2].

While these works illustrate potential advantages of integrating graphene within a magnetic stack, the influence of graphene on the magnetic properties of a FM is still largely unexplored. In particular, non-magnetic overlayers generally affect the magnetic anisotropy energy (MAE) of thin layers, where interfaces play an important role. We can then wonder how an interface with graphene would influence the MAE of a thin FM film. However, the fabrication of atomically flat graphene/FM and FM/graphene interfaces is not an easy task (graphene growth on metals is usually conducted at temperatures for which thin film dewetting can occur, and metal evaporation on graphene often yields clustered deposits).

Using spin-polarized low-energy electron microscopy (SPLEEM) and Auger electron spectroscopy, we study the intercalation of cobalt deposited on top of graphene/Ir(111) and find that a graphene top layer affects the magnetic properties of nm-thick Co films on Ir(111) [3,4]. We show that in the intercalated cobalt, perpendicular magnetic anisotropy is favored over an unusually large thickness range. Compared to the vacuum/Co interface, the MAE is significantly larger for a graphene-terminated Co surface. The hybridization of the Co and graphene electron orbitals very likely plays a key role in this unusual MAE. These result open new

perspectives for graphene-based spintronic devices with perpendicular magnetic anisotropy.

Isolated Pd sites on low indexed surfaces of intermetallic PdGa catalysts

T13 Surface Science

#SS-2-Or-10

R. Widmer.

**Empa, Swiss Federal Laboratories for Materials Science and Technology,
nanotech@surfaces - Dübendorf (Switzerland).**

With its highest technological and economic importance, catalysis is an extremely active research area, which yields in a great impact on the development of new catalyst systems with the aim to produce chemical compounds highly selective and more efficient. To this point the development and optimization of novel catalysts most commonly proceed via the modification of composition and surface treatment in a trial and error fashion. On the other hand, surface science methods offer the possibility to change this paradigm by gaining a fundamental understanding of the chemical reaction on a molecular level and determining the relation between catalytic properties and atomic structure of the surface. The obtained insight can then be applied to a knowledge-based development on novel catalysts showing increased activity and/or selectivity. In this context, intermetallic compounds have been identified as a promising materials class for novel catalysts with tailored properties [1]. Among these compounds PdGa, with the FeSi type of structure, has attracted considerable attention due to its exceptional selectivity and activity as a heterogeneous catalyst for the semi-hydrogenation of acetylene [2]. These properties were assigned to the separation of catalytic sites on the surface of the intermetallic material [3]. Originating from its structure there are non-equivalent surface terminations of the different low indexed surfaces of PdGa [4, 5]. Special emphasis is put on the intrinsic chirality of the {111} surfaces with regard to enantioselective catalytic reactions. Here, we present a detailed atomic and electronic structure analysis on low Miller indexed PdGa surfaces based on XPD, LEED-I(V), STM, ARPES and DFT based stability calculations. Additionally, TDS and FT-IR investigations were performed to probe the chemisorption behavior of CO. In particular we will address the very different local arrangement of Pd atoms on the different PdGa surface, which qualifies this intermetallic compound as ideal model system to study the role of site

separation on the catalytic properties. These insights in the surface structure are essential inputs for the determination of catalytic reaction pathways and theoretical calculations of molecular adsorption energies.

SS-P3-05

Surface free energy of self-assembled pure and mixed lipid layers

T13 Surface Science

#SS-P3-05

D. Risović, B. Gašparović, A. Penezić.

Rudjer Boskovic Institute - Zagreb (Croatia).

The supported lipid mono and bilayers are widespread tool for mimicking the structure and functions of biomembranes. Lipid layers are also used as sensor element host in development of various novel sensors incorporating membrane based films. The surface free energy (SFE) of lipid films plays a crucial role in physicochemical processes occurring at the interface and its magnitude arises from the kind and strength of involved intermolecular interactions [1, 2].

The surface free energy of solid supported self-assembled pure and mixed lipid layers was studied using contact angle measurements in conjunction with Fowkes and Owens-Wendt-Rabel-Kaelble (OWRK) theories [3]. The measurements of contact angles were conducted using four standard liquids (water, formamide, diiodomethane and ethylene glycol). The investigation comprehended 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC), 1-Palmitoyl-2-oleoylphosphatidylcholine (POPC), and oleic acid triglyceride - triolein (TO). Pure and mixed lipid mono and bi-layers on solid substrates were formed by spontaneous spreading and by transfer of the self assembled monolayer from a subphase of 0.55 M NaCl water solution using the Langmuir–Blodgett / Schaefer techniques. The results of SFE determination of the investigated mixed and single lipid layers on hydrophilic and hydrophobic substrates are presented and discussed in terms of influence of the mixing ratio on the intermolecular interactions and film stability.

¹J.E. Purkinje University - Usti Nad Labem (Czech republic), ²Masaryk University - Brno (Czech republic), ³VAKUUM PRAHA - Praha (Czech republic).

The polymers are important material for many applications from the flexible electronics (displays, solar cells) to biocompatible materials for implants and tissue engineering.

Surface modifications of PET, PEN, PMMA and PEEK polymers by the atmospheric low cost DBD plasma discharge in ambient air and nitrogen at atmospheric pressure were studied. The samples were treated in the 400 W powered DBD plasma discharge. The samples were exposed directly to the plasma. The treating time was from 1 s up to 10 s. A comparison was made to low pressure experiments with oxygen and argon, nitrogen and air ions from MW plasma source (Tectra Sputter Gun) at energies from 100 eV up to 2500 eV.

The surface modifications were investigated by various surface sensitive techniques for example XPS, the contact angle measurement for surface energy evaluations, FTIR, AFM and the electro kinetic potential was also investigated on the modified surfaces over wide range of pH.

For example, the DBD plasma treatment on PEN had no significant influence on the surface morphology. But the water contact angle was reduced by the treatment from initial 79° to 31° (air) and 20° (nitrogen) when after 3 day at normal conditions the contact angles was still about 50° and 40°, respectively.

The oxygen concentration in the PEN foil measured by XPS was increased from an initial 22 at. % up to 45 at. % after first 5s in DBD air plasma. The nitrogen DBD plasma modified surface composition only by implanted nitrogen up to 5 at. %. But the surface modifications in air plasma resulted in the formation of new chemical

bonds between the carbon and the oxygen, e.g., C=O, O–C–O. The O-C bond was reduced significantly on the treated surface.

The physical sputtering process was dominant for the treatment by argon ions at both energies and oxygen ions treatment at higher energy 2.5 kV in low pressure conditions. The O/C ratio evaluated on PEN surface decreased fast from initial value about 0.29 to 0.19 and 0.09 by argon ions treatment with energy 0.2 keV and 2.5 keV, respectively. In contrary the low energy 0.2 keV oxygen ions treatment can increase O/C ratio up to 0.43. The argon ions treatment was the physical sputtering process with the preferential removal of oxygen when the oxygen ions treatment had both physical interactions and chemical reactions. The 2.5 keV oxygen ions treatment modified the PEN surface dominantly by physical interactions therefore the O/C ratio was reduced but certain increase in relative abundance in C-O bonds was observed. The 0.2 keV oxygen ions treatment also faster increases C-O bond then C=O bonds but they are in contrary to other treatments also increased.

The surface modification under various condition evaluated together gives opportunity to compare those techniques under identical conditions.

In this communication, we show that graphene grown on Ru(0001) electronically decouples 7,7',8,8'-tetracyano-p-quinodimethane (TCNQ) molecules from the Ru(0001) [1]. Graphene on Ru(0001) presents a moiré pattern with a periodic chemical interaction between carbon atoms and the ruthenium, leading to a modulation in the electronic structure and surface potential [2][3][4]. Low Temperature scanning tunneling microscopy/spectroscopy (LT-STM/STS) measurements and Density Functional Theory (DFT) calculations show that isolated TCNQ molecules deposited on a monolayer graphene epitaxially grown on Ru(0001) acquire charge from the substrate and develop a sizeable magnetic moment, which is revealed by a prominent Kondo resonance. The magnetic moment is preserved upon dimer and monolayer formation. The energy position and spatial distribution of the molecular frontier orbitals for a single molecule are measured by STS maps at 4.6K in ultra high vacuum and compare well with the DFT calculations. When the molecular coverage is increased the molecules begin to form chains that finally cover completely the graphene surface. The self-assembled 2D monolayer of magnetic molecules develops spatially extended spin-split electronic bands visualized in the real space by STM (see Figure 1), where only the majority band is filled, thus becoming a 2D, purely organic magnet whose predicted spin alignment in the ground state is visualized by spin-polarized STM at 4.6K.

Influence of the spin-orbit coupling of the BiAg₂ surface alloy on electron scattering

T13 Surface Science

#SS-10-Or-2

J. Lobo-Checa ¹, F. Schiller ¹, P. Gambardella ², E. Ortega ¹, A. Mugarza ².

Transport properties of the solid are interweaved to its electronic wavefunctions. Further inside into them can be achieved through the study of scattering processes at defects, such as adsorbates or steps. The inelastic lifetime and quantum coherence are dependent upon the nature of the system, i.e, the type of defect, the chemistry, and the morphology of the Brillouin zones.

Unraveling the fundamental scattering aspects of electronic states which exhibit no spin degeneracy is nowadays a key goal in the Solid State scientific community. An observation that has fostered this research activity is the lack of back-reflected waves near steps at the surface of topological insulators [1]. The reduction of scattering has been attributed to the topological protection of surface states in the material, which is directly related to the strong spin-orbit interaction.

In order to further understand the effect of spin-orbit coupling on the scattering phenomena, we have investigated by angle resolved photoemission (ARPES) the surface alloy of BiAg₂. This system exhibits a giant spin-orbit splitting, that is orders of magnitude larger than, e.g., in semiconductor heterostructures [2]. The spin-splitting is originated from the Rashba-Bychkov effect at the surface-vacuum interface and, in contrast to the topological insulators, the spin-orbit coupling strength can be tuned by alloying [3]. We investigate the BiAg₂ surface alloy within the scattering analysis framework previously performed on a Ag(111) curved crystal [4]. The beauty of this substrate is that the density of steps changes progressively as we move along the curvature of the crystal so that the terrace size is continuously tuned from 400 nm to just 10 nm. Our results show unambiguously that the scattering of the surface

electron wavefunctions by the steps is rather weak, much smaller than the underlying substrate of Ag with values of transmission close to the topological insulators. Furthermore, three different type of molecules deposited onto this surface alloy are not observed to interact with the spin-split BiAg₂ states. We assign this unexpected behavior to the large spin-orbit coupling that protects these electronic states from impurities, in a similar fashion to the topologically protected surface states in topological insulators [5].

Unusual two-stage kinetics: unraveling the adsorption of ethylene on Si(100) by real-time optical reflectance measurements and Monte-Carlo approach

T13 Surface Science

#SS-18-Or-4

Y. Borensztein, R. Coustel, O. Pluchery, N. Witkowski.

INSP-CNRS - Paris (France).

As ethylene is the simplest alkene molecule, its adsorption on Si(100)2x1 can be considered as a paradigm for the reactivity of the C=C double bond with the Si dimers at the surface. There is a general agreement concerning the mode of adsorption: it is non-dissociative and almost every ethylene molecule is adsorbed on one Si-dimer by a [2+2] cyclo-addition reaction, the single C-C bond being nearly parallel to the Si-Si bond of the dimer ("di-sigma" on-top configuration) [1].

On the contrary, the kinetics of adsorption has not been understood clearly, and a couple of experiments have shown that, after a fast adsorption until about half monolayer, the sticking coefficient is strongly reduced. Recently, from a Kings-Well-type experiment, it has been proposed that, at room temperature, the adsorption follows a Kisliuk kinetics until about half-monolayer [2]. Unfortunately, so far no complete and detailed investigation of the kinetics has been proposed on the full range of adsorption for RT.

In the present work, we used a real-time and quantitative optical method, the Surface Differential Reflectance Spectroscopy [3], in order to investigate the kinetics of adsorption at room temperature until full saturation. We demonstrate that the adsorption follows a clear two-stage process. An intermediate saturation at 0.45 monolayer is obtained for 1 Langmuir, which corresponds to ethylene molecules adsorbed onto one Si dimer out of two, with a sticking coefficient close to 1, and with some pairs of Si dimers still unreacted. The second stage is shown to be dramatically

slower, yielding the full saturation of 1 monolayer for an exposure of about 400 L. This unusual kinetics for a surface with only one kind of adsorption site is successfully reproduced by a Monte-Carlo calculation taking into account the diffusion of the molecules on the surface, and a decrease by a factor of 400 of the adsorption probability on the Si dimers neighboring already reacted dimers. The Figure gives the full range kinetics in logarithm representation, which shows clearly the two successive stages.

University - Krakow (Poland).**

One of the most intriguing promises of nanotechnology is an ultimate level of control in fabrication of nano-scale structures, machines and devices. To achieve this goal in formation of larger 1D or 2D nanostructures, taking an advantage of thermally induced processes is a very encouraging strategy among others. Recently, there have been interesting reports in the literature on direct, on-surface formation of large covalently bonded molecular structures, both 1D and 2D (see [1] and references therein). Unfortunately, most of them discuss experiments performed on coinage metals with the only exception, i.e. the study of Kittelmann et al. demonstrating the successful covalent linking of four different halide-substituted benzoic acids on calcite [2]. In such a situation the field of on-surface polymerization on semiconducting and insulating surfaces is practically unexplored. Approach that will offer direct formation of a complex molecular structure in predefined form on a desired substrate surface is very attractive from technological point of view. First, functionalizing individual molecular precursors with precisely chosen linking sites should allow for future bottom-up construction of miscellaneous molecular devices [3]. Second, the possibility to induce the covalent linking on desired substrate will allow to choose the substrate best suited for desired application.

In the following, we would like to report on successful realization of on-surface polymerization on metal oxide surface [4]. Molecular precursors (10,10'-dibromo-9,9'-bianthryl, provided by St-Jean Photochemicals Inc.) are deposited on rutile titania surfaces using standard Knudsen cell. Next, the intermolecular colligation is thermally activated, through the sample annealing. The on-surface polymerization reaction can be described as a two-step process [3]: (1) C-Br cleavage resulting in bi-radical formation and (2) followed by bi-radical addition resulting in oligomer formation. The cleavage of carbon-halide bond is possible on TiO₂ surfaces by

thermal activation and the decomposition process is enhanced by the presence of surface hydroxyl groups [5]. The influence of surface reconstruction on polymerization process is discussed through the comparison between two rutile titania surfaces, i.e. (110) and (011) used as a substrate of interests. The fivefold coordinated titania, Ti_{5c} , atoms play an important role in both chemi- and physisorption of organic molecules on the rutile titania surfaces. These Ti_{5c} atoms are present on both discussed surfaces, however, in a very different surroundings that influences their “accessibility”, and thus influences polymerization process.

University of Wisconsin - Madison (United states).

Formic acid (HCOOH) is a simple molecule that is an abundant product of biomass processing and can serve as an internal source of hydrogen for oxygen removal and upgrading of biomass to chemicals and fuels. In addition, HCOOH can be used as a fuel for low temperature direct fuel cells. We present a systematic study of the HCOOH decomposition reaction mechanism starting from first-principles and including reactivity experiments and microkinetic modeling. In particular, periodic self-consistent Density Functional Theory (DFT) calculations are performed to determine the stability of reactive intermediates and activation energy barriers of elementary steps. In addition, pre-exponential factors are determined from vibrational frequency calculations. Mean-field microkinetic models are developed and calculated reaction rates, orders, etc are then compared with experimentally measured ones. These comparisons provide useful insights on the nature of the active site, most-abundant surface intermediates as a function of reaction conditions and feed composition. Trends across metals on the fundamental atomic-scale level up to selectivity trends will be discussed. Finally, we identify from first-principles alloy surfaces, which may possess better catalytic properties for selective dehydrogenation of HCOOH than monometallic surfaces, thereby guiding synthesis towards promising novel catalytic materials.

In fabrication of GaN nanocrystals, the surface diffusion of Ga adatoms is one of the key parameters. To study this phenomenon and its influence on island formation, we use the Ising lattice gas model with the Metropolis algorithm [1]. For speeding up the simulations, a graphic card GPU was involved.

This model allows us to simulate the related surface behavior such as Ostwald ripening[2] and TDS measurement which have not a simple character in this case. Using the model we have examined the influence of different temperature, coverage and adatom energy on these surface processes as well.

Further, the influence of nucleation centers on Ga-island formation was simulated and compared to the experimental results on Si samples pre-patterned by e-beam lithography . The simulation for the nucleation sites lattice 5x5 after 1 k MCS and after 50 k MCS is shown in the figure.

Adsorption of isolated Au adatoms on the Fe₃O₄(001)

T13 Surface Science

#SS-7-Or-12

Z. Novotny, G. Argentero, Z. Wang, M. Schmid, U. Diebold, G.S. Parkinson.

Institute of applied physics, Vienna university of technology - Vienna (Austria).

We present a scanning tunneling microscopy investigation of transition metals deposited at the magnetite Fe₃O₄(001) surface at room temperature (RT). This surface forms a reconstruction with $(\sqrt{2} \times \sqrt{2})R45^\circ$ symmetry [1], where pairs of Fe and neighboring O ions are slightly displaced laterally, forming undulating rows with 'narrow' and 'wide' adsorption sites. At fractional monolayer coverages, Au [2] and other metals (Fe [3], Pd [4]) adsorb as a single adatoms at the 'narrow' sites of the surface unit cell, forming an ordered overlayer on the surface.

Up to coverage of 0.12 ML (1 ML = 1 atom per surface unit cell = 1.42×10^{14} atoms/cm²), Au adsorbs as isolated adatoms at RT (see Figure 1). With increased Au coverage, the surface contains both Au adatoms and three-dimensional clusters (smallest clusters contain 5 ± 1 atoms), no Au dimers and trimers were observed at RT. For low coverage (only isolated Au adatoms and no clusters) no significant sintering is observed up to annealing temperatures of 400 °C [2], indicating a strong bond of the adatoms to the 'narrow' site of the supporting surface. Mobility of Au adatoms was never observed at RT. However, mobility of Au clusters was regularly observed at RT, and moderate annealing of the surface with higher coverage (adatoms and clusters) causes sintering of the adatoms and growth and merging of the clusters. The Au adatoms stay isolated and do not sinter when exposed to a background pressure of up to 10^{-4} mbar CO. Because of their high thermal stability, the ordered Au adatoms at Fe₃O₄(001)- $(\sqrt{2} \times \sqrt{2})R45^\circ$ should provide useful insights into the chemical reactivity of single atomic species.

This material is based upon work supported as part of the Center for Atomic-Level Catalyst Design, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences under Award Number #DE-SC0001058.

LEED, AES and XPS investigation of the thin indium films on the Si(111) surface

T13 Surface Science

#SS-P3-33

M. Skiscim, K. Idczak, S. Bilinska, L. Markowski.

Institute of Experimental Physics, University of Wroclaw - Wroclaw (Poland).

The growth of indium on the Si(111) surface has been studied over past two decades using various techniques, in many aspects. The deposition of indium on the Si(111)

7×7 surface leads to formation of different one- and two-dimensional ordered structures, depending on the coverage and substrate temperature. In certain conditions Stranski-Krastanov growth occurs [1]. Nowadays In-nanowires formation [2] and electronic properties of In/Si system [3] are of particular interest. While the growth mode is generally accepted, the type of surface structures remains open for discussion. The good example is " $(1 \times 1)R30^\circ$ " reconstruction, which was later recognized as $\sqrt{7} \times \sqrt{3}$ [4] (LEED image obtained by us is shown in the picture below).

In this work we carried out a detailed study of In/Si(111) 7×7 system for coverage up to few atomic layers in order to systematize and verify the current knowledge. The structural information was provided by Low Energy Electron Diffraction (LEED) and growth behavior and some chemical information by Auger Electron Spectroscopy (AES). Additionally X-ray Photoelectron Spectroscopy (XPS) was used to precisely determine the chemical environment. We propose the phase diagram for a wider range of temperature and coverage than before [5]. We also point to the influence of deposition conditions and subsequent treatment of the sample on the results obtained in the experiment.

Chemical vapor deposition growth of graphene on metal surfaces is an important and efficient synthesis method. Theoretically however, the dispersive metal-graphene interactions are not well understood or easy to describe. Here, we investigate the interaction of graphene with various metal surfaces [1] using density functional theory (DFT) and the meta-generalized gradient approximation M06-L functional [2]. We demonstrate that this method is of comparable accuracy to state-of-the-art calculations using the random phase approximation (RPA) [3].

Hydrogen adsorption on graphene on Ir(111) is studied in detail by combining fast X-ray photoelectron spectroscopy studies with DFT calculated core level shifts [4]. We reveal the presence of two types of hydrogen adsorbate structures at the graphene/Ir(111) interface, namely graphane-like islands and hydrogen dimer structures (see Figure 1a and b). In graphane-like islands every other C atom binds to an H atom above and every other to a metal atom below, thus giving rise to a very stable structure similar to graphane (see Figure 1c). Our data reveal distinctive growth rates and stability of both types of structures, thereby allowing to obtain well defined patterns of hydrogen clusters. Recently it was shown [5], that such graphane-like clusters are responsible for opening a gap in the graphene band structure, which is very desirable for electronic applications. The ability to control and manipulate the formation and size of hydrogen structures on graphene furthermore facilitates tailoring of its properties for a wide range of applications by means of covalent

functionalization.

Spin resolved photo emission of Fe₃O₄: The effect of surface structure

T13 Surface Science

#SS-P3-38

J. Pavelec, Z. Novotny, M. Setvin, M. Schmid, U. Diebold, G.S. Parkinson.

Institute of Applied Physics, Vienna University of Technology - Vienna (Austria).

Magnetite (Fe₃O₄) is widely considered as an ideal material for future spintronics applications. Density functional theory local spin density approximation (DFT-LSDA) calculations [1] predict half metal magnetite with band gap for the majority spin states, and density of states at the Fermi level for the minority spin states. However, magnetite exhibits strong electron correlation effects, casting doubt on the validity of the DFT-LSDA calculations. Consequently, several groups have attempted to measure the Fermi level spin polarization of magnetite using spin resolved photoemission, with widely varying results (20-80%). One potential problem with such measurements is that photoemission is an inherently surface sensitive technique, and not suited for measuring the bulk properties of materials in which the surface properties differ significantly; a mixture of both regions is probed.

In recent years, the ($\sqrt{2} \times \sqrt{2}$) R45° - Fe₃O₄(001) surface has been shown to exhibit a band gap [2], potentially explaining the low spin polarization measured for (001) oriented samples. In prior work [3], we showed that saturation exposure to atomic H lifts the surface reconstruction (by LEED and STM) and metallizes the surface (UPS).

Here, we report spin resolved photoemission spectroscopy (SPES) measurements of two different magnetite samples; thin films [4] of magnetite (001) grown on MgO(001) and a synthetic single crystal. The influence of the surface preparation and termination on the measured spin polarization was investigated for three surfaces: the ($\sqrt{2} \times \sqrt{2}$) R45° surface, an Fe-rich terminated surface formed by Fe deposition, and the hydrogenated (metalized) surface [3]. The experiments were performed using synchrotron light with kinetic energies $E_k=130$ eV and $E_k=706.8$ eV. Tuning the photo energy with the 2p-3d transition ($E_k=706.8$ eV) allows enhanced count rate with high bulk sensitivity [5].

Our results show that surface termination has low impact on the measured spin polarization of the state near E_F . The spin polarization value (approx. 25%) is in line with the measurements of ref.[4], suggesting that the magnetite state near E_F is not 100% spin polarized.

Substrate-mediated interactions between chlorine atoms adsorbed on Au(111), Ag(111) and Cu(111): STM and DFT approach

T13 Surface Science

#SS-18-Or-7

B. Andryushechkin ¹, V. Zheltov ¹, G. Zhidomirov ¹, B. Kierren ², K. Eltsov ¹.

¹A.M.Prokhorov General Physics Institute of Russian Academy of Sciences - Moscow (Russian federation), ²Institut Jean Lamour - UMR CNRS 7198 - équipe 102, Université H. Poincaré - Nancy (France).

In this work, we present a combined LT-STM and DFT study of chlorine adsorption on (111) planes of Au, Ag and Cu at low coverage. According to LT-STM data (Fig.1), chlorine forms chain-like structures at $\theta < 0.1$ ML. In the contrast to the case of the $(\sqrt{3} \times \sqrt{3})R30^\circ$ structure (0.33 ML) characterized by the Cl-Cl distance of 5.0 Å for Au and Ag, and 4.4 Å for Cu, we detected noticeably shorter distances within the chains. To find out the driving forces of this unusual coupling of chlorine atoms, we performed the DFT calculations using VASP code.

Different configurations of two chlorine atoms on the Au(111) surface have been tested. As a result, two local minima were found at the distances of 3.83 and 5.02 Å. In the first configuration, one chlorine atom occupies fcc position, while the other one appears to be in the bridge position. In the second case, Cl atoms occupy fcc threefold sites. Adsorption energies per Cl atom calculated for these two configurations appear to be close to each other: 0.961 and 0.964 eV, respectively. This fact is consistent with the experimental STM image in Fig.1 demonstrating the coexistence of the both configurations.

The proximity in the adsorption energy for Cl-Cl distances 3.83 Å and 5.02 Å is surprising, since the bridge position is less energetically favorable than fcc position at the single atom adsorption. To clarify the situation, we calculated the interaction energy between two chlorine adatoms on the relaxed and frozen Au(111) surfaces for different Cl-Cl distances. The calculations for the relaxed substrate shown a

noticeable attraction (-56 meV) at the distance 3.83 Å. In the case of the frozen substrate, no local minimum was found at this distance. However, more weak attraction (-22 meV) was detected at the distance 4.5 Å. These results indicate that there is an attractive interaction between Cl atoms adsorbed on Au(111) which gives rise to the short distance of 3.83 Å and this interaction is mainly mediated by the elastic substrate distortion. The same kind of calculations performed for Cl atoms adsorbed on Ag(111) and Cu(111) shown that, unlike Au(111)/Cl system, the electronic part of the interaction dominates and is responsible for the short fcc-hcp distances.

The formation of chlorine chains has been also tested with DFT. The third chlorine atom was placed at the 12-14 different positions around the pair of chlorine atoms in different fcc and hcp sites. The formation of compact islands was found to be is strongly unfavorable, whereas making the chain is the most energetically favorable scenario for a third atom.

Using a combination of scanning tunneling microscopy (STM) and temperature-programmed desorption (TPD) measurements and density functional theory (DFT) calculations, we have investigated the effect of surface OH groups on the adsorption and clustering of water on a monolayer FeO film grown on Pt(111). The FeO/Pt(111) oxide thin film has been well-studied with regard to both structure and chemical properties, is easy to prepare in situ, chemically rather inert and electrically conductive and therefore well-suited to fundamental studies by STM. By use of an atomic hydrogen source, we can also create OH groups with a controlled surface concentration (tunable between ~0 and 20%ML) by protonation of the FeO lattice oxygen [1].

STM characterization reveals that the 25 Å moiré structure of the FeO film has a strong impact on the spatial distribution of the OH groups, which prefer FCC-type domains of the surface, causing them to form distinct groups arranged in a hexagonal pattern. The templating effect of the moiré structure on the OH groups is transferred to adsorbed water; although on the bare FeO surface water adsorbs in extended 2D islands whose morphology is only weakly affected by the moiré pattern, the presence of OH causes the water to form small clusters at the FCC domains. TPD measurements of water adsorbed in various coverages and with varying OH concentrations reveal distinct adsorption states associated with binding at OH groups and clustering on the bare FeO surface, respectively. DFT simulations and high-resolution STM measurements suggest that the OH-associated state consists of an ice-like hexagonal structure stabilized by hydrogen bonding to the substrate. The calculations also suggest that the protons involved in hydrogen bonding may be

transferred from the surface to the adsorbed water forming stable, solvated hydronium species, consistent with our previous observations of water-mediated proton hopping at higher temperatures [2].

Accurate thickness assessment of metal oxides can be achieved through X-Ray Photoelectron Spectroscopy (XPS) measurements by means of the peak areas of the oxide and the underlying base metal. However, in some cases, determination of these areas has been a major challenge due to difficulties with background removal and line shape representation, the combination of which make up the curve fitting process required to precisely and accurately determine the peak areas. One source of complication arises when the peaks are asymmetrical. As is the case for all metals, the Fe 2p peak and its oxides present this asymmetry. By comparing the results of combinations of the available line shapes and background removal techniques, it was found that the challenges presented by asymmetry, and possibly the entire collection of curve-fitting issues, can be overcome with the use of the double-Lorentzian asymmetric line shape (which is an integrable form), and "Active Shirley" background removal, in which the background intensity is optimized during the peak-fitting process. This method, in comparison with traditional, provides more precise areas for the thickness determination, which has been confirmed with high-resolution transmission electron microscopy.

A better understanding of the interaction of iron-based materials with liquid metals (Na, Hg, In, Pb, Bi) has important applications in technological areas such as liquid-metal nuclear reactors or spallation sources. The wettability of iron by liquids metals is a fundamental quantity for the evolution of various phenomenons such as grain-boundary grooving, surface faceting, corrosion or liquid-metal embrittlement. This constitutes the driving force for this work as a better knowledge of the wettability for these systems will bring valuable informations of the behavior of iron based materials in liquid metals. This work describes the use of modern surface analysis techniques to analyse wetting experiments performed mainly on the Fe/In system.

We performed an experimental study of the wettability of polycrystalline iron surfaces by In, Pb, Bi using the sessile-drop experiment. After equilibration at 450°C under a protective atmosphere (Ar-5%H₂), these systems exhibit partial wettability with maximum wetting angle near 60° (the experiment is carried out such that iron is in its metallic state during the sessile-drop experiment). The wetting angle is found to increase in the following order: In < Pb < Bi. The surface energy of iron is lowered upon adsorption by these low melting point metals. At the triple line, the wetting angle selection requires the equilibrium between 3 energies: the solid-vapor surface energy, the solid-liquid surface energy and the liquid-vapor surface energy. The equilibrium leads to the well-known Young's equation:

$$\gamma_{sv} \cos \theta = \gamma_{sl} - \gamma_{lv}$$

Among the 3 surface energies, the solid-vapor one depends on the surface coverage of the adsorbate. While the experimental measurement of the wetting angle is

performed in-situ, one missing experimental quantity is the surface coverage reached on the solid-vapor side. High spatial resolution nano-Auger mapping of the main elements was achieved on polycrystalline substrate and reveals that the surface coverage of adsorbate depends on the orientation of the substrate. To simplify the analysis, iron monocrystal sheets were produced by the critical work hardening technique. Wetting experiments were performed and semi-quantitative XPS and Auger spectroscopy were used to measure at a global (400-50 μm probe size) and a local (12-20 nm probe size) scale the surface coverage using the Seah relation [1]. The detailed quantification procedure to Fe/In will be described. The preliminary results indicate that the coverage ranges from one to two monolayers, in line with studies on other systems [2]. The use of such measurement in models of the triple line will be outlined, particularly how one can hope to obtain a thorough description of wettability by combining experiments with density functional theory.

Within the framework of metal-organic coordination networks, we have studied two different systems on the Au(111) surface (Fig.1). The first one is obtained by evaporation of F4TCNQ ($C_{12}F_4N_4$) molecules onto the metal surface, and the second one consists of TCNQ ($C_{12}H_4N_4$) molecules and co-deposited Mn atoms. In both cases well-ordered quasi-rectangular superstructures are formed. These systems are characterized by scanning tunneling microscopy and dI/dV spectroscopy, combined with density functional theory (DFT) calculations to interpret the observations. F4TCNQ and TCNQ are strong electron acceptors and have been shown to be efficient in controlling the electron charge transfer at the metal-organic interface [1]. The metal centers play an active role in the formation of the two-dimensional arrays by favouring particular coordination numbers, being crucial in the determination of particular stoichiometry, charge transfer and magnetic moment. Additional coordination with transition metal atoms [2], like Mn, that have magnetic moment, is expected to permit the localization of spins in the 2D metal-organic network and, therefore, represent an interesting challenge for the design and fabrication of nano-scale devices.

In this work [3], we find that native Au ad-atoms are segregated from the pristine Au surface at room temperature, and are two-fold coordinated with F4TCNQ. However,

in the Mn-TCNQ case the Mn ad-atom is fourfold coordinated to the TCNQ ligands. In line with this, our DFT calculations show significant differences in the electronic structure close to the Fermi level as a result of the differences in type of bond and degree of charge transfer, this latter being higher from Mn to the TCNQ molecule than from Au-adatoms to F4TCNQ. That result is also in agreement with dI/dV point spectra observations. Finally, we have found a different level of mixing (or hybridization) between Au surface states (SS) and the lowest unoccupied molecular orbital (LUMO) in each system, being higher for Mn-TCNQ/Au(111) as compared with Au-F4TCNQ/Au(111).

Concerning to magnetic moment of Mn atoms in the self-assembled monolayer, we have found almost no variations ($4.6 \mu_B$) from its atomic value and a weak AFM coupling between Mn centers.

The epitaxial graphene formed on silicon carbide substrate is obtained by the annealing of the substrate at temperatures up to 1200°C. On the silicon terminated face of the hexagonal SiC(0001), it is formed a graphene layer partially covalently bonded to the substrate called buffer layer (BL) above which the actual graphene layer which shows the expected linear dispersion is formed. Epitaxial Graphene (EG) exhibits n type doping which is induced by the substrate. Inspired by the works of I. Gierz et. al who proposed a simple way to shift Fermi level and induce p type doping by deposition of gold atoms on top of graphene [1], we have performed detailed Scanning Tunneling Microscopy studies of the deposition of gold atoms under ultra_high vacuum conditions and revealed that gold atoms can intercalate between the buffer layer and monolayer graphene in different forms depending on the specific preparation procedure. An inhomogeneous intercalation of gold atoms (DP) or continuous atomic thin film (FP) was first observed [2] then more exotic forms of intercalation such as stripes (SP) as shown in figure below, were also recently observed. Using Fourier transform scanning tunnelling spectroscopy [3], confirmed by Angle-resolved photoemission spectroscopy measurements [4], we have shown that the band structure of the upper monolayer graphene is modified by the inhomogeneous intercalation. Despite the intercalation process, the relativistic character of the quasiparticles is preserved and moreover showed a higher Fermi velocity than that for pristine graphene. The band structure is modified around the Van Hove singularity which shows a large extension [4]. With the help of periodic DFT calculations we discussed the position of the intercalated gold atoms between the ML and BL graphene (or under the BL) and showed the expected STM images and the DOS modifications.

High energy surface X-ray diffraction for in situ surface structure determination - A new view of reciprocal space

T13 Surface Science

#SS-3-Or-7

J. Gustafson ¹, M. Shipilin ¹, C. Zhang ¹, A. Stierle ², U. Hejral ², U. Ruett ², O. Gutowski ², P.A. Carlsson ³, M. Skoglundh ³, E. Lundgren ¹.

¹Lund University - Lund (Sweden), ²Deutsches Elektronen-Synchrotron (DESY) - Hamburg (Germany), ³Chalmers University of Technology - Gothenburgh (Sweden).

In recent years, the aim of bridging the gap towards industrial catalysis has driven surface scientists to develop in situ methods that are able to characterize surfaces in realistic gas pressures during a catalytic reaction. Examples of implemented methods are infrared spectroscopy, scanning tunneling microscopy, high pressure X-ray photoelectron spectroscopy and surface X-ray diffraction. All of these methods have their advantages as well as disadvantages.

Surface X-ray diffraction (SXRD) is a very powerful tool for structure determination, with capability to do detailed quantitative analysis. Since the X-rays interact weakly with gas molecules, it is not affected by a high pressure sample environment and function just as well in realistic reaction gas mixtures. The disadvantage is that the result is given in reciprocal space, which for many is a bit difficult to grasp, especially since one usually only measures a very small part of reciprocal space at the scans the reciprocal space line by line. To produce a two-dimensional map of a certain part of reciprocal space is very time consuming and to map out the three-dimensional space is not to think about. Hence one has to have a good idea about what to look for, and it is very easy to miss an unknown structure. Similarly, producing a proper quantitative data set (of a fairly well known structure) takes in the order of 10 hours.

By using a photon energy of 85 keV at beamline P07 at PETRA III at DESY in Hamburg, we have performed high energy surface X-ray diffraction (HESXRD), which gives a new view of reciprocal space and solves many of the problems. The high energy reduces the diffraction angles, such that a large part of reciprocal space can be caught on a two dimensional detector. By simply rotating the sample, we can then map out the three-dimensional reciprocal lattice in about 10 minutes for qualitative use or about 1-2 hours in order to get a complete data set for quantitative analysis. These data sets include the whole three-dimensional reciprocal space, and we do not risk missing important information just because we do not know where to measure. Furthermore, the measurements enable the presentation of reciprocal space and reciprocal lattices in a much more visual way, which in our view is significantly easier to grasp. Since we get more information into the detector simultaneously, one can also do better time resolved measurements following changes in surface structure for instance as a function of catalytic activity.

In this contribution we present a new view of reciprocal space enabled by HESXRD. We give an introduction to the method and differences to standard SXRD, and show how it can provide visual images of the reciprocal lattice. We also show how to use HESXRD for time resolved measurements of surface structure as a function of catalytic activity and an example of quantitative structure determination.

SS-4-Or-5

Non-contact atomic force microscopy characterization of a crystalline transition alumina surface

T13 Surface Science

#SS-4-Or-5

T. Jensen, K. Meinander, F. Besenbacher, J. Lauritsen.

Aarhus University - Aarhus (Denmark).

Heterogeneous catalysis plays a crucial role in the society today, both as the means for environmental protection and as the backbone technology for most of the chemical industries. The development of new catalysts is given a very high priority since they facilitate a much better utilization of our scarce energy reserves and it can drive the concept of waste-free 'green' chemistry and the development of a sustainable energy sector.

Metal oxides like Al_2O_3 play major roles in heterogeneous catalysis as supports for catalytically active nanoclusters because of their excellent mechanical and thermal stability. Of all the transitional aluminas, $\gamma\text{-Al}_2\text{O}_3$ is the most important in catalysis, but so far surface science studies have been unable to address the surface structure of this insulating material in detail. A better understanding of the surface structure of support materials seems to be a prerequisite for the synthesis of more sintering stable catalysts and the realization of nanocatalysts implementing catalyst particles with a tailored size and morphology.

Benefitting from a nearly perfect structural match between the (100) surface of MgAl_2O_4 and $\gamma\text{-Al}_2\text{O}_3$, we show that we can use $\text{MgAl}_2\text{O}_4(100)$ as a template to grow thermodynamically stable and crystalline alumina films with $\gamma\text{-Al}_2\text{O}_3$ -like properties. Previous atom-resolved nc-AFM studies have shown that the $\text{MgAl}_2\text{O}_4(100)$ surfaces terminates by an Al-O rich termination, which turns out to be ideal for the continuously grown alumina films [1]. Preliminary nc-AFM studies reveals a perfect crystalline film-like growth (see Fig. 1), where up to 4ML thick films of Al_2O_3 were prepared using e-beam evaporation of pure Al onto a $\text{MgAl}_2\text{O}_4(100)$ substrate followed by annealing at 1473 K in an oxygen atmosphere (1×10^{-7} mbar). Subsequent analysis of atom-resolved NC-AFM images reveals a structure with a

quadratic grid and a high concentration of atomic defects on Mg positions, which is suggesting a surface structure reflecting Al-terminated γ -Al₂O₃.

The stable γ -Al₂O₃(100) films make it possible to open up a whole new range of fundamental studies of the metal/support interaction for catalytic systems based on surfaces with real γ -Al₂O₃ properties. The synthesis of stable well-defined alumina films with transition alumina characteristics will allow us to address important catalytic properties such as acid-based properties, cluster adhesion strength and sintering scenarios for model systems of supported nanoclusters that incorporate the real oxide support structure.

First stages of 4H-SiC crystal growth: ab initio study

T13 Surface Science

#SS-15-Or-5

E. Wachowicz, A. Kiejna.

Institute of Experimental Physics, University of Wrocław - Wrocław (Poland).

The wide band-gap semiconductor silicon carbide has attracted a great interest during the past decades because of number of properties which make it very attractive for many applications in electronic devices. For electronic applications purposes hexagonal 4H-SiC is the preferred polytype. One of the main problems in the development of the SiC-based electronics is still poor quality of the SiC crystals. Therefore, it is necessary to understand the interaction of basic building bricks like Si, C, Si₂C and SiC₂ with the surface. Since hexagonal SiC crystals grow along <0001> direction the interaction of Si, C and Si₂C interaction with Si- and C-terminated {0001} surfaces is examined within DFT framework. The most favourable adsorption sites are identified. Qualitative *ab initio* molecular dynamic simulations show that molecules bind to both examined surfaces without dissociation. It is confirmed by quantitative DFT studies showing that there is no barrier for the molecule adsorption. Moreover, a possible mechanism of Si₂C on-surface dissociation is examined (Figure 1). Our research show that dissociation on C-terminated surface is favourable energetically although there are two barriers to overcome. On the other hand, Si₂C dissociation on Si-terminated substrate is not favorable energetically.

Figure 1: Adsorption energy E_{ads} changes during Si₂C molecule dissociation on Si- and C-terminated surfaces 4H-SiC{0001}. x indicates the coordinate of the Si atom withdrawn from the molecule.

Cl-Fe-porphyrins and Cl-Mn-porphyrins monolayers adsorbed on Co and Ni films show a ferromagnetic coupling with the magnetization of the substrates [1-4] while, apparently, there is no evidence for magnetization of the second metallo-porphyrin layer [3]. Moreover, according to DFT calculations [1,4,5], the balance between ferromagnetic vs antiferromagnetic behaviors strongly depends on the presence of Cl attached to Fe and Mn ions: if Cl is desorbed from the molecules, the monolayers behaves as ferromagnetic, while the presence of Cl makes the antiferromagnetic behavior more stable.

Here we analyze the influence of the magnetization at room temperature on the second layer of metallo-TPP by preparing in-situ in ultra high vacuum monolayer (ML) of metalated Mn-TPP (obtained by evaporation of Mn atoms on H₂-TPP) deposited on 1 ML of metalated Fe-TPP/Fe(110)/Cu(110) [6]. For this second adsorbed metalated Mn-TPP layer we will study the magnetic properties using NEXAFS and XMCD measurements, in combination with theoretical calculations of the electronic structure. We will demonstrate that the easy axis of magnetization is reversed in the second layer made of Mn-TPP from the in plane Fe magnetization of the first metalated Fe-TPP layer deposited on Fe(110)/Cu(110). We also verified the magnetic behavior of 1 ML of Cl-Mn-TPP deposited on Fe(110)/Cu(110). Surprisingly, contrary to the behavior of Cl-Mn-TPP deposited on Co and Ni films,

also in this case the coupling is antiferromagnetic. The presence of Cl attached to the Mn ions is confirmed by XPS and STM.

Molecular self-assembly is a well-known strategy for fabrication of devices and systems in the size range of ~0.1-100 nm: organic molecules deposited on surface self-organize into well-defined structures. The process occurs without any external source and is driven by a multitude of atomistic phenomena which determine the shape and the physical properties of these structures[1]. In this sense the ability to control the formation of non-covalent bonds is the key ingredient for the fabrication of supramolecular nanostructures. Recently much effort is being invested in transforming these weakly-bonded supramolecular nanostructures into more robust, covalently linked ones, and the field of organic chemistry on surfaces is starting to develop. One way to create a covalent bond between two molecular subunits is represented by the “click” reactions, in which alkyne groups are made to react with azide-containing molecules (see scheme 1). In bulk the reaction is well studied and use Cu(II) salts as catalyst[2].

We explored this reaction on different metal surfaces using the surface itself like catalyst, thereby eliminating external catalysts. In this study we have characterized each reactant molecule and the final product of the reaction with STM and XPS that give us a complete characterization of the physical-chemical process. Moreover we studied the role of various noble metal surfaces (Au, Ag, and Cu) in promoting or hindering the reaction, comparing their efficiency. In figure 1 we show STM images of the final products of the reaction on Au(111) surface. The potential applications of this bottom-up approach are various. In particular, we will try to use this knowledge to control the formation of new donor-acceptor species directly at metal surfaces. This is a relevant topic for the realization of organic-based optoelectronic and photovoltaic devices

University Denis Diderot Paris 7 - Paris (France).

The bidimensional BiCu₂ alloy belongs to the family of surface alloys with potential applications in spintronics (1). We report the direct observation of a surface alloying and dealloying transition during the submonolayer growth of Bi on the Cu(111) surface. In-situ scanning tunneling microscopy (STM) analysis reveals that at low coverage, embedded Bi atoms are randomly distributed within the first Cu plane, example of a stress driven alloy formation (2). Near the ideal coverage of 1/3, an ordered BiCu₂ bidimensional alloy forms, the hard-hexagon-model explains this behavior (3). Between 1/3 and 1/2 monolayer a dealloying process takes place where the surface alloy coexists with a Bi overlayer supported on Cu(111). In order to understand the mechanisms behind this process driven by stress, the ordered alloy has been used as a template for subsequent Bi adsorption. An apparently explosively etched surface develops during deposition and thanks to STM pictures analysis, we propose that this growth mode is caused by subsurface Cu atoms diffusion or equivalently by a surfactant effect of Bi on BiCu₂. During annealing, the kinetically limited Ostwald ripening is surpassed and a complete phase separation occurs at local thermodynamic equilibrium.

Nitrates photolysis plays a key role in the chemistry of the polar boundary layer and of the lower troposphere over snow-covered areas (1). Using a combination of vibrational(2) and photoemission spectroscopies, we show that nitric acid is mostly dissociated upon its adsorption onto, and its dissolution in ice at temperatures as low as 45K. By irradiation in the environmentally relevant n- π^* transition, we also observe that the photolysis rates are significantly higher for surface-bound nitrates compared to that of dissolved nitrates. Surface-enhanced photolysis rates on ice may contribute to the intense photochemical NO_x fluxes observed to emanate from the sunlit snowpack upon polar sunrise.

KolibriSensor™, Tyto™ and Nanonis™ Control System: New Milestones in Scanning Probe Microscopy

T13 Surface Science

#SS/NST-1-Or-7

A. Thissen ¹, H. Torben ¹, D. Yuriy ¹, A. Pioda ².

¹SPECS Surface Nano Analysis GmbH - Berlin (Germany), ²SPECS Zurich GmbH - Zurich (Switzerland).

The KolibriSensor™ represents a new quartz sensor on the market that excels in its performance and its reliability. It is based on a symmetrical length extension resonator. The high resonance frequency of 1 MHz and the good signal-to-noise ratio allows for faster data acquisition in scanning microscopy and force spectroscopy. Oscillation amplitudes may be set below 20 pm. High stiffness prevents snap-in and the low noise floor continues to give a good frequency shift signal. The tip of the KolibriSensor™ has a separate contact, guaranteeing clean separation of the signals from the tunneling tip and from the quartz force sensor.

The new TYTO™ scan head is a milestone in the technology of Scanning Probe Microscopy. The modular design allows for various experimental configurations and for the usage of different sensors. A kinematic mount is used for both the sample and sensor. For the first time, this enables different sensors to access identical locations on a sample and to repeat the procedure after successive sample preparation steps. This opens up opportunities for new experiments and will advance the research of surfaces at the nanometer scale. Additional features of the Tyto scan head are: Four openings for in-situ evaporation, two specular ports for simultaneous optical experiments, and large front openings and windows situated on each side of the body and at the back for broad visual inspection of the sample and sensor. Various sample receptors can be installed in the Tyto scan head, with four electrical contacts to the sample. Optional extra features include a calibrated Cernox temperature sensor located directly under the sample plate, and a small heater to control the sample temperature to within 1 mK.

For controlling state-of-the-art SPM experiments a new generation of the leading NANONIS™ Control System is presented.

We investigate the chemisorption structure of CO molecules on the quasi-one-dimensional Cu(110)-(2×1)-O surface by low temperature scanning tunneling microscopy and density functional theory. Contrary to metal surfaces, where CO molecules adsorb in an upright geometry and interact through repulsive intermolecular interactions, we find the most stable CO adsorption structure to be at Cu atoms of substrate Cu-O- chains with the Cu-CO unit bent by ~45° in two equivalent structures at low coverages, and combining in the same structure into highly ordered rows perpendicular to the substrate chains in an approximately 8×1 full monolayer structure. First-principles calculations attribute the unprecedented chemisorption behavior of CO molecules to lifting of the host Cu atoms by 1Å from the surface Cu-O- chains, in order to optimize the bonding and reduce the repulsive interactions with the substrate. This structural distortion enables counter-paradigmatic, short-range intermolecular dipole-dipole attraction and orthogonal long-range surface-mediated repulsion leading to unusual self-assembly of CO molecules into nanograting structures.[1, 2]

Figure 1. (a) STM topographic images of CO monomers and dimers obtained by dosing 0.01ML of CO onto Cu(110)-O surface at 77K, and recorded at 77K and 4.5K (inset). The change in appearance of CO monomers and dimers at the two temperatures indicates that CO molecules interconvert between two equivalent tilted adsorption structures at 77K, whereas they are frozen in one of the two structures at 4K. The atomic resolution STM image also shows that CO is adsorbed on Cu atoms of -Cu-O- chains. (b) Ball and stick model showing the adsorption structure of CO monomer on -Cu-O- chains obtained by DFT calculation and the total energy surface for the pendular motion of the Cu-CO unit between the equivalent tilted forms. (c) The distribution of CO molecules around CO sampling monomers in the range of 12 lattice sites along the x- and y-directions, showing that the short range repulsion between two CO molecules is strictly along the same -Cu-O- chain, i.e. y direction. (d) STM topographic image showing the propensity for CO self-assembly into 1D linear clusters, indicating attractive interaction along the x-direction. The insert shows the STM image with enhanced contrast showing bias voltage independent, i.e. topographic origin, bright contrast indicative of the lifting of -Cu-O- chains that decays away from adsorbed CO molecules.

Water molecules form characteristic hydration structures having oscillatory density distributions at solid-liquid interfaces due to their geometrical asymmetry and/or various interfacial interactions. The hydration structures are often strongly related to a wide variety of physical and chemical phenomena including crystal growth/dissolution processes, of which atomic-scale mechanisms have not been fully understood.

Nowadays, three dimensional (3D) force mapping by frequency-modulation atomic force microscopy (FM-AFM), operating in liquid environment, allows us to directly visualize local interaction forces at the solid-liquid interface with subnanometer resolution. In fact, a 3D hydration structure at the interface between an electrolyte solution and a muscovite mica surface was revealed by this technique[1]. However, it has been mainly applied to the studies of the hydration structures on insoluble surfaces so far because the measurements of the rapidly changing surfaces in the growth/dissolution processes are difficult. In this study, the hydration structures on alkali halide crystal surfaces in aqueous solution were investigated by FM-AFM.

In this measurement, the concentration of electrolyte solution was kept nearly saturated such that the growth or dissolution rate of the crystal was lowered. It was actually self-controlled by the balance of the solution evaporation and the crystal dissolution in a non-sealed liquid cell. Figure 1(a) and (b) show a NaCl (001) cleaved surface model and the FM-AFM topographic image. A 2-dimensional (2D) frequency shift (Δf) map measured along the line X1-X2 in Fig. 1(b) indicates a molecular-scale hydration structure on the NaCl surface, as shown in Fig. 2(a). A frequency shift curve (Fig. 2(b)) taken along the line Z1-Z2 in 2(a) clearly exhibits an oscillatory feature of the hydration structure.

Magnesium oxide ultrathin films grown on metal substrates have received considerable attention because of their technological importance in many research fields, such as spintronics and heterogeneous catalysis [1, 2]. In particular, the artificial manipulation of the local structure at the oxide/metal interface is expected to play a pivotal role in controlling the catalytic activity of oxide films [3]. Interface engineering thus appears as a versatile way to tune the electronic properties of the oxide/metal system without altering the thickness or the structure of the oxide overlayer [4]. However, few experiments concerning the oxide/metal interface, especially involving interface defects, have been performed due to the practical difficulties related to buried systems. In this study, we present combined X-ray excited Auger electron diffraction experiments and multiple scattering calculations and we reveal a layer-resolved shift for the Mg KLL Auger transition in MgO ultrathin films (4-6 Å) on Ag(001). This resolution is further exploited to demonstrate the possibility to control Mg atom intercalation at the MgO/Ag(001) interface and extract the structural parameters of the films. The induced work function changes and the large interlayer relaxation at the metal/oxide interface are evidenced using UV photoelectron spectroscopy and show an excellent agreement with density functional theory calculations [5]. These results are of relevance for the understanding of the relationship between the structural and electronic properties at doped metal-oxide interfaces.

On a number of metal surfaces single layers of graphene may be grown with a high degree of perfection. The strength of the interaction between graphene and metal substrate may differ between strong chemisorption, e.g. on Ni(111), and weak physisorption, e.g. on Pt(111).

This provides an opportunity to experimentally address a number of intriguing questions: What is the effect of a substrate on the electronic structure of graphene and vice versa? How far does the metal substrate influence, e.g., the adsorption of single atoms or molecules on graphene? To what extent can graphene be used to decouple functional molecules from the metal substrate?

Here we study graphene on Ru(0001) and on Ir(111) as representatives for substrates with strong and weak interactions by low temperature scanning tunneling microscopy (STM) and density functional theory (DFT). We locally probe the chemical reactivity of the graphene C atoms by controllably contacting the graphene sheet with the tip of a cryogenic STM with atomic precision. Comparing with DFT results we find an increased reactivity of specific C atoms of graphene on Ru(0001).

On pristine and graphene-covered Ir(111) surfaces scanning tunneling spectroscopy reveals a hole-like surface resonance which is shifted below graphene, as confirmed by DFT calculations. Nanosized graphene islands confine the resonance and induce

characteristic standing wave patterns. These results invalidate previous reports of confined Dirac states.

The nature of dynamics of hydrogen and its isotopes on metal surfaces has attracted enormous theoretical and experimental attention in the past decades due to its crucial role in fundamental and important surface processes such as heterogeneous catalysis and hydrogen fuel cells.

In this presentation, we report Helium Spin-Echo (HeSE) measurements [1] of H₂ and D₂ dynamics on Ni(111) surface, which provides terrace, as opposed to over-step, diffusion measurements in equilibrium situations on atomic length scales and ultrafast time scales (pico-seconds) with unparalleled accuracy and reliability. Our experiments show a clear coverage-dependent crossover between classical overbarrier hopping and quantum tunnelling. The temperature dependence of the classical dynamics region follows Arrhenius behaviour with activation energy consistent with previous studies [2], however, the quantum diffusion rates are surprisingly high. We also present first HeSE momentum dependent dynamics data in deep tunnelling regime.

Additionally, we report first principle calculations of hydrogen atom energy states in the atom-surface potential (atomic band structures) based on density functional theory, and extend them to determine the rate of hydrogen diffusion with a formalism

that does not make the arbitrary distinction between 'overbarrier' and tunnelling states. We compare HeSE data on the diffusion of H and D on the Ni(111) surface with diffusion rates derived from H and D atom band structures evaluated from DFT calculations of 3D potential energy landscapes of H on Ni(111). We show that the activated diffusion rates predicted from our calculations are in remarkably good agreement with experimental results.

In metal-organic complexes, it is mainly the structure of the ligand that governs the adsorption on metal surfaces and thereby influences the magnetic interaction between the central ion and the conduction electrons. We use Scanning Tunneling Microscopy and Spectroscopy (STM/STS) at 4.5 K to show for an Fe-Porphyrin on Au(111), how the modification of the ligand structure alters the Kondo screening of the paramagnetic iron ion.

We anneal Fe(II)-Octaethylporphyrin (FeOEP) on Au(111) to temperatures of 470 K and above. This induces a step-wise electrocyclic ring closure of the ethyl groups and finally produces Fe-Tetrabenzoporphyrin (FeTBP). In STS, complex features at low energies around the Fermi level result from Kondo screening of the iron ion's spin. Changes in width and shape show the tuned interaction of the local spin with the conduction electrons depending on the actual chemical structure of the ligand. These results highlight the importance of chemical engineering for controlling the magnetism of single molecules on surfaces.

III-V semiconductors constitute a promising absorber material class for solar-driven water splitting due to their tunable electro-optical properties [1]. For this application, the water-semiconductor interface is of fundamental interest as it impacts corrosion processes as well as the charge-transfer efficiency to the electrolyte [2]. We present model-experiments employing water adsorption in UHV on differently prepared GaP(100) surfaces.

Metal-organic vapour phase epitaxy (MOVPE) is the method of choice for the preparation of III-V semiconductors and features specific surface reconstructions due to process gases such as hydrogen. We prepare atomically well-defined surfaces under in-situ control by reflection anisotropy spectroscopy (RAS) and transfer them contamination-free from the near-ambient pressure MOVPE environment to UHV [3]. After characterisation with LEED and ultraviolet/X-ray photoelectron spectroscopy, the surfaces are exposed to water vapour in UHV, again under RAS in-situ control [4], see Figure 1. The influence of water on the surface is subsequently monitored with photoelectron spectroscopy and LEED. Annealing of the water-covered surfaces in ultra-pure hydrogen or nitrogen atmosphere under RAS control allows further insight into the nature of the water-induced surface changes.

GaP(100) prepared in MOVPE features two surfaces, the Ga-rich, (2x4) mixed-dimer reconstruction and the MOVPE-unique (2x2)-2D-2H P-rich reconstruction [5]. Their identification with highly surface-sensitive RAS is well established and allows for in-situ monitoring of the surfaces on an atomic scale. Upon water exposure, the P-rich

surface is significantly more stable and can be restored more easily than the Ga-rich surface. Stability of the surfaces and their interaction with water will be discussed in the context of RA and PE spectra.

Ab initio calculations were performed using the methodology based on the quantum version of the Virtual Crystal Approximation (VCA) and the method of density functional theory with generalized gradient approximation (GGA) improved by Wu-Cohen (WC), which methodology is more consistent for calculating lattice constants, crystal structures, the surface energy of metals is improved to functional Perdew-Burke-Ernzerhof (PBE) GGA. The methodology was applied to the case of the binary alloy $\text{Fe}_{1-x}\text{Co}_x$ disordered. Our results show that the surface magnetic moment is higher than that the bulk to the same concentration x , which indicates that the $3d$ -band is narrower in the surface according to the surface magnetic moment is greater than the bulk value.

Our main intention is to study the interface and surface of metal uranium on different substrates. In this paper, uranium thin films were deposited on Si(111)-7×7 and W(110) surface at room temperature. The interface and surface with different annealing temperatures were studied by LT-STM, XPS, LEED and ARPES. STM results showed that the film was disordered as deposited, and ordered crystal structure appeared when annealed at 870 K, see Fig.1. The films were consisted of ordered films and disordered regions, for the ordered films triangle structures were seen very clearly. When annealed at 1200K, the surface of the films turned out to be the same as Si(111) -7×7 reconstruction. And also band structures for the films annealed at different temperatures were obtained and compared with the first-principles calculations, see Fig.2.

Also uranium films were deposited on W(110) substrate, the interaction of uranium with small amount of oxygen was studied. STM results showed that reconstructions were seen when annealed at 1000K and 1200K. Reconstruction structures were studied with STM and LEED, and also band structures were obtained by ARPES.

DFT studies of polaron dynamics for the (110) surface & bulk Ceria

T13 Surface Science

#SS-7-Or-6

A. Green ¹, J. Kullgren ², K. Hermansson ², C. Castleton ¹.

¹School of Science & Technology, Nottingham Trent University - Nottingham (United Kingdom), ²Department of Chemistry-Ångström, Uppsala University - Uppsala (Sweden).

CeO₂ (Ceria) is an intrinsic n-type fluorite structure semiconductor with numerous applications in gas sensing, car exhaust catalysis and solid oxide fuel cells. When an oxygen vacancy is created at the surface, two extra electrons are left behind from the (mainly) ionic bonding. Each electron enters a Ce4f band-like state and becomes localized in nature, forming a polaron with a single Ce³⁺ ion at the centre, and these can be arranged in various patterns around the vacancy itself [1]. The conductivity in Ceria is mixed ionic-electronic. The ionic conductivity is due to thermally activated hopping of oxygen vacancies (V_o²⁺), and the electronic conductivity is due to thermally activated hopping of the f-electron polarons through the material. These transport processes of both O vacancies and polarons occur through bulk Ceria, and also across the surfaces. Depending on the dopants added to Ceria and their relative concentrations, the conductivity can vary from mainly ionic to mainly electronic.

We present periodic DFT+U studies of the properties of polarons in bulk Ceria systems, and also across the (110) surface. Previous experimental work [2] for pure CeO₂ finds a polaron activation energy range for polaron hopping in single crystals of CeO_{2-x} of around 0.4–0.52 eV. Results presented are focused on polarons away from the influence of oxygen vacancies or any other defects. For bulk studies, we use the supercell approximation, adding a single localized electron [3]. We examine the critical dependence of results upon various details of calculation methods. A variety of functionals have been tested including LDA+U= 6eV and GGA+U=5 eV, where U is the added on-site coulomb repulsion Hubbard term, as well as popular hybrid functionals. Results include electron localization energy (E_{LOC} = the energy difference between a delocalized and localized f-electron), the level of bond distortion around the polaron site, radial charge distribution of the Ce4f electron and hopping barrier (fig.1).

The LDA+U=6eV functional has been used to study the polaron properties and dynamics at the (110) surface of Ceria. While the (111) surface is more stable, much of the interesting surface chemistry takes place on the (110) surface of Ceria. We will present results for electron localization at the surface and a description of thermally activated polaron hopping across and below the (110) surface. We discuss the various pathways implicated for polaron transport [4].

T. Fukuda ¹, I. Kishida ¹, K. Umezawa ².

¹Osaka City University - Osaka (Japan), ²Osaka City University - Sakai (Japan).

Metal silicides are the most studied materials and they have been widely utilized in microelectronics. Although thin silicide films have been extensively studied, most silicides were formed on silicon substrates and Si-rich phases were stabilized. By contrast, metal-rich phases formed by Si deposition onto metal substrates have not been drawn attention and scarcely studied so far. Here we address initial reaction of Si and ultrathin silicide film formation on Ni substrates including Ni(111), Ni(100), and Ni(110) surfaces under UHV by employing STM and LEED. We find several superstructures on these surfaces and their STM images were compared with first principles calculations.

Si reacts with Ni(111) substrate beyond 373 K, and when Si is deposited less than 1/3 ML two dimensional silicide with a $\sqrt{3}\times\sqrt{3}$ R30° structure ($\sqrt{3}\text{-}\alpha$) is stabilized. If an initial Si coverage exceeds 1/3 ML, a honeycomb structure with $\sqrt{3}\times\sqrt{3}$ R30° periodicity ($\sqrt{3}\text{-}\beta$) is formed at 673 K. The surface is very flat and a part of the honeycomb is filled with excess Si adatoms in the image. (Fig.1)

On the Ni(110) surface, deposited Si is embedded into the Ni substrate even at room temperature. For higher temperatures, STM images exhibit irregular defect-like structure with an atomic dimension. (Fig. 2) By increasing the substrate temperature during Si deposition, local order with c(2×2) and p(2×1) reconstructions is stabilized up to 0.5 ML and beyond 373 K. Further increasing Si deposition, unique zigzag islands elongates along [001] direction is seen as the second layer.

We constructed structure models for these structures and calculated their electronic band structures as well as total energy with first-principles local density approximation. STM images were also simulated and they were well reproduced by our models.

Fig. 1: STM images for (a) $\sqrt{3}$ - α and (b) $\sqrt{3}$ - β structures, respectively. Scanning areas 2.5 nm \times 2.5 nm. $\sqrt{3}\times\sqrt{3}$ R30 $^\circ$ unit cell is indicated as a solid parallelogram for each image.

Fig. 2: Si deposited Ni(110) surface at 473 K. Scanning area is 10 nm \times 10 nm.

The demonstration that high quality epitaxial oxides, such as SrTiO₃ (STO), VO₂ and Gd₂O₃ can be grown on silicon by Molecular Beam Epitaxy (MBE) was considered as a materials breakthrough and opened the door to a wide variety of new potential applications. Strontium titanate, SrTiO₃ (STO), is an incipient ferroelectric very promising for use in high storage capacity devices such as dynamic random access memory (DRAM) capacitors. It features high permittivity and absence of hysteresis loop even at low temperature. Its high dielectric constant (~300) provides an order of magnitude higher capacitance density than the conventional gate dielectrics, such as SiO₂ and Ta₂O₅. The lack of fatigue and ageing (paraelectricity) problems make this material advantageous with respect to other perovskite ferroelectrics for this particular application. Nevertheless, the grain boundaries of polycrystalline films tend to induce high leakage current and amorphous films have low dielectric constant. Heteroepitaxial growth of SrTiO₃ on Si is therefore of immense importance. Since the discovery of its incipient ferroelectricity and first polar soft mode behavior, SrTiO₃ has become one of the most studied materials. The optical properties of SrTiO₃ bulk material have been extensively analysed experimentally and theoretically. Concerning surface thin layer, we recently measured infrared which presents important differences with bulk material suggesting a different crystallographic structure. The interpretation is hampered by the complicated spectral behaviour which varies with epitaxial conditions and material properties. We have thus performed theoretical calculations using the ab initio periodic LCAO-B3LYP method developed in the CRYSTAL03 code. Relaxed atomic structures of each system (bulk and surface) are carefully analysed and vibrational spectra of SrTiO₃ bulk and thin layer are calculated at the Γ point by using the CRYSTAL program. The full set of frequencies is calculated and compared with the experimental ones. The present work permits to clarify some of the assignment and interpretation problems raised by experiment.

Formation of extended and well-ordered molecular networks on surfaces has received considerable attention recently, not least motivated by potential applications in areas such as functionalized surface coatings, sensors or heterogeneous catalysis. Here, we investigate adsorption of the structurally relatively simple molecule tetrahydroxybenzene (THB) on the Cu(111) surface under ultra-high vacuum conditions. High resolution scanning tunneling microscopy (STM) reveals formation of a close-packed molecular overlayer at room temperature. Annealing to 440 K, however, results in extended domains of a porous honeycomb network with a periodicity of 1.75 nm. This network formation is surprising given the molecular structure/symmetry and cannot be explained from a simple hydrogen bonding model. By combining STM with in-situ X-ray photoelectron spectroscopy (XPS) and Density Functional Theory (DFT) modeling, we elucidate factors leading to the observed network formation.

At low temperature (115 K) THB adsorbs essentially intact, but annealing to 370 K induces gradual dehydrogenation of the hydroxyl groups as shown by the O1s XPS signal and confirmed by control experiments using the chemically related compound dihydroxy benzoquinone (DHBQ) where two hydroxyl groups are replaced by carbonyls. The energetics of the dehydrogenation is modeled by DFT, pointing to the importance of the entropic contribution of desorbed hydrogen for the dehydrogenation to occur. Subtle contrast differences between close packed structures formed from THB and DHBQ are explained from DFT-based STM image

calculations. The ensuing network formation observed at 440K involves complete dehydrogenation of the THB hydroxyl groups. The observation of etch pits on the Cu(111) surface upon network formation as well as high-resolution STM images of the network nodes furthermore suggest that Cu adatoms liberated from the substrate participate in the network formation. Based on DFT calculations, we attribute the observed network to an array of Cu adatom trimers each coordinating to three fully dehydrogenated THB molecules, leading to a structure in agreement with STM observations regarding dimensions and symmetry. Overall, the study provides new insights into how on-surface synthesis of a highly reactive coordination ligand in combination with native metal ad-atoms can lead to formation of ordered molecule-metal coordination networks on surfaces.

Ar⁺ ion sputtering is the process which may lead to the creation of quasi 2D metallic layer on the surfaces of primarily insulating materials [1]. Such transformation from band insulator to metallic conductor was previously investigated in binary and ternary transition-metal oxides regarding the changes in oxygen stoichiometry and macroscopic surface conductivity [1,2]. However, the description of the nature of this transition in nanoscale is still insufficient, especially that such processes can be significantly complex and based on serious modifications of both electronic and crystallographic structure [3]. To overcome the existing gap we analyze the sputtering induced insulator to metal transformation in the surface layer of TiO₂ (110) single crystals with complementary surface sensitive techniques. The scanning probe microscopic techniques (atomic force microscopy (AFM), local conductivity atomic force microscopy (LC-AFM)) both with X-ray/UV photoelectron spectroscopy (XPS/UPS) allow us to understand the complexity of transformations that occur in electronic and crystallographic structure of the surface and in the local conductivity of the surface layer. The latter we analyzed both in- and out-of-plane, which gave the possibility to estimate the depth of the changes introduced to the crystal by the ion sputtering process. We track and analyze the changes that occur on the surface in consequence of selective removing of oxygen (during sputtering process). Our results provide evidence, that from the early beginning of the sputtering process, with increasing sputtering time we deal with a surface structure transformation, which leads to formation of new Ti-O phases. We connect the presence of quasi 2D conducting layer on the TiO₂ with changes of the valence of Ti ions during the formation of clearly visible grain-like surface structures. The phenomena that we analyzed in nanoscale can be essential not only for understanding the transport properties in the surface layer of the investigated material, but are also important for nanoelectronics, optics and catalysis. The changes of the resistivity of the material

described here are specifically related to the mechanisms of resistive switching processes in TiO_2 [3]. The presented investigations shed light on the important aspects of the origin of this phenomena (as in-plane heterogeneity) and can extend the knowledge about this material in the application for redox-based resistive random-access memory (ReRAM) [4].

The project was co-financed by the University of Lodz: Grant supporting young scientists.

Self-Assembled Monolayers of Polyhedral Dicarbadodecaborane Dithiols: A Computational Comparison of Bonding through Adatoms and Directly

T13 Surface Science

#SS-P1-04

J. Macháček.

Institute of Inorganic Chemistry AS CR, v. v. i. - Řež (Czech republic).

During the last decade, carborane thiols were introduced as building blocks for self-assembled monolayers on metal surfaces.[1][2][3][4] This work tries to contribute computationally to our understanding of the way the dicarbadodecaborane dithiolate moieties bind to a gold surface. DFT calculations of periodical systems are employed, using the projector-augmented waves method as implemented in the Abinit program.[5]. First, the bonding of the moieties to a flat (111) gold surface was explored, and the geometry of the highest possible coverage, that is one moiety over six surface gold atoms, was optimised. Such a coverage compares well to the experimentally found 6—7 surface atom per molecule on nano-particles and 7—8 on a thin film,[1] especially taking the inevitable imperfection of the samples into account. Then, by simple geometrical considerations, adatom patterns of various density were constructed, and the pattern containing 1 adatom per 7 surface atoms, best matching the experimental data, was selected to study. The geometry was optimised and the adsorption energies calculated for the moieties bound to the surface through the adatom, as well as in the same arrangement with the adatom removed. All the three geometry forms being consistent with the available experimental information, the calculated adsorption energies were used to select the most realistic one; the calculated stabilities of the monolayers formed by 9,12-dithiolate were compared with those of the layers build from 1,2-dithiolate moieties, and related to experimental observations.

The work was supported by the projects M200321201 of the AS CR, and P205100348 of the GACR. Computing and storage facilities provided by National Grid Infrastructure MetaCentrum under the programme LM2010005 were used.

Three dimensional topological insulator crystals consist of an insulating bulk enclosed by metallic surfaces, and detailed theoretical predictions about the surface state band topology and spin texture are available. While several topological insulator materials are meanwhile known, the existence and topology of these metallic states was only ever been probed for one particular surface orientation of a given material. For most topological insulators, such as $\text{Bi}_{1-x}\text{Sb}_x$ and Bi_2Se_3 , this surface is the closed-packed (111) surface and it supports one topologically guaranteed surface state Dirac cone. Here we experimentally realize a non closed-packed surface of a topological insulator, $\text{Bi}_{1-x}\text{Sb}_x(110)$, and probe the surface state topology by angle-resolved photoemission. As expected, this surface also supports metallic states but the change in surface orientation drastically modifies the band topology, leading to three Dirac cones instead of one, in excellent agreement with the theoretical predictions but in contrast to any other experimentally studied TI surface. The surface state band structure of $\text{Bi}_{1-x}\text{Sb}_x$ is calculated by a transfer-matrix technique and Green's function approach. The results confirm the surface state topology of $\text{Bi}_{1-x}\text{Sb}_x$, though the calculated band dispersion dilates from that of experimental results.

Our work illustrates the possibility to tailor the basic topological properties of the surface via its crystallographic direction. Here it introduces a valley degree of freedom not previously achieved for topological insulator systems.

Scanning tunnelling microscopy (STM) has emerged as a multidisciplinary tool in surface characterization. However, the interpretation of atomic scale image contrasts is not straightforward as the structure and chemistry of the probe tip influence the measurements to a large extent. In the present study on a model Cu(100)-O surface, we combine STM experiments with density-functional theory (DFT) and Non-Equilibrium Green's Function (NEGF) calculations [1] to investigate the role of tip apex chemistry in contrast formation mechanisms and understand how it may be exploited to achieve functional imaging.

At the outset, we systematically applied calculations to explore the STM imaging characteristics of Cu-O tips with different chemical terminations as a function of STM tip height and bias voltage. We were able to identify the imaging modes of tips terminating in a metal, non-metal and an intermediate adatom-contamination geometry and interpret them in terms of the contrasting tunnelling properties of Cu and O chemical species for a range of typical experimental parameters. Simulated imaging of a high-symmetry surface with asymmetric tip structures produced insight into asymmetric image features (fig. 1), STM image offsets and the imaging of surface domains on Cu(100)-O.

Based on these results, we conducted an extensive comparison of the computed

STM image database with the bank of experimental image. We found remarkable agreement, which validated the chosen tip models. Our simulations show that dynamic contamination of metallic tips on the Cu(100)-O surface is highly likely, leading to STM image offsets and varied asymmetry effects observed in experiments. O-terminated tips were particularly stable and frequently identified in experimental images: our simulations of their conducting properties show their imaging mode could be manipulated to selectively image metallic or non-metal surface species (fig. 1). By providing a comprehensive understanding of the STM contrast formation mechanisms, we suggest how controlled changes in tip apex chemistry could be employed to enhance the functionality of SPM probes, thus allowing in-depth, species-specific analysis of complex compounds.

CO oxidation at nanoporous gold: a combined TPD and XPS study

T13 Surface Science

#SS-P3-15

V. Zielasek, S. Röhe, L. Moskaleva, A. Schaefer, A. Wittstock, M. Bäumer.

University of Bremen, Institute of Applied and Physical Chemistry - Bremen (Germany).

More than 25 years ago, the discovery of high catalytic activity of oxide-supported nanosized gold particles for CO oxidation [1] came as a surprise because the noblest of all metals has, above all, a low affinity towards molecular oxygen. The debate on basic mechanisms of oxygen supply in gold-catalyzed gas-phase oxidation reactions received new impetus when, more recently, it turned out that neither any support nor finely dispersed gold particles are required: unsupported nanoporous gold (np-Au) which has a sponge-like morphology consisting of interconnected ligaments with diameters typically on the order of some ten nanometers, is also an efficient catalyst for CO oxidation, even at room temperature and below [2].

In order to gain insight into the mechanisms and surface species relevant for the catalytic performance of np-Au, we employed temperature-programmed desorption (TPD) and x-ray photoemission spectroscopy (XPS) in ultra-high vacuum directly at np-Au samples which were produced by leaching of silver from AgAu alloy and then activated for CO oxidation in a continuous-flow reactor. The experiments, supported by DFT calculations, indicate that the catalytic activity of np-Au for CO oxidation is based on a complex interplay of gold, silver, CO, and several oxygen species on and within the surface.

Residual silver is crucial for the ability of np-Au to dissociate and chemisorb molecular oxygen, resulting in a presumably atomic oxygen species (O_{act}) at the surface available for CO oxidation. The initial activation step at elevated temperatures in the reactor is required to render the np-Au surface capable of O_2 dissociation, probably by uncovering silver sites at the surface. Pronounced CO and CO_2 desorption at temperatures above 200 K observed after exposing np-Au to CO at 105 K indicates an additional, more stable type of CO binding sites on np-Au as

compared to pure gold. Only CO at these binding sites is oxidized by O_{act} . DFT calculations demonstrate that the strong binding of CO to np-Au cannot be explained by the presence of silver residues. It can be conceived, however, that it is induced by the formation of O-Au-CO complexes at low-coordinated surface sites. In fact, besides silver and O_{act} , we find various resident oxygen species on and within the np-Au surface. Strongly bound oxygen, possibly at subsurface sites and stemming from the leaching process, is present as a major species and not consumed by CO oxidation. We propose that the presence of these resident oxygen species stabilizes CO adsorption on np-Au, thereby being as crucial for the observed catalytic activity of np-Au as residual silver.

The tuning the electronic properties of low dimensional carbon materials is a current challenge for the development of carbon based technology. The doping by insertion of foreign atoms in the atomic lattice is a promising strategy to reach the control of the electronic structure of carbon materials. Nitrogen atoms are good candidates for chemical doping due to their suitable atomic radius and the additional electron that they contain as compared to carbon. They can adopt different local environments (graphitic-like, pyridinic-like) which can have various effects on the electronic structure [1].

Experimentally, the link between the local atomic structure and electronic properties can be achieved using scanning tunneling microscopy (STM) and spectroscopy (STS) by combining atomic scale imaging with local spectroscopy. Using STM/STS operating in ultra high vacuum and at low temperature, we have investigated nitrogen doped graphene grown on SiC(000-1) and nitrogen doped carbon nanotubes. In doped graphene, substitutional nitrogen has been found to be the most common configuration observed characterized by a specific triangular pattern. The spatial distribution of the local density of states in high resolution images indicates a charge transfer between the nitrogen atom and its neighboring carbon atoms. Local spectroscopy reveals that doping induces a shift of the Dirac energy as expected for n-doping together with the formation of an additional localized state in the valence band [2]. This finding is in agreement with Density Functional Theory (DFT) calculations. Beside the observation of single substitutional nitrogen atoms, various other atomic configurations have been observed revealing different electronic properties that will be discussed.

These findings can were compared with nitrogen doped carbon nanotubes where substitutional nitrogen as well as more complex structures was observed. The electronic signature of these doping sites in nanotubes will also be discussed.

Photoluminescence of TiO₂ - Effect of UV Light and Adsorbed Molecules on Surface Band Structure

T13 Surface Science

#SS-7-Or-13

A. Stevanovic, J.T. Yates, Jr..

University of Virginia - Charlottesville (United states).

The photoluminescence of powdered TiO₂ was found to be a sensitive indicator of the modification of the band structure¹⁻³. It was found that upon continuous UV irradiation (3.88 eV) under high vacuum conditions, the degree of upward band bending of a reduced n-type TiO₂ surface gradually diminishes decreasing the depth of the depletion region and leading to more positive surface photovoltage and enhancement of PL intensity³. Also, the alteration of the surface potential of TiO₂ by adsorbates (electron acceptor and electron donor molecules) results in a change of the PL intensity as a result of the band bending effects. Reversible band bending, due to the adsorption/desorption of the electron donor NH₃ and CO molecules, has been observed in measurements which combine PL with FTIR surface spectroscopy⁴. In addition, it was found that O₂ acts in two ways- as a reversibly adsorbed electron acceptor molecule and as an irreversibly adsorbed molecule which heals natural oxygen defects in the near surface region⁵⁻⁶.

STM studies of self-assembled C₆₀ and C₇₀ fullerenes on reconstructed SrTiO₃ (111) surfaces

T13 Surface Science

#SS-7-Or-8

S. Rahman, C. Wu, M.R. Castell.

University of Oxford - Oxford (United kingdom).

Organic nanomaterials such as fullerenes provide a versatile synthetic base for a variety of applications in (opto)electronics [1]. In order to further exploit their properties there is a desire to arrange these molecules into particular ordered patterns [2, 3]. This is achieved through molecular self-assembly and organisation on surfaces with specific surface periodicities and chemical reactivity that can act as templates. We have used the polar (111) surface of SrTiO₃ for this purpose because it shows a variety of surface reconstructions [4]. The work presented here focuses on the self-assembly of C₆₀ and C₇₀ on the 5×5, 6×6 and 4×4 reconstructions of SrTiO₃ (111). We show that fullerenes produce epitaxial hexagonal packed monolayer structures with ordered vacancies on the 5×5 and 4×4 reconstructions. However, disordered islands with random orientations are observed on the 6×6 reconstruction. This demonstrates that the 6×6 reconstruction interacts less strongly with the fullerenes than the other reconstructions and hence indicates that the 6×6 surface is less reactive.

Enantioselective separations on chiral metal surfaces

T13 Surface Science

#SS-12-Or-4

A. Gellman, Y. Yun.

Carnegie Mellon University - Pittsburgh (United states).

Although the bulk structure of pure metals are highly symmetric and achiral, various high Miller index surfaces of single crystal metals have chiral structures and have been shown to interact enantiospecifically with chiral adsorbates. [1] These surfaces have nanoscaled kinked step edges separating low Miller index terraces. These monoatomic step edges impart chirality to the overall structure of the surface and induce enantiospecific surface chemistry in chiral adsorbates. There are many demonstrations of this phenomenon originating in several laboratories around the world. One example is the enantiospecific adsorption of R-3-methylcyclohexanone on Cu(hkl)^{R&S} surfaces. [2,3] The adsorption energies of R-3-methylcyclohexanone adsorbed at R- and S-kinks are enantiospecific and the orientations of the molecule at the R and S kinks differ. Recently, we have observed highly enantioselective surface explosion reactions on naturally chiral Cu surfaces. It has been demonstrated that the decomposition of tartaric acid and aspartic acid on Cu surfaces occurs by an explosive mechanism with highly non-linear kinetics. The decomposition of tartaric acid on naturally chiral metals surfaces is more enantioselective than any previously observed process. The extremely high enantioselectivity arises from both the chirality of the substrate and the highly non-linear nature of the decomposition reaction kinetics. The naturally chiral Cu surfaces induce enantioselective separations of racemic mixtures of chiral species, thus enabling enantiomeric purification. The use of ¹³C isotopic labeling of the L-aspartic acid has made possible to use mass spectrometry to discriminate between the two enantiomers. Exposure of Cu(3,1,17)^{R&S} surfaces to a racemic mixture of L-¹³C-1,2-aspartic acid and D-aspartic acid results in establishment of an equilibrium with the surfaces that favors the adsorption of L-aspartic acid on Cu(3,1,17)^R and D-aspartic acid on Cu(3,1,17)^S. This represents the first definitive demonstration of an enantioselective separation on a naturally chiral metal surface. [4]

Laser-photoemission spectroscopy (LPES) at metal surface with low-energy photons of $\sim 5\text{eV}$ can probe vibrations at surfaces through the observation of photoelectrons inelastically scattered by the vibrations. The inelastic interaction produces a spectral component whose shape is a replica of the elastic one downshifted by the vibrational energy relative to the Fermi level. One of the examples is the observation of vibrational modes of adsorbed CO on Cu(001) [1]. These examples show the rich possibility of LPES as a novel probe of surface vibrations. However, the mechanism of the vibration excitation together with the selection rule is still an open question.

The simplest system in which the characteristic inelastic feature appears in LPES spectra is Cu(110) (Fig. 1 and ref. [2]). In order to gain the insight, we carried out the theoretical calculations for the electronic state and surface phonon modes on Cu(110) based on the density functional theory (DFT) and density functional perturbation theory (DFPT)[3]. From the calculation results of electronic and phonon band structure and electron-phonon coupling, we conclude that the source of

inelastic feature on Cu(110) is the photoelectron-phonon interaction at $\bar{\Gamma}$ point of surface Brillion zone. What is more, we found that the phonon modes which strongly

coupled to photoelectron at $\bar{\Gamma}$ point are distributed between subsurface and bulk region (Fig. 2). These results indicate the possibility of LPES as a novel technique to detect phonon at subsurface and deeper region.

Electrical conductance through surface states with large Rashba-type spin splitting

T13 Surface Science

#SS-15-Or-6

S. Hatta, T. Noma, H. Okuyama, T. Aruga.

Department of Chemistry, Kyoto University - Kyoto (Japan).

Strong spin-orbit interaction (SOI) and relevant spin splitting of valence bands have drawn much attention due to its potential application in spintronics. For the Rashba SOI, the coupling of spin polarization and electric field or charge current is one of the most important problems in association with the creation of spin-polarized current. In recent years, large spin splitting (>100 meV, typically) was discovered on several semiconductor surfaces including heavy elements and ascribed to the Rashba-type SOI enhanced by the coupling of atomic SOI and inversion asymmetry at surfaces. Although the Rashba type of spin splitting is also realized in an asymmetric potential well of a semiconductor heterostructure, typical splitting is only about ten meV at the Fermi level (E_F), which would be easily obscured by thermal excitations. From this point of view, surfaces with large spin splitting have an advantageous for studying the effect of Rashba SOI to electron transport properties if one can distinguish the contributions of a surface and a substrate to electrical conductance.

In this work, we performed four-point-probe conductivity measurements of Ge(111) covered with Pb and Bi. The Pb/Ge(111)- β -($\sqrt{3} \times \sqrt{3}$) $R30^\circ$ surface (called Pb- $\sqrt{3}$) has a metallic surface state[1]. The surface state displays a nearly parabolic dispersion relation with Rashba-type spin splitting of 200 meV at E_F . The Fermi surfaces are composed of dual closed Fermi surfaces with reversed in-plane spin polarization. On the other hand, the electronic structure of Bi/Ge(111)-($\sqrt{3} \times \sqrt{3}$) $R30^\circ$ (called Bi- $\sqrt{3}$) is insulating[2]. The temperature dependence of conductivity on Bi- $\sqrt{3}$ showed two drops at ~ 300 and ~ 50 K. This behavior is explained by the decrease of intrinsic carriers and electrons from the donor levels in the Ge substrate (n -type). As a result, we found that the conductivity through the substrate is quite small (<0.5 mS/ \square)

below 50 K. On the other hand, the conductivity of Pb- $\sqrt{3}$ continuously rose with decrease in temperature below 250 K and reached ~ 10 mS/ \square at 9 K. In the temperature range, the linear temperature dependence of resistivity was observed. Assuming that the metallic state is confined between the Pb and the topmost Ge layers, the volume conductivity of the Pb monolayer corresponds to $3 \mu\Omega \cdot \text{cm}$. Surprisingly, the conductivity is comparable to those of noble metals, indicating that the injection of spin-polarized current to the Rashba system is possible without conductivity mismatch.

Instituto Madrileño de Estudios Avanzados en Nanociencia (IMDEA-Nanociencia) - Madrid (Spain).

The TCNQ molecules are deposited on graphene/Ru(0001) at 300 K and imaged with STM at 4.6 K. The adsorption geometry and the electronic structure of isolated molecules have been calculated from first principles by using density functional theory (DFT) as implemented in the VASP code and accounts for the properties of graphene/Ru(0001)[1,2,3,4]. The lower part of the moiré constitutes a preferential adsorption site for strong acceptors and the topographic images show intramolecular resolution that changes with the bias voltage applied between tip and sample (Fig.1a).

The calculations for individual TCNQ molecules reveal indeed that graphene, which is n-doped from the interaction with the Ru substrate, transfers efficiently electrons to TCNQ, while the Ru substrate is essentially unaffected. The additional electron mainly goes into the LUMO of the neutral molecule, which splits into a Single Occupied Molecular Orbital (SOMO) and a Single Unoccupied Molecular Orbital (SUMO). dI/dV spectroscopy at the level of single molecule allows us to identify the maximum of the HOMO at -2.0 V and provides an unequivocal confirmation of the

existence of an occupied SOMO orbital around -0.8 V. Spatially-resolved dI/dV maps of the HOMO does not show a node in the central plane of the molecules, while both the SOMO and the SUMO are practically identical and display clearly the characteristic central node, indicating that they originate from the same, previously empty LUMO orbital.

The STS spectra measured on top of the TCNQ molecules reveal the existence of a sharp resonance centered at the Fermi level with a width at half maximum of 10 mV, which is absent in the graphene surface. As shown in Fig.1b,c, the Kondo resonance exhibits also a strong dependence of its lineshape on the STM tip location within the TCNQ molecules. Fig.1c shows dI/dV spectra measured on different locations of the TCNQ molecule and on graphene. A sharp peak at zero bias is observed when the STM tip is located on top of the cyano groups (spectra 2) or on top of the carbon atoms a both ends of the central ring connecting the cyano groups (spectra 4). When the tip is moved to the middle of the central ring (spectra 3) the intensity of the Kondo resonance decreases and simultaneously two side peaks appear at ± 45 meV attributed to an inelastic Kondo effect mediated by vibron-assisted tunneling.

In Keggin type phosphovanadomolybdate acids (HPAs), vanadium appeared to be the most crucial element for oxidative processes and the strong acidity of HPAs is known to be favourable to functionalization of alkanes [1]. However, the major drawback of this type of materials is their low surface area (< 10 m²/g). This disadvantage can be bypassed by supporting them on suitable materials with large surface area.

The mesoporous silicates such as MCM-41, HMS and SBA-15 are known to have large surface area and high pore volume with uniform mesopores and high thermal stability [2,3]. Among them, the most studied is MCM-41.

In this work, we selected SBA-15 mesoporous silicate, for its larger pore size and its better resistance to acidic media than MCM-41, as support. Thus, a series of Keggin-type heteropolyacids, H_{3+x}PMo_{12-x}V_xO₄₀.nH₂O where x = 0, 1, 2 or 3 were supported on SBA-15 with HPA loadings of 30 wt.% using the dry impregnation method. All systems were characterized by different techniques (elemental analysis, X-ray diffraction, transmission and diffuse reflectance (DR) FT-IR, Raman and X-ray photoelectron spectroscopies, nitrogen physisorption, thermal analysis (TG-DTA) and scanning electron microscopy (SEM)). The catalytic properties of supported HPAs were compared to those of bulk ones in the propene oxidation by molecular

oxygen at 350 °C.

The obtained results showed that the presence of HPAs modifies the textural properties of mesoporous SBA-15 material (decrease of surface area) without destroying its structure. The interaction support–heteropolyacid leads to the formation of $(\equiv\text{SiOH}_2^+)(\text{H}_2+\text{xPMo}_{12-\text{xVxO}_4}^-)$ surface species (Scheme 1) more stable than $\text{H}_3+\text{xPMo}_{12-\text{xVxO}_4}$ species. These surface species appear to be the active sites in the propene oxidation. The supported HPAs exhibit higher catalytic activity (ca. 21–31% of propene conversion) and favoured the formation of acrolein, acetaldehyde and acetic acid, compared to the bulk catalysts (< 5% of conversion) that lead only to the formation of COx. It is noted that the distribution of products seems to be independent on the vanadium number in the acid.

¹Synchrotron SOLEIL - Saint Aubin (France), ²INSP - Paris (France).

Semifluorinated alkanes ($C_nF_{2n+1}C_mH_{2m+1}$, FnHm for short) exhibit a lipophobic and an hydrophobic character inducing interesting properties[1]. Despite the lack of polar head group these molecules are able to form Langmuir monolayers ie. monomolecular thick layer at the air-water interface. Due to these antagonist characters the two parts (fluorinated and hydrogenated) tend to avoid each other. Using Grazing Incidence Small Angle X-ray Scattering (GISAXS - see figure 1), we demonstrated that these molecules on liquid surface self assemble to form an hexagonal array of nano-domains with a very large parameter (typ. 30 nm) [2]. This network is observed on water for non zero surface pressure for different hydrocarbon chain length (n=8, 10, m=14, 16, 18, 20)[3].

This structure is in agreement with the domain size observed by Atomic Force Microscopy (AFM) on the same kind of monolayers prepared on silicon substrate [4]. However, the reason of the stability of such domains remains unknown. On high-resolution AFM images, the shape of domains is revealed as faceted domains separated by a hump. Experimentally, macroscopic measurement combined with grazing incidence small (GISAXS) and wide (GIXD) angle x-ray scattering suggest that some molecule within the monolayer do not belong to the domains made of upright molecules. Looking more carefully to the GISAXS off specular (Q_{xy} - Q_z) intensity distribution of the diffraction peaks seems to confirm the presence around the upright molecules domains of a corona of lying molecules. Theoretical paper has predicted the possibility of such lying molecules on the surface of water. The presence of molecule in such state could explain the stability of the structure against coalescence of the domains upon compression of the monolayer.

Charging and Bond formation of Adsorbates on Ultrathin, Insulating Films Supported by a Metal Substrate : A DFT Study based on a Perfect Conductor Model

T13 Surface Science

#SS-17-Or-1

M. Persson, I. Scivetti.

University of Liverpool - Liverpool (United kingdom).

The ability to characterise and manipulate single atoms and molecules on ultrathin, insulating films by scanning probe techniques has opened up a new frontier in atomic scale science. A most interesting aspect of these systems is the decoupling of the electronic states of the adsorbates from the metal substrate, which still allows for characterisation and manipulation by tunnelling electrons.

The description of the electronic and geometric structure and the dynamics of these systems exhibiting multiple charge states is very challenging for theory [1]. Density functional theory calculations are in many cases prohibitive because of the size of these systems and the delocalization error in current exchange-correlation functionals. In this presentation, we present a new, simplified DFT scheme in which the metallic support is replaced by a perfect conductor. This scheme circumvents these problems and allows us to treat various charge states of adsorbates in a controllable way, together with a considerable reduction of the computational effort. In particular, we are able to carry out ab-initio molecular dynamics on an excited state potential energy surface. We will show some interesting applications of this scheme to different charge states of metal adatoms and the dynamics of reversible bond formation in a metallo-organic molecule [2,3].

Pure dephasing rate on image state of Cu(001) investigated by high-energy resolution two-photon photoemission

T13 Surface Science

#SS-P3-26

T. Nakazawa ¹, R. Arafune ², N. Takagi ¹, M. Kawai ¹.

¹The University of Tokyo - Kashiwa (Japan), ²National Institute for Materials Sciences - Tsukuba (Japan).

Electron dynamics in the photoexcited states are governed by inelastic scattering and elastic scattering processes. The contribution of the inelastic scattering to the electron lifetime is characterized by the decay rate, and the latter the so-called pure dephasing rate. For complete understanding of the electron dynamics, both of them are needed. As a model system, image potential induced states are intensively studied by two-photon photoemission (2PPE) spectroscopy[1]. Time-resolved 2PPE can evaluate the decay rate and related technique (quantum beat spectroscopy) can evaluate the pure dephasing rate. However, quantum beat spectroscopy is applicable for limited cases. More general way to determine the dephasing rate is linewidth analysis. Since quasielastic scattering alters the relative phase of the wave packets, the decoherence appears as spectral broadening. Spectral linewidth (defined by the full width at half maximum: FWHM) in 2PPE spectra is described as $\Gamma_{\text{total}} = \Gamma_{\text{decay rate}} + 2\Gamma_{\text{dephasing rate}}$ [2]. In conventional 2PPE, ultrashort pulse (20-200 fs) lasers are used for the excitation source. Since contribution of quasielastic scattering is small as compared to the inelastic scattering and $\Gamma_{\text{inelastic}}$ is comparable with the linewidth of the fs laser pulse, it is difficult to discuss the linewidth from 2PPE spectra excited by the fs laser.

To investigate the effect of the pure dephasing on the electron lifetime in the excited states, we have improved energy-resolution of 2PPE by using relatively narrower band pulse ($\Delta E \sim 1$ meV, $\Delta t \sim 2$ ps) laser for the excitation. Figure 1 shows 2PPE spectrum of image potential states of the Cu(001) at normal emission. The energy resolution was set at better than 10 meV. Higher series of image states are well separated up to $n=4$. Femtosecond 2PPE cannot resolve these peaks spectroscopically. From analytical approach, we reveals that the broad peak near the vacuum level consists of $n=5, 6,$ and 7 at least. From these high-resolution results, we have succeeded in measuring the pure dephasing rate for the $n=1$ image states.

Manipulating Magnetism of the Co Ultrathin Films on Epitaxial Graphene by Au Decoration

T13 Surface Science

#NST/SS-3-Or-4

C. Kuo, Y.J. Chan, S.Y. Wu, D.H. Wei.

National Sun Yat-sen University - Kaohsiung (Taiwan, republic of china).

The issue on tailoring magnetism of transition metals on graphene become of the significance in the past years. The perfect spin filtering effect at the interface between magnetic ultrathin film and graphene layers was theoretically predicted. It can be used to optimize the spin injection for the development of spintronics devices. Nevertheless, the suppression of ferromagnetism of the magnetic ultrathin film grown on graphite or graphene surface and lower than expected MR ratio was observed in experiments. These imply that the magnetic films prepared on graphene might not be ideal as expectation, and suppress the spin polarization at the interface. Here we inserted a submonolayer Au on the epitaxial graphene before the film preparation. Integration of experiments were conducted, including X-ray magnetic circular dichroism, X-ray absorption spectroscopy, scanning tunneling microscopy, low energy electron diffraction, and Auger electron spectroscopy, to measure the magnetism, thin films structures and the hybridization of the magnetic thin film and graphene. An enhanced ferromagnetism of Co ultrathin film were observed on the Au/graphene surface as compared to the Co/graphene system. A further discussion will also be addressed in this contribution.

Investigation of wetting phenomena at the limit of small-scale surface topography in the sub-nanometer regime

T13 Surface Science

#SS-6-Or-4

J. Knauf ¹, L. Reddemann ², A. Böker ³, K. Reihls ⁴.

¹Advanced Molecular Films GmbH, DWI an der RWTH Aachen e.V., Lehrstuhl für Makromolekulare Materialien und Oberflächen, RWTH Aachen University - Köln (Germany), ²Advanced Molecular Films GmbH, Universität zu Köln, II. Physikalisches Institut - Köln (Germany), ³DWI an der RWTH Aachen e.V., Lehrstuhl für Makromolekulare Materialien und Oberflächen, RWTH Aachen University - Aachen (Germany), ⁴Advanced Molecular Films GmbH - Köln (Germany).

Surfaces with defined wetting properties allow for a broad variety of interesting applications in various technical areas. Surface design and manufacture, however, require detailed understanding of fundamental aspects of wetting at the solid/liquid interface which can be strongly affected by topographic features at the surface. We are primarily interested in such effects at the limit of small-scale surface topography with structures in the sub-nanometer range. Such topography shows wetting effects that behave much differently compared to surface topography at longer length-scales.

As a model system we prepare surfaces of hydrophobic monolayers from binary mixtures of *1H,1H,2H,2H*-perfluoroalkyl thiols of different chain lengths on gold. Detailed characterization by static secondary ion mass spectrometry and ellipsometry confirm a binary monolayer of randomly mixed constituents. Owing to their stiff helical conformation such perfluoroalkyl chains create topographic features of well-characterized sub-nanometer dimensions. As a result, we obtain surface topographies of randomly distributed long and short chains of a defined height difference of 1.2 Å per CF₂ group and a next neighbor distance of 5.8 Å.

We present comprehensive investigations of wetting properties of such binary

monolayers of various molar fractions and chain length differences.

As a first example, a binary mixed monolayer from *1H,1H,2H,2H*-perfluorodecyl and *1H,1H,2H,2H*-perfluorododecyl thiols, thus differing by two CF_2 groups, increases the advancing water contact angle from 116.0° for either one of the single component monolayer by about 2° to 117.7° for a surface of an equimolar composition of the two constituents. Such increase is considerably less than expected from simple thermodynamic models. Wenzel's equation of wetting on rough surfaces predicts an advancing angle difference of 7° . Longer chain length differences thus yielding larger but still sub-nanometer-size features display correspondingly larger deviations from thermodynamic theory. We propose to explain these deviations by an apparent effective reduction of surface energy at short length scales, similar to results obtained from grazing-incidence X-ray scattering experiments [1]. Results of contact angles on various sub-nanometer size topographies will be presented and discussed, using probing liquids with different molecular structures and interactions.

¹Department of Advanced Materials Science, The University of Tokyo - Kashiwa (Japan), ²National Institute for Materials Science - Tsukuba (Japan).

In the conventional photoelectron spectroscopy, the photoelectron emitted from a surface have a spectrum that is the convolution of the density of states with the Fermi-Dirac distribution function. Hence the photoelectron spectra have been assumed to arise exclusively from the photoelectrons emitted elastically. However, if we consider the process of photoemission carefully, it becomes clear that the photoelectrons should excite vibrations at the surface and lose their energy when they go across it. Indeed, we found inelastic components arising from the excitation of the surface adsorbate vibrations and the substrate phonon in the laser photoelectron spectra [1-3]. The inelastic photoemission process produces a spectral component whose shape is a replica of the elastic component down-shifted by the vibration energy.

To develop a novel vibrational spectroscopic technique based on this inelastic phenomena and to gain a deeper understanding of the process, we have measured the inelastic photoemission spectra of the CO covered Cu(001) surface. For this purpose, we have constructed a laser-based photoelectron spectroscopy system equipped with a two-dimensional CCD camera detector. At normal emission ($\theta=0$), the photoelectron spectra excited by the low energy laser photon ($h\nu=4.80$ eV, $T=7.6$ K) contain the inelastic structures arising from the excitation of the frustrated translational (FT) and frustrated rotation (FR) mode. Since the energy shift for the FT mode (i.e. the vibrational energy) is low (~ 5 meV), we cannot measure its angle dependence. On the contrary, the inelastic component for the FR mode shows a very small but systematic dependence on the emission angle (~ -1 meV/7 degree). We conclude that this angle dependence of the inelastic component originates from the phonon dispersion of the FR mode. These results demonstrate that the angle resolved inelastic photoemission spectroscopy is a useful tool for measuring the dispersion relation of the low-energy vibrational mode.

Perylene di-imides are n-type compounds that recently demonstrated improved charge transport capabilities also in ambient conditions,[1] thus filling the historical gap with the p-type counterparts (e.g. pentacene). We present a detailed structural study on the adsorption of PTCDI on the TiO₂(110)-(1x1) surface revealing how its adsorption geometry is quite similar to the planar phases reported for the acenes, [2] notwithstanding a much different mechanism of growth.

PTCDI domain formation proceeds via island growth due to a significant interaction with the substrate, which pins the molecules into a unique structural arrangement that is commensurate with the substrate. By polarization dependent NEXAFS, we observe that molecules adsorb with their long axis parallel to the [001] direction, tilted by an angle of ~35°, and with negligible distortion of the carbon backbone. According to STM measurements, the molecular tilting allows to accommodate side-by-side one molecule atop each O_{br} row, yielding closely coupled molecular domains. From comparison with surface diffraction (He scattering and RHEED), domains are found to display a (1x5) symmetry, which molecular structure (see picture) is much more compact than the (2x6) monolayer phase recently reported for PTCDA.[3] The geometry we found is quite uncommon for perylenes, where the molecular orientation in the surface phases is rather driven by intermolecular H-bonding and leads to the renowned canted, domino and brickwall phases.[4] The interaction with the substrate is large enough to overcome the intermolecular head-head repulsion and to keep PTCDI straightly parallel to the O_{br} rows. The PTCDI orientation of the (1x5) phase is equivalent to that of pentacene in the monolayer phase [2], which is rather driven by an interplay between side-by-side intermolecular attraction and head-to-head intermolecular repulsion. The resulting close molecular packing (>1 molecule/nm²)

and π - π overlap is expected to enhance the intermolecular transport and to hamper the interdiffusion of atmospheric gases, thus improving the environmental stability of the organic film.[1]

Measurement of hydrogen permeability of stainless steel membrane by ESD ion mapping

T13 Surface Science

#SS-P1-15

A. Itakura ¹, M. Tosa ¹, Y. Murase ¹, S. Suzuki ², S. Takagi ², T. Gotoh ².

¹National Institute for Materials Science - Tsukuba (Japan), ²Toho university - Funabashi (Japan).

We are looking for a new clean energy in Japan such as wind, solar cells, biomass energy, geothermal energy, etc. Hydrogen fuel would be one of the biggest energy resources. Hydrogen in metals causes hydrogen embrittlement, which is the process for various metals to become brittle and crack ¹⁾. Presently this phenomenon is not completely understood and hydrogen detection, in particular, seems to be one of the most difficult aspects of the problem. In this study we try to investigate hydrogen behavior in metal from observation of two-dimensional hydrogen concentration on metal surface using electron stimulated desorption (ESD) method ²⁾. ESD is one of surface analysis technique used an excitation of adsorbed atoms or molecules by electrons. Using a scanning electron beam it is possible to map a two dimensional distribution of adsorbed atom. From the ESD mapping, we can know where the hydrogen comes from, e.g. surface of grains or grain boundaries. The experiment is performed with the good spatial resolution of a scanning electron microscope (SEM). A hydrogen reservoir with a sample and a heater, which is a halogen bulb, is set in the sample chamber of the SEM. Hydrogen gas is supplied to the reservoir up to about 1 atm. Preliminarily SUS304 steel is used as the sample, which thickness of 300 μ m and diameter of 18mm. The surface has ring shape lines made by lathe when the sample surface was flattened. The sample is welded to a miniature flange in order to suppress to leakage of hydrogen especially under sample heating. The sample can be heated up to 300 C. Hydrogen penetrates from the reservoir side surface of the sample membrane to the UHV side surface through a sample material. The penetrated hydrogen on the surface is detected as an ESD ion by a channel electron multiplier. From comparison of ESD image to the secondary electron image, the position of hydrogen is determined accurately. Since ion yield by the ESD is relative to a hydrogen concentration on the surface, information of diffusion coefficient is estimated from time dependence of ion yield under constant

temperature. In present work each ion image is taken for 400 s to one photograph. Image processing and ion counting are performed by Photoshop. In ESD image, we detected ring like patterns with the same pitch, 40 micro meters, with lathe made pattern. Consider the lathe moving when it made the pattern on surface, one side of the valley slope has a stress under higher pressure than other slope. Bright ring which is area of higher number of ESD ions were from the area. SUS304 steel is an alloy of Fe, Cr and Ni and formed austenite structure. Under the stress, martensite structure formed in austenite, and which has higher permeability of hydrogen compare with austenite area.

The structure and electronic properties of the contact layer between a π -conjugated organic semiconductor and a metal substrate are of great importance for the performances of opto-electronic devices based on organic thin films. Bonding strength to the substrate as well as the alignment of the electronic levels can be controlled by tuning the interface interaction [1]. Recent studies have shown that the nature of molecule-substrate bonding can influence the growth mode even in the sub-monolayer (ML) regime [2]. Very interestingly the nature of the interface bond does also influence the intra-molecular forces which can have a repulsive term in addition to the usual attractive van-der-Waals interaction [2,3].

The present paper focuses on the effects of molecular conformation on the electronic and supramolecular structures as a function of coverage of the first adsorbed ML. The system under investigation is 5,10,15,20-tetrakis(4 aminophenyl)porphyrin (TAPP) deposited in UHV on Au(111). Employing different techniques such as STM, LEED, UPS and combining the experimental results with theoretical analysis of the molecular orbitals (quantum calculation, Gaussian03 package), the growth of the overlayer was studied from sub-ML coverage to a thick film. The sub-ML coverage is characterized by a 2D gas-phase that condensates close to a ML completion. The features of the UPS spectra of the thick film (4 ML) were interpreted with the help of density of states (DOS) issued from quantum calculations. Two well separated features are present at low binding energy (BE) corresponding to HOMO and HOMO-1. Surprisingly, at sub-ML coverage only one feature is present at low BE. Such spectroscopic feature is related to a conformational change with respect to the relaxed geometry of the free molecule where the phenyl moieties are oriented at 62°

w.r.t. the molecular plane. Indeed, by constraining the four phenyls to lie parallel to the macrocycle plane, the calculated DOS reveals that the HOMO-1 has now shifted towards higher BE. At the completion of the first ML two features become clearly visible at low BE in the UPS spectrum. It is thus clear that a conformational change accompanies the transition to the condensed phase: the phenyls bend back in their relaxed orientation, most probably to accommodate further molecules within the contact layer thereby reducing the total energy. Finally, the behavior of the work function as a function of coverage was also addressed.

In conclusion, these results show that the initial molecular conformation, perturbed by the molecular-substrate interaction, recovers through inter-molecular interactions close to the full-monolayer coverage, allowing a higher stacking density.

Furthermore, UPS reveals that such behavior has important consequences on the value of the hole-injection barrier at the metal-molecule interface.

Graphene, as the first 2D crystalline material, carries many promises to be the next candidate which could result in a new technical revolution [1]. Literally, every day we see progress in using this new "wonder" material in many applications. A recent interest, amongst others, is in its stabilizing properties of ultra-thin magnetic layers [2]. However, during the preparation process, the sample must be heated to elevated temperatures in order to intercalate Co deposited on top of graphene/Ir surface. The interface between Co and Ir might also change as a result of preparation and induce synergistic effects in the overall behaviour of such a system. In this work, we focus on the Co/Ir interface, rather than the graphene/Co interface, and we study possible effects of elevated temperature on this interface. The studied layers differ in intercalation temperature, the thickness of deposited Co, and the presence of the graphene layer.

The samples are prepared in a UHV environment and studied by LEED, ARXPS and SMOKE techniques. Depending on the Co layer thickness (calibrated by XPS), we find two magnetic transitions. At Co coverage of 4 ML we observe a first transition between no magnetization and vertical magnetic anisotropy. At about 8 ML the layer switches between vertical and horizontal magnetic anisotropy. When the coverage is at the critical value of 4 ML and the layer is heated to 500 °C, the magnetic behavior changes as a result of heating and the magnetization curve corresponding to applied perpendicular magnetic field becomes wider. We hypothesize that this is due to the formation of surface alloy on Co/Ir interface. Angle resolved XPS measurements support this conclusion as the Co/Ir peak intensity ratio decreases when the sample is annealed and the decrease is dependent on the photoelectron exit angle. Two processes can cause this effect: surface roughening or Co/Ir surface alloy formation where Co intermixes with the first few monolayers of Ir substrate. This first option is ruled out by LEED measurement, where we observe clear sharpening of the

diffraction spots, indicating a sign of a smooth surface.

The same set of experiment was repeated with graphene/iridium surface. We observe the same behavior after the Co intercalation at 500 °C: surface alloy formation and changes in magnetic response. However, it is clear that graphene has some further effect on magnetization of the layer, the second transition between in-plane and out-of-plane magnetic anisotropy is less sharp, and both magnetic anisotropies are observed simultaneously within larger Co thicknesses.

Our results show that not only the presence of graphene determines the magnetic properties of ultra-thin Co layers but also that the Co/Ir interface plays an important role. A good knowledge of this interface effects is vital to properly understand the role of the graphene in such magnetic systems.

Electron Scattering Study of Dehydrogenation on Platinum Nanoparticles with Oxide Support

T13 Surface Science

#SS-18-Or-14

M. Van Spyk, K. Perrine, J.C. Hemminger.

University of California, Irvine - Irvine (United states).

Catalytic activity can be impacted by nanoparticle morphology and support type, and further studies are required to investigate the role of nanoparticle size in dehydrogenation mechanisms on oxide-supported nanoparticles. High resolution electron energy loss spectroscopy (HREELS) was used in this study to characterize the dehydrogenation of cyclic hydrocarbons on oxide-supported platinum nanoparticles. An Al_2O_3 film was chosen as a support because it is a good representation of the high surface area oxides used as catalyst supports in industry, and the flat surface enables investigation by electron inelastic scattering techniques. The alumina film was grown by oxidation of a NiAl(110) single crystal and platinum nanoparticles were deposited at cryogenic temperatures. Platinum deposition was monitored by the reduction in elastic peak intensity in the HREEL spectra relative to clean Al_2O_3 and also by Auger electron spectroscopy. Cyclohexane was used as a model hydrocarbon because the dehydrogenation on Pt(111) has been studied extensively by vibrational techniques and thus provides a good point of comparison for the nanoparticle studies. The HREELS spectra of cyclohexane on Pt(111) show a distinct low frequency peak at 2600 cm^{-1} which can be monitored to determine the temperature at which dehydrogenation begins.^{1,2} The HREELS annealing profile from an alumina film does not exhibit adsorption of cyclohexane or benzene at 170 K, or upon successive annealing. In contrast, the HREEL spectra from platinum nanoparticles on alumina exhibit cyclohexane adsorption at 170 K with the $\nu_{\text{C-H}}$ stretch energy loss peak observed at 2930 cm^{-1} . Interestingly, HREEL spectra from cyclohexane on platinum nanoparticles do not resemble spectra from cyclohexane on Pt(111). Specifically, the additional $\nu_{\text{C-H}}$ energy loss peak observed at 2600 cm^{-1} for cyclohexane adsorbed on Pt(111) is not seen in the case of platinum nanoparticles.^{1,2} Our spectra agree more closely with those for cyclohexane adsorbed to a Pt{100}(1×1) surface where a low frequency peak is not observed.³ In addition, the $\nu_{\text{C-H}}$ energy loss peak from cyclohexane on platinum nanoparticles does

not shift or decrease in intensity until annealed to room temperature. Our results indicate that the platinum nanoparticles may have predominantly Pt{100}(1×1) surfaces.

Titanium(IV) oxide (TiO₂), as a photoactive support for photocatalysts and sensitizers, has applications in catalysis and energy science. Utilizing ambient pressure synchrotron x-ray photoelectron and absorption spectroscopies, we explore the properties of TiO₂ thin films and ordered linear arrays of TiO₂ nanoparticles under in situ water vapor exposure and heating. Our nondestructive depth profiles (obtained by varying the photoelectron kinetic energy) of electronic and surface structures, combined with density-functional theory calculations, indicate an enhancement of the density of states (DOS) near the Fermi level due to surface Ti³⁺ and oxygen vacancies. Introducing water on the interface suppresses this DOS enhancement. Polarized x-ray absorption spectra (Ti L-edge and O K-edge spectra) provide information on the valence electron configuration of the Ti atom and its ligand crystal field environment, helping determine the phases of TiO₂ particles. Our in situ studies suggest that isolated TiO₂ nanoparticles may enhance solar absorption efficiency, and the TiO₂ band gap can be tuned reversibly under water exposure and heating.

Graphene nanoribbons and graphene nanoflakes (GNFs) have been proposed to exhibit such peculiar phenomena like localized edge states [1] or edge magnetism [2]. Recent attempts of measuring the properties of GNFs on Ir(111) have revealed detrimental edge bonding of graphene to the employed Ir substrate [3,4]. The aim of the present scanning tunneling microscopy (STM) study is the investigation of structural and electronic properties of epitaxial GNFs on the Au(111) surface to further reduce the graphene edge - substrate interaction.

In the present work the preparation of GNFs was performed by a two step process. At the first step, well-shaped GNFs of different sizes down to several nanometers are prepared on the Ir(111) substrate by the temperature programmed growth. At the second step, a thick Au layer was deposited on top of the sample followed by a high temperature annealing, yielding GNFs on a high-quality Au(111) surface. After the preparation two types of GNFs are observed: Whereas embedded GNFs are incorporated in the gold surface, we also observe quasi-freestanding GNFs floating on top of the Au(111) surface.

The structure of both types of GNFs is investigated by STM and shows a moiré contrast depending on the rotation of the flake with respect to the Au lattice, which is additionally modulated by the Au(111) herringbone reconstruction. The hexagonal moiré structure undergoes a switch of the ring-fcc to ring-hcp positions when crossing a Herringbone reconstruction line as a result of the switching of Au positions from fcc to hcp.

We show that quasi-freestanding flakes can be easily manipulated across terraces by the STM tip regardless the size by scanning with appropriate tip parameters.

Furthermore eminent quantum interference patterns at the flake edges are observed which propose very weak coupling of the graphene to the Au(111) surface.

Eley-Rideal reactions with N atoms

T13 Surface Science

#SS-18-Or-12

T. Zaharia, M.A. Gleeson, A.W. Kleyn.

FOM Institute DIFFER - Nieuwegein (Netherlands).

Almost all chemical reactions at surfaces proceed via the Langmuir-Hinshelwood mechanism. In environments where hyperthermal reactive atoms are present, also Eley-Rideal type reactions can be expected. However, these have not yet been observed for heavy atoms such as nitrogen. In this work we present results of a systematic study into the importance of such reactions and report the observations thereof.

For this purpose, the interactions of hyperthermal argon (average energy 7.8 eV) and nitrogen (N/N_2 ; average energies 3.9/4.8 eV, respectively) beams with a Ru (0001) single crystal are discussed. The high energy beams are produced in a cascaded arc plasma source [1] that is coupled to a UHV scattering chamber via a series of differentially pumped stages [2], as illustrated in Figure 1. The chamber has a rotatable mass spectrometer, allowing for detection of scattered particles in a wide angular range.

Studies on bare and adsorbate (N; O) covered surfaces are presented, that focus on the scattering and reaction dynamics of the incident species. Angular and energy distributions of the in-plane scattered species are analyzed and correlated to the incident beam intensity, allowing for direct cross-comparison between different incident species and different surfaces. The effect of adatoms on the physical and chemical nature of the surface and its interaction with incident species is discussed. At the beam energies being utilized the incident particles are sensitive to the atomic structure of the surface. Hence, the measured angular distributions provide information about the ordering of the surface and adsorbate-induced reconstructions.

Additionally, the highly reactive incident N atoms probe the chemical topography of the surface. Evidence for displacement and direct pick-up reactions induced by these

atoms is presented. The likelihood that this represents an Eley-Rideal type reaction in a non-hydrogenic system is discussed.

Coulomb blockade is an electronic phenomenon occurring in ultra-small capacitance such as metallic nanoparticles when their size is about 5nm. A tunnel junction can be fabricated if such a nanoparticle is placed above a conductive substrate with a thin insulating layer junction (thickness ca. 1.5nm). By placing an STM tip above this nanoparticle a **double barrier tunnel junction** (DBTJ) is built. The number of electrons simultaneously trapped in the nanoparticle is controlled by the STM bias (see Figure) and can be adjusted at a single electron level. This phenomenon raised many expectations a couple of years ago. But the lack of reproducibility stopped the enthusiasm of fabricating single electron transistors or single electron memories.

We present a method to prepare highly controlled samples based on an organic layer directly grafted on oxide-free silicon, where **gold nanoparticles** have been deposited through covalent bonding. The organic layer is made by hydrosilylation of alkene molecules of various lengths. Gold nanoparticles are prepared from colloidal solutions and grafted through the amine end of the organic layer [1].

Using STM and STS in UHV we report on the Coulomb blockade of these DBTJ at 25K [2]. We discuss the STS curves as a function of gold nanoparticle diameter, of organic layer thickness. We present an interpretation of our data with a model based on the orthodox theory. Finally the use of a silicon substrate and the fact that it is possible to modulate its doping offers a supplementary handle to adjust the Coulomb blockade effects through band bending at the silicon-organic interface.

It has been suggested that the phenomenon of Coulomb blockade could be achieved by placing a metallic nanoparticle between two tunnel junctions. While the Coulomb blockade has been well established theoretically and demonstrated on metal substrates¹, it is more challenging to observe on semiconductor surfaces due in part to the defective nature of the interfaces. We present an experimental study of two ultra small-capacitance normal tunnel junctions connected in series on silicon substrates. To achieve such a structure, we use an amine terminated self assembled monolayer (SAM) grafted on silicon (111) as insulator and linker to attach gold nanoparticles on the surface (fig). The SAM layer is grafted directly on oxide-free silicon through a Si-C bond formation using hydrosilylation reactions and yield to surfaces with low interface state densities^{2, 3}. Moreover, this SAM layer provides a long term passivation (weeks) of the interface that prevents oxidation of the substrate. The SAM quality is characterized using an extensive range of characterization techniques, including in-situ IR spectroscopy, spectroscopic ellipsometry, X-ray photoelectron spectroscopy (XPS) and Atomic force microscopy (AFM). The second capacitance is formed by the gap between the gold nanoparticle and the tip of the Scanning tunneling microscope/spectroscopy (STM/S). The current-voltage measurements are performed in ultra high vacuum. Several parameters are investigated: silicon doping level, SAM thickness, and size of the gold nanoparticles (AuNps) ranging from 1 to 15 nm. The junction is achieved by grafting synthesized AuNps. Data suggest that coulomb staircases are observed under different conditions⁴ (fig): lower temperature is a dominant parameters for a clear observation of the stairs. Steps width and height, which ranges from 100mV to 400mV and 5 to 30pA, respectively, shows a dependence on particle size and SAM thickness. These results are an important step toward future control for single electron transistor applications.

Adsorption of H₂ and O₂ on the stable and metastable Ir(100) surface studied with X-ray photoelectron spectroscopy

T13 Surface Science

#SS-P1-06

M. Arman ¹, K. Jan ¹, F. Pascal ², V. Abhilash ³, M. Florian ³, G. Johan ¹, S. Alexander ², H. Lutz ², L. Edvin ¹.

¹Division of Synchrotron Radiation Research, Lund University - Lund (Sweden), ²Lehrstuhl für Festkörperphysik, Universität Erlangen-Nürnberg - Erlangen (Germany), ³Center for Computational Materials Science, Vienna University of Technology - Vienna (Austria).

Hydrogen and oxygen adsorption structures on metastable Ir(100)-(1×1) and stable Ir(100)-(5×1) have been studied with scanning tunneling microscopy (STM), low energy electron diffraction (LEED), and density functional theory (DFT) in the past, and very detailed structural models exist today [1-3]. In contrast to the detailed structural information, the amount of spectroscopic data is very limited. Such spectroscopic data are important reference data for understanding chemical reactions on Ir(100) surfaces.

Here, we present the first detailed X-ray photoemission spectroscopy (XPS) study of the Ir 4f core level binding energies of the stable Ir(100)-(5×1) and meta stable Ir(100)-(1×1) surfaces. Further, we studied the effect of oxygen and hydrogen adsorption on these surfaces.

With XPS we determined the fingerprints of the stable and the metastable Ir(100) surfaces. In addition, we studied hydrogen and oxygen adsorption on both surfaces and observed the following characteristics:

i) For the clean Ir(100)-(1×1) surface we observed two separate components originating from bulk and surface atoms. The Ir 4f_{7/2} surface component is shifted by -0.75 eV with respect to the bulk Ir 4f_{7/2} component.

ii) For the stable Ir(100)-(5×1) surface we observed four different Ir 4f_{7/2} surface

components consistent with the structural model [3].

iii) H₂ adsorption onto the Ir(100)-(1×1) surface leads to Ir1 (Ir-H) and Ir2 (H-Ir-H) components shifted +0.16 eV and +0.31 eV with respect to the surface component.

iv) The presence of hydrogen on the Ir(100)-(5×1) surface lifts the reconstruction, and rows of Ir atoms are formed due to the higher density of atoms in the (5×1) structure. In agreement with this structural model we observe three different Ir 4f_{7/2} surface components.

v) After oxygen adsorption onto the Ir(100)-(5×1) surface we observed one Ir1 (Ir-O) component shifted -0.22 eV with respect to the bulk Ir 4f_{7/2} component. Simultaneously, the four Ir 4f_{7/2} surface components characteristic of the clean Ir(100)-(5×1) surface disappeared. Thus, our measurements very clearly show that the Ir(100)-(5×1) surface reconstruction is lifted upon oxygen adsorption consistent with the literature [4].

vi) Finally, the O 1s binding energy of oxygen adsorbed on Ir(100) reveals one component shifted -0.5 eV as compared to oxygen adsorbed in threefold hollow sites on Ir(111). This observation is fully consistent with O atoms in bridge sites as predicted by the Johnson model [4]; therefore, we have no indications for the model proposed by Sander et al. with bridge and fourfold adsorption sites [5].

Overall, the current status of our analysis demonstrates an excellent agreement between measured and DFT calculated core level shifts, which validates the existing structural models.

The interest in graphene has been growing in recent years since the discovery of a method for easy preparation of this material with high quality and bigger size. Due to interesting properties of graphene, conductivity and transparency together, this material is very attractive for a lot of industry applications. The Raman spectroscopy is usually used for graphene thickness determination [1] but for the study of material quality, the lateral resolution of the device is not sufficient. That is why the electron microscopy is very important for characterization of this material.

The preparation methods can be divided into two groups: exfoliation (preparation from existing graphite crystal) and direct grow on substrates by diverse deposition methods. In this work, the graphene has been prepared by the CVD and after removal of substrates, the various thickness flakes of this material has been put on a copper grid.

The experiments were performed in low voltage scanning transmission electron microscope Magellan 400, which is equipped by cathode lens (CL) system and a multichannel detector of transmitted electrons enabling to acquire the BF, DF and HAADF micrographs. The lower energy of impacted electron caused the higher contrast between graphene frakes of different thickness [2] and the observation by units of eV even enables to determine a single graphene layer.

Raman measurements were performed using the 514.5 nm line from an argon ion laser and analyzed using a Jobin Yvon T64000 spectrometer (triple monochromator, resolution ~ 0.5 cm⁻¹) equipped with a charge coupled device.

The ferroelectric domain structure of epitaxially polished NaNbO₃ crystal surfaces is studied by means of energy-filtered PEEM with 100nm lateral spatial resolution. Images were taken at low binding energies of a few eV using a standard Hg lamp as a photon source. In the PEEM images prominent stripe structures are visible, indicative of the complex domain structure in NaNbO₃ at room temperature (see Figure). Typically, the width of the stripes ranges from 1μm to 10μm. The absence of ordered domain structures over larger distances suggests a multiphase state with an antiferroelectric phase as the main phase but coexisting ferroelectric inclusions. Different annealing procedures before the experiment as well as the variation of the measuring temperature give further information on domain formation.

Figure: Example of a stripe structure seen in energy-filtered PEEM on a NaNbO₃ crystal at room temperature. The total length of the shown stripe is ~ 300μm.

Study of the substrate influence on the properties of physisorbed self-assembled molecular layers: Azabenzene 1,3,5-Triazine on graphite and graphene on metals

T13 Surface Science

#SS-13-Or-4

L. Rodrigo, P. Pou, A.J. Martínez-Galera, J.M. Gómez-Rodríguez, R. Pérez.

Universidad Autonoma de Madrid - Madrid (Spain).

The properties of molecular overlayers on inorganic substrates depend on a delicate balance between intermolecular and overlayer-substrate interactions [1]. Here we present a combined experimental and theoretical study of azabenzene 1,3,5-Triazine layers grown on both graphite and graphene on Pt(111). VT-STM experiments (see fig. 1) show large overlayer islands with Moiré structures on both substrates [2]. While in both cases the last layer is graphene, the atomic arrangements, the measured molecule diffusion barriers and the growing properties are different [2]. This system is, therefore, a perfect model for the study of the properties of physisorbed self-assembled molecular layers [1]. We have carried out ab initio DFT calculations (using VASP) trying with all the functionals available (LDA, PBE and hybrids) and different approaches for the van der Waals interactions [3] to fully characterize the intermolecular (H bonds and vdW) and molecule-substrate (vdW attraction and Pauli repulsion) interactions (see fig. 2). We have found that the graphene layer, even for these physisorbed molecules, modifies the intermolecular interactions respect to an isolate layer but not significant differences are found between graphite and graphene on Pt substrates. This exhaustive characterization shows the theoretical limitations to describe these weakly interacting systems even with state-of-the-art approaches.

One of the most useful tools in surface science is scanning tunnelling microscopy (STM), which can often achieve atomic precision images of surfaces. A great many studies of ionic semiconductors and oxides have relied upon STM to identify surface structures, native defects and impurities. Bright spots in images taken at negative tip bias map out filled valence band states, and hence generally indicate the location of anions. Likewise, bright spots in images taken at positive tip biases map out empty conduction band states, generally indicating the location of cations. Brighter spots or additional spots may then be expected to indicate the location of native adatoms, impurities or antisite defects, and missing spots to indicate the location of surface vacancies. However, we will present density functional theory (DFT) studies indicating that this is not always the case: some impurities look almost exactly like vacancies.

We will show filled and empty state theoretical STM images of vacancies, adsorbed hydrogen and substitutional impurities, and compare them to existing experimental images. We will show that in some cases vacancies and impurities are extremely hard to tell apart, with examples taken from the (110) surfaces of III-V semiconductors and from rare earth oxides. (See Fig.) In the case of many III-Vs, the situation is even more complex, as genuine cation vacancies are not always stable [1], but relax into anion vacancy-anion antisite pairs, leaving no “real” cation vacancies but even more defects that could be taken for anion vacancies in STM.

When preparing materials for applications or for use in surface science investigations, considerable effort goes into avoiding impurities. However, this is not fully possible, and some impurities will remain. Hydrogen, for example, is known to be “ubiquitous” [2], often involved in many stages of material growth and processing,

and extremely difficult to remove without elevated temperatures. We will review evidence that hydrogen and other impurities should indeed be present in the example materials we study, even when if not yet identified in STM images. We propose that this failure to detect hydrogen etc in existing STM studies is due to their similarity to vacancies. In most cases, we propose that both genuine vacancies and fake STM vacancies due to impurities should be present. However, in other cases, stability calculations suggest that the presence of genuine surface layer vacancies is unlikely, so that the apparent vacancies in STM images are probably due mainly to impurities.

Real-Time Characterization of Nucleation and Step-Edge Crossing during the Growth of the Fullerene C₆₀ using X-ray Scattering

T13 Surface Science

#SS-16-Or-3

S. Bommel¹, N. Kleppmann², C. Weber³, H. Spranger³, P. Schäfer³, J. Novak⁴, S.V. Roth¹, F. Schreiber⁴, S.H.L. Klapp², S. Kowarik³.

¹Deutsches Elektronen-Synchrotron (DESY) - Hamburg (Germany), ²Institut für Theoretische Physik, Technische Universität Berlin - Berlin (Germany), ³Institut für Physik, Humboldt-Universität zu Berlin - Berlin (Germany), ⁴Institut für Angewandte Physik, Universität Tübingen - Tübingen (Germany).

The popular organic semiconductor C₆₀ is a promising material for organic optoelectronic and photovoltaic devices. C₆₀ is widely used as a buffer layer in organic light emitting diodes (OLED) and as an acceptor in organic solar cells [1]. The structural order and morphology is crucial for the performance of most organic devices. By the unique combination of X-ray scattering methods and kinetic Monte-Carlo simulations (KMC) we are able to obtain deeper insight into the physical nucleation and growth processes, that is diffusion, lateral binding, and step-edge crossing occurring during the growth of the fullerene C₆₀ on the silicate mica.

In this work we characterize the surface morphology and structural order during the growth of C₆₀ with simultaneous real-time and in-situ measurements of x-ray diffuse scattering and anti-Bragg growth oscillations during molecular beam deposition of the molecules [2],[3]. The experiments were carried out at the MiNaXS beamline P03, PETRA III (DESY, Hamburg) [4]. For the characterization of the morphology during growth, the island density and island diameter were extracted from the 2D x-ray diffuse scattering pattern as a function of temperature, deposition rate and film thickness. We show that increasing temperature, decreasing deposition rate and a rising film thickness lead to smaller island density and larger island diameters, respectively. Within the growth of one monolayer we quantitatively describe for all temperatures and rates three different growth regimes occurring during 2D island

growth: the nucleation process is followed by the lateral growth of the islands, which again is followed by coalescence. For a more complete understanding not just the in-plane structure, but also the out-of-plane layering was investigated simultaneously by measuring anti-Bragg growth oscillations. High structural order and layer-by-layer growth during molecular beam deposition of multilayer films of C₆₀ on mica were found. Additionally we were able to extract the layer coverage and the thin film roughness from the anti-Bragg growth oscillations. From a comparison of the nucleation/ island formation process (island density and island diameter) and the growth oscillations (layer coverages) with kinetic Monte Carlo simulations, we are able to determine the diffusion energy (0.54eV), step-edge barrier (0.11 eV) and binding energy (0.13 eV). This model enables a detailed understanding and predictive simulation of C₆₀ growth.

Photoelectron Spectroscopy of Ammonium-based compounds

T13 Surface Science

#SS-6-In-1

A. Margarella ¹, K. Perrine ¹, M. Van Spyk ¹, B. Winter ², J. Hemminger ¹.

¹University of California, Irvine - Irvine, Ca (United states), ²Helmholtz-Zentrum Berlin für Materialien und Energie / Elektronenspeicherring BESSY II - Berlin (Germany).

Ammonium –based compounds are very prevalent in the atmosphere and environment. In particular, ammonia is found in atmospheric aerosols and is the primary basic compound that neutralizes acidic compounds. Ammonia (NH₃) can be protonated to ammonium (NH₄⁺), and in bulk aqueous solution, this equilibrium is well understood.

In this experimental study, the equilibrium between NH₄⁺ and NH₃ for different ammonium compounds is investigated using liquid-jet photoelectron spectroscopy. In this technique, photoelectron spectroscopy is performed on a thin, fast-flowing jet of solution. Utilizing synchrotron light, the surface of the sample is measured, independent from the bulk of the sample. In the N1s photoelectron spectrum, the binding energies of NH₄⁺ and NH₃ are separated well enough to deconvolute the spectrum into the different nitrogen containing species. The intensity of the NH₄⁺ and NH₃ species qualitatively follow the pH, i.e. at lower pH values (more acidic), there is more NH₄⁺. The integrated areas of the photoelectron peaks are used to provide relative ratios of the nitrogen species in solution. The NH₄⁺ / NH₃ ratio is presented as a function of bulk solution pH values for both the surface and bulk of the solution.

Effects of Coulomb interaction on one-dimensional Rashba chain

T13 Surface Science

#SS-10-Or-3

K. Makoshi, T. Mii, N. Shima.

University of Hyogo - Ako-Gun (Japan).

Both the time-reversal and spatial inversion symmetries lead to spin-degenerate electronic states. Rashba and Bychokov proposed a way to get spin-splitting electronic band by breaking the spatial inversion symmetry, so-called Rashba effect [1]. On the other hand, in one-dimensional atomic chains, on-site Coulomb interaction may cause anti-ferromagnetic order and spin-split bands, which sometimes is called Mott physics. Our main interest is crossover physics of these two phenomena.

We discuss effects of Coulomb interaction on one-dimensional Rashba chain based on an extended Hubbard model. The random phase approximation is introduced to analyze the model. The electronic hopping in conventional Hubbard model results in anti-ferromagnetic coupling. In contrast, Rashba type spin-orbit interaction gives rise to ferromagnetic coupling. These competing two couplings lead to several complex phenomena, including spin-splitting electronic states, magnetic order and spin-polarized current. We show “Coulomb energy”-“Rashba parameter” phase diagram in which paramagnetic, ferromagnetic and anti-ferromagnetic states are come out. A helical magnetic order also appears. These magnetic orders spontaneously break the time-reversal symmetry and may allow spin-polarized current.

Large π -conjugated organic molecules are attracting considerable interest due to their potential applications; however, their valence bands necessarily consist of closely spaced molecular states, which is often challenging for both theory and spectroscopic experiment. We propose a tomographic method that uses the energy and momentum dependence of photoemission from adsorbed molecules to deconvolute the valence band into individual orbitals. The method allows the purely experimental determination of molecule-projected densities of state, to be compared to theoretically calculated. The method further allows the direct observation of the effects of bonding on individual orbitals, and in so doing, provides stringent tests for the development of ab-initio electronic structure theory.

Photoemission experiments on differently ordered phases of perylene-tetracarboxylic-dianhydride (PTCDA) molecule on low index surfaces of silver single crystal were performed at BESSYII using a toroidal electron energy analyzer. The valence band of PTCDA was unambiguously disentangled into contributions from six molecular orbitals within a binding energy range of 4 eV, four of them within an energy range of only 0.4 eV [1]. For the PTCDA phases containing differently oriented molecules in the unit cell, the method grants an access to electronic properties of either molecule separately [2]. This enables detailed description of site- and orientation-specific bonding of organic molecules at metals.

Friction stir tool is a feature playing an important role in Friction Stir Welding (FSW) process. it is well known that the heat generation and the material flow are controlled by the pin geometry. Therefore, the pin can affect the soundness, microstructure and mechanical properties of the weld. The main problem in the FSW of AZ31 by using cylindrical pins is the formation of defects, which deteriorate the mechanical properties of the welds. From this, the possibility of obtaining sound welds with proper characteristics was studied by using a taper pin. For this purpose, microstructure and mechanical properties comparisons were made between the AZ31 joints welded by cylindrical and taper pins in same conditions. Microstructure examinations revealed that the microstructure of the joints welded by taper pin shows no defects (figures1 and 2) and consist of finer grain size (table1) compared to those of cylindrical ones. These findings could be discussed in terms of the generated frictional heat, and the amount of material flow. Moreover, using the taper pin resulted in increasing the micro-hardness, tensile strength, as well as elongation significantly (table2) due to different obtained microstructure characterizations.

Pin geometry	Grain size (μm)
Cylindrical	25.8
Taper	15.7

Table 2. Ultimate tensile strength (UTS), elongation and micro hardness of the joints

Pin Geometry	UTS, MPa	Elongation %	Microhardness, Hv
Cylindrical	162	1.58	60
Taper	223	2.80	73

Chemical imaging and Nano-ARPES at Synchrotron SOLEIL: A new concept in scanning photoelectron microscopy

T13 Surface Science

#SS-P3-39

S. Lorcy, J. Avila, I. Razado-Colambo, M.C. Asensio.

Synchrotron SOLEIL - Gif Sur Yvette (France).

In recent decades we have witnessed exponential advances in new nanotechnologies. Many nano-objects (acting as "building blocks units") have shown remarkable properties in rather different technology areas. However, they had been unexplored if new tools had not been available for viewing and scrutinizing them, at the nanometer scale. In particular, with the latest third generation synchrotron sources, the highly improved photon flux is essentially profited in the area of the X-ray microscopy.

In such a context, a new scanning photoelectron microscope beamline has been constructed at SOLEIL. Contrary to the PEEM microscopy, the imagery in SPEM is generated by a simple nanometric sweeping of the samples and a focusing of the incident light by a set of Fresnel zone plates. Our innovative project is attempting to extend the classical SPEM technique to the domain of low photon energies, for which the states of the valence band have a particularly high cross section. Hence, at the nanoscale, the detection of electronic states close to the Fermi level as well as their dispersions can be guaranteed by Nano angle resolved photoelectron spectroscopy (or Nano-ARPES), with high angular and energy precision. In essence, this new beamline of SOLEIL is fitting the existing emptiness between the atomic electronic information provided by the STM spectroscopy and the low-spatially resolved data supplied by classical ARPES and NEXAFS techniques.

In this presentation, the first results of the ANTARES microscopy beamline will be disclosed. This instrument, with a spatial resolution of several tens of nanometers, is able of carrying out the direct imaging of core levels, their chemical shifts and the band electronic structures of crystalline ordered materials. High precise Chemical images and valence band information of nano-objects like exfoliated grapheme, granular materials and Nanowires will be disclosed

Graphene has attracted enormous interest in recent years among the scientific, technological and industrial communities due to its very interesting and novel electronic properties. Graphene is a single sheet sp^2 -bonded carbons atoms, which are atomically organized in hexagons. The electronic band structure of graphene shows a linear dispersion at the Fermi energy at the K-point of the surface Brillouin zone instead of a parabolic relation, as it is observed in graphite. However, its electronic band structure is dependent on several factors among others, such as number of layers, symmetry of the lattice, stacking order and interlayer distance. For the 3D graphite, it is known to have the AB stacking structure and an interlayer distance of 3.35 Å, which have been verified in both experiment and theory. However in the case of 2D graphene, the stacking and interlayer spacing between layers are still unclear.

We have investigated the structural properties of bilayer graphene on SiC(0001) using a high-resolution photoemission and a combination of experimental and theoretical photoelectron diffraction. The stacking and interlayer distances between graphene layers have been determined with good accuracy. Photoelectron diffraction holograms of the graphene C1s component at two photon energies, 600 and 900 eV, have been measured from which azimuthal curves at specific polar angles have been deduced. Consequently, these sets of experimental data have been utilized in the multiple scattering photoelectron diffraction calculation program developed by Fritzsche to determine the stacking and interlayer distances between graphene layers. Based on the theoretical PED (photoelectron diffraction) calculation performed in this study, it was verified that the bilayer graphene on the Si-terminated SiC(0001) has an AB stacking structure. Furthermore, the distance between the C

buffer layer and the first graphene layer is found to be 3.30 Å and an interlayer distance of 3.50 Å between the first and second graphene layers.

Electronic band structure of Chemical Vapor Deposition graphene on polycrystalline copper foils by nano-ARPES

T13 Surface Science

#NST/SS-2-Or-7

J. Avila ¹, I. Razado-Colambo ¹, S. Lorcy ¹, R. Fleurier ², E. Pichonat ², D. Vignaud ², X. Wallart ², M.C. Asensio ¹.

¹Synchrotron SOLEIL - Gif Sur Yvette (France), ²IEMN, UMR CNRS 8520 - Villeneuve D'ascq (France).

The electronic properties of polycrystalline graphene films are strongly dependent on the size, shape and orientation of their constituent single-crystal grains. Hence, the ability to produce large and free-defects films of graphene is presently a major challenge for multiple graphene applications. Here we report a high angle and lateral resolved photoelectron spectroscopy (nano-ARPES) study of one-atom thick graphene films on thin copper foils synthesized by chemical vapor deposition. In today's state-of-the-art ARPES, probed areas are routinely in the range from tens to hundreds of microns. Notwithstanding in advanced materials, length scales from the nano- to the mesoscopic-scales dictate and characterize the electronic and other relevant properties. Thus it is not possible access relevant length scales for many complex engineered materials using conventional ARPES.

At the Synchrotron SOLEIL, we have recently built a new instrument by combining ARPES principles with scanning microscopy, in which a focused soft x-ray beam is raster-scanned over the samples to create an image one pixel at time while a suitable signal is monitored under computer control. This new nano-probe is capable of investigating innovative materials in their earlier stage of synthesis, which often are initially isolated in small crystalline form or in polycrystals constituted by small grains. With this new instrumentation, we have been able to characterize polycrystalline one-atom-thick graphene films. They were composed by single-crystal grains differently oriented, which appeared patched together like in a quilt. By mapping the electronic dynamics down to single pristine graphene grains, we have shed light on essential

characteristics like doping, gap-size, Fermi velocity and electron-phonon coupling of this unique Dirac system. Randomly-oriented graphene grains showed a giant enhancement of flexural phonon modes, while in highly-oriented grains, they are nearly quenched. These findings provide a new benchmark in our understanding of many-body effects in graphene.

“More than Moore”: Could silicene be the future of electronics?

T13 Surface Science

#NST/SS-2-Or-8

M.C. Asensio¹, J. Avila¹, G. Le Lay², P. De Padova³, C. Quaresima³, P. Vogt⁴, A. Resta².

¹Synchrotron SOLEIL - Gif Sur Yvette (France), ²Aix-Marseille University, CNRS-CINaM - Marseille (France), ³CNR-ISM - Roma (Italy), ⁴Technische Universität Berlin, Institut für Festkörperphysik - Berlin (Germany).

Finding novel materials with smart properties is one of the major challenges of material science research activity. In particular, the electronics market demand for increased performance cannot be met anymore with conventional packaging and interconnect technologies. Consequently, the technology roadmap for semiconductors or Moore's Law, which states that the number of components integrated in a circuit would increase exponentially over time, should be replaced by a more effective approach regarded as “More than Moore” [1]. This new trend adds value to devices by incorporating new functionalities, which do not necessarily scale according to “Moore's Law”.

Graphene is one of such novel materials with Dirac-type electrons near the Fermi level behaving as massless fermions, which give rise to intriguing phenomena such as Klein paradox, anomalous integer quantum Hall effect and appealing properties as strong resistance, stretchable and impermeable attributes. A close relative of graphene, a 2D honeycomb lattice of Si atoms called Silicene has been recently reported as nanoribbons and single layers on silver monocrystals, oriented (111)[2-4]. Silicene has been theoretically predicted as a buckled honeycomb arrangement of Si atoms and having an electronic dispersion resembling that of relativistic Dirac fermions[5]. In this presentation we will provide, (for the first time to our knowledge), compelling evidence, from both structural and electronic properties, for the synthesis of epitaxial silicene sheets on silver single crystals. We have combined scanning tunneling microscopy and synchrotron radiation angle-resolved photoemission spectroscopy to fully characterize this new exciting material.

VALENCE BAND TOMOGRAPHY AND THE RECONSTRUCTION OF MOLECULAR ORBITALS FROM ANGLE RESOLVED PHOTOEMISSION

T13 Surface Science

#SS-13-In-1

M. Ramsey.

Institute of Physics, Karl-Franzens University Graz - Graz (Austria).

With examples of chain- and plate-like molecules it will be shown that the combination of studies of conjugated molecules with modern electron energy spectrometers has led to advances in understanding valence band photoemission in general and the electronic structure of “organic semiconductors” in particular. Examples of intra- and inter-band dispersion in thick molecular films will demonstrate that a simple Fourier transform of molecular orbitals predicts the, hitherto apparently complex, angular/momentum distribution of emitted photoelectrons. For adsorbate monolayers it will be shown how this orbital tomography can be used to determine molecular geometries, gain insight into the nature of the surface chemical bond, unambiguously determine the orbital energy ordering and reconstruct orbitals in real space.

SS-9-In-1 METAL–ORGANIC INTERACTION PROBED BY FIRST PRINCIPLES STM SIMULATIONS

T13 Surface Science

#SS-9-In-1

M.L. Bocquet.

Ecole Normale Supérieure de Lyon, Laboratoire de Chimie, CNRS UMR 5182 - Lyon (France).

Density Functional Theory (DFT) has now reached the point to mimic in a quantitative way two pillars of the Scanning Tunneling Microscope (STM) probe: the imaging mode convoluting the topographic and electronic properties and the spectroscopy modes comprising of elastic and inelastic detection ways. We present a selection of hybrid interfaces ranging from isolated benzene derivatives, phthalocyanines and porphyrines to thin honeycomb carbon film – a single graphene layer – deposited onto ideal transition metal surfaces. The direct experimental analysis of these interfaces was error-prone, necessitating the confrontation with First Principles atomistic simulations. The few examples thus illustrate the power of different kinds of STM simulations to complement the STM data, in order to unambiguously identify the chemical structure of organic adsorbates.

T13 Surface Science

#NST/SS-2-In-1

H. Gao.

Institute of Physics, Chinese Academy of Sciences - Beijing (China).

Graphene (G) is considered as a serious contender for being the reference material for a post-CMOS technology. Nevertheless, the use of graphene for applications requires mass production of high quality material and also its transfer to insulating substrates. While epitaxial growth in SiC and CVD growth in metal surfaces have seen enormous progress, transfer techniques are still a major challenge and a limiting factor of the material quality. I will present a new strategy for graphene growth on metallic Ru(0001) followed by silicon-layer intercalation that not only weakens the interaction of graphene with the metal substrate but also retains its superlative properties. This G/Si/Ru architecture, produced by silicon-layer intercalation approach (SIA), was characterized by Raman spectroscopy, scanning tunnelling microscopy/spectroscopy, and angle resolved electron photoemission spectroscopy. The SIA eliminates the need for the graphene transfer and also allows for an atomic control of the distance between the graphene and the metal gate, opening doors for a new generation of graphene-based materials with tailored properties.

T13 Surface Science

#NST/SS-6-In-2

A. Schmid.

National Center for Electron Microscopy, Materials Sciences Division, LBNL - Berkeley (United states).

When a spin-polarized electron beam is scattered on the surface of a magnetic material, reflectivity is a function of the relative alignment between the spin direction of the beam and the magnetization vector in the surface of the sample. The spin-polarized low-energy electron microscope (SPLEEM) uses this effect to resolve the orientation of the magnetization vector at high spatial and angular resolution. This talk highlights capabilities of the technique to reveal in situ and in real time quantitative information on micromagnetic configurations and structure-property relationships in nanomaterials.

THEORY OF KONDO PHENOMENA IN NANOCONTACTS AND IN STM/AFM SPECTRA OF MAGNETIC ATOMS AND MOLECULES

T13 Surface Science

#SS-8-In-1

E. Tosatti.

SISSA, ICTP, and CNR-IOM Democritos - Trieste (Italy).

The properties of atom and molecule- bridged metallic nanocontacts leading to conductance anomalies at break junctions and in STS spectra and in AFM dissipation are difficult to access, yet very rich of phenomena also in connection with magnetism. Electronically, first principles calculations can account well for the gross features of the ballistic conductance of magnetic metal nanocontacts. [1,2] Magnetic impurities bridging nonmagnetic metal contacts yield subtle zero bias anomalies in STS spectra due to the Kondo effect. Qualitatively similar to those of quantum dots, these anomalies are dominated in this case by the specificities of the atomic and molecular states involved, only accessible through a first principles electronic structure approach. The difficulty to combine the Kondo many body physics with the mean-field electronic structure poses a problem. We address this problem by means of a joint density functional plus numerical renormalization group approach recently devised.[3] I will illustrate applications to transition metal impurities on carbon nanotubes,[4] and to magnetic molecules on gold surfaces. The possibility of Kondo-related AFM dissipation will also be discussed. Finally, the circumstances conducive to ferromagnetic Kondo effect, as opposed to ordinary antiferromagnetic Kondo, will be outlined along with possible systems where that unusual situation could be realized.[3,5]

MOLECULAR ARCHITECTURES AT SURFACES: EMERGENCE OF COMPLEXITY IN FUNCTION AND STRUCTURE.

T13 Surface Science

#SS-11-In-1

R. Raval.

The Surface Science Research Centre, Department of Chemistry, University of Liverpool - Liverpool (United kingdom).

Molecules represent the most versatile, functional entities available in Nature and are central components in the machinery of life. Recently, the use of powerful microscopes and spectroscopies have revealed the nanoscale details of how molecular entities nucleate, organise and propagate functionality at surfaces. This talk will outline how collections of molecules yield beautiful nanoscale architectures and organised patterns. From these assemblies arise complex functions like molecular recognition, mirror-symmetry breaking, adaptive behaviour and non-linear responses[1-6]. Finally, on-surface synthesis of robust, covalently linked soft-matter using clean, generic connection strategies will be demonstrated, with the direct emergence of structural and topological complexity [7,8].

SS-12-In-1 SITE-SPECIFIC IMAGING OF REACTION STEPS IN CATALYTIC CONVERSION OF DIOLS ON TiO₂(110)

T13 Surface Science

#SS-12-In-1

Z. Dohnalek.

Pacific Northwest National Laboratory, Fundamental and Computational Sciences Directorate and Institute for Interfacial Catalysis - Richland (United states).

Variable-temperature scanning tunneling microscopy, temperature programmed desorption and dispersion-corrected density functional theory were employed to study chemistry of diols (ethylene glycol and 1,3-propane diol) on TiO₂(110) surfaces. Atomically resolved imaging reveals information about the preferred adsorption sites, O-H bond cleavage, and formation of high temperature reaction intermediates. Further details are uncovered about the translational and rotation dynamics of surface intermediates. The coverage dependent desorption kinetics of alkene and aldehyde as final gas phase products are determined via temperature programmed desorption. Comprehensive theoretical calculations yield a deep insight into the mechanism and energetics of the observed reaction steps.

ATOMIC FORCE MICROSCOPY OF MOLECULES ON INSULATING FILMS: STRUCTURE DETERMINATION AND IMAGING THE CHARGE DISTRIBUTION WITHIN SINGLE MOLECULES

T13 Surface Science

#SS-17-In-1

G. Meyer.

IBM RESEARCH - Rueschlikon (Switzerland).

Ultrathin insulating films on metal substrates are unique systems to use the scanning tunneling (STM)/ atomic force microscope (AFM) to study the electronic and structural properties of single atoms and molecules, which are electronically decoupled from the metallic substrate. Recent work demonstrates the imaging of molecular orbitals, the molecular structure and the intramolecular charge distribution of single molecules with highest resolution. This opens up the possibility to study molecular processes as bond breaking/formation, conformational switching, charge transfer etc. in utmost detail.

Ultimate spatial resolution of scanning tunneling microscope (STM) enables us to observe the inner electronic, vibrational and spin structures of a molecule adsorbed on solid surfaces. Experimentally defined environment surrounding a molecule such as symmetry of the adsorption site and spatial distribution of electronic structure enables precise theoretical consideration. Examples will be given for spin nature of an iron(II) phthalocyanine (FePc) molecule, electronic structure of which is modified by the interaction with the substrate. With precise determination of the symmetry of the adsorption site, we were able to configure the appearance of novel feature of spin + orbital SU(4) Kondo effect.

Like hydrogen molecules, many other molecules also exist as spin isomers, with the nuclear magnetic moments of the atoms either parallel or anti-parallel. Unlike hydrogen which can be easily separated to its para and ortho states, separation of the spin-isomers of other molecules is not readily available. The development of spin separation methods is motivated by the currently limited knowledge of the physical properties of spin isomers and their interaction with surfaces as well as by their potential applications in a wide variety of research fields, ranging from astrophysics to hyper sensitive nuclear magnetic resonance (NMR).

In this work we present an experimental setup which has been successfully used to form a focused molecular beam of spin selected molecules and produce thin films with a very high spin-purity[1,2]. The general idea, experimental system, different technical issues and experimental results for both water and methane molecules will be presented.

Electron transport in atomic-scale devices is an important research area where both fundamental physics and technological opportunities are simultaneously addressed. From the theoretical point of view one of the great challenges is to develop general methods for quantitative simulations of real devices taking into account the atomistic details. In this talk I will describe recent developments based on the DFT+NEGF approach and discuss capabilities and limitations to various quantum transport problems. A prototype system is electron transport through single-C60 junctions where a critical comparison with various low-temperature STM experiments can be made and where simulations help to provide insight into the roles of interface geometry, chemical nature of the electrodes, and bond formation/rupture under finite voltages.

EDGE STATES OF 1D AND 2D TOPOLOGICAL INSULATORS

T13 Surface Science

#SS-8-In-2

H.W. Yeom.

Department of Physics, POSTECH (Pohang University of Science and Technology) - Gyungbuk (Korea, republic of).

While 3D topological insulators are attracting huge interests in recent days, we are interested in new low dimensional topological insulators. For example, 1D charge density wave (CDW) systems are 1D topological insulators with solutions as their edge states. 2D topological insulators such as HgTe/CdTe have quantum spin Hall states as their edge states. Since edges states of 1D and 2D topological insulators possess exotic spin-charge characteristics, they can be exploited for unprecedented forms of spin and electronic devices. We have tried to directly observe the edge states of new 1D and 2D topological insulators formed on solid surfaces with scanning tunneling microscopy and spectroscopy. The CDW state of In atomic wires self-assembled on Si(111) was used to observe solitons in real space [1]. The edge electronic states were also clearly resolved for the Bi single bilayer grown on BiTe₂Se, which was claimed as a 2D topological insulator. The characteristics of these 1D and 2D edge states are discussed.

P. Thiel.

IOWA STATE UNIVERSITY - Ames (United states).

The formation and thermal stability of metal islands on carbon surfaces is relevant to promising future applications that range from biomass conversion to magnetic storage. In this talk we will discuss metals deposited on flat surfaces of graphene and graphite in ultrahigh vacuum, highlighting both experimental results and theoretical understanding. Energetic values derived from density functional theory show that most transition metals, and noble metals, as well as rare earth metals, should exhibit 3D growth on graphene, and this is confirmed in selected experiments. We describe some specific cases where characteristics of those 3D islands—such as number density and shape—can be related to the energetics of individual processes. Differences and similarities expected for graphene and graphite surfaces are discussed.

SURFACE-CONFINED MOLECULAR SWITCHES AND ROTORS

T13 Surface Science

#SS-11-In-2

J.V. Barth.

Physik Department E20, Technische Universität München - Garching (Germany).

The confinement of functional molecular species in tailored environments leads to new nanoscale phenomena. Notably the organisation and dynamics of individual molecules were controlled by carefully designed supramolecular host architectures. Here we employ temperature-controlled scanning tunneling microscopy to explore open 2D coordination networks on a smooth metal surface, and to steer the assembly of atomic and molecular guests. We identify caged supramolecules performing concerted rotary motions within the template honeycomb pore, which are monitored and quantitatively analyzed. Following a different route, novel bis(porphyrinato) double-deckers (Ce(TPP)₂) and tris(porphyrinato) triple-deckers (Ce₂(TPP)₃) were synthesized directly on a Ag(111) surface (TPP=tetraphenylporphyrin). With such double- and triple-decker moieties the respective top ligands are rotatable by STM manipulation provided spatial constraints do not interfere. Furthermore C₆₀-buckyballs have been selectively positioned and oriented on top of double-decker arrays, which combination represents a donor-acceptor dyad. Finally we use free-base porphyrin modules to realize four-level conductance switches based on single proton transfer as depicted below. The atomically sharp tip of an STM is used to selectively remove one of the two hydrogen atoms from the macrocycle cavity, whence the position of the remaining hydrogen atom can be switched between four equivalent pyrrole moieties giving rise to distinct electric current levels.

EXPERIMENTAL REALIZATION OF QUANTUM ANOMALOUS HALL EFFECT IN MAGNETIC TOPOLOGICAL INSULATOR

T13 Surface Science

#SS-10-Kn-1

Q. Xue.

Department of Physics, Tsinghua University - Beijing (China).

Anomalous Hall effect (AHE) was discovered by Edwin Hall in 1880. In this talk, we report the experimental observation of the quantized version of AHE, the quantum anomalous Hall (QAH) effect in thin films of Cr-doped (Bi,Sb)₂Te₃ magnetic topological insulator. At zero magnetic field, the gate-tuned anomalous Hall resistance exhibits a quantized value of h/e^2 accompanied by a significant drop of the longitudinal resistance. The longitudinal resistance vanishes under a strong magnetic field whereas the Hall resistance remains at the quantized value. The realization of the QAH effect paves a way for developing low-power-consumption electronics.

This work was carried out in collaboration with Ke He, Yayu Wang, Xucun Ma, Xi Chen, Jinfeng Jia, Li Lu, Lili Wang, Shuaihua Ji, Zhong Fang, Xi Dai, and Shoucheng Zhang.

On the Porosity of Cu Coatings Formed in Earth-Based and Space Conditions

T14 Thin Films

#SE/TF-P2-22

L. Skatkov ¹, G. Cheremskoy ², P. Gomozov ².

¹PCB "Argo" - Beer Sheva (Israel), ²NTU "KhPI" - Kharkov (Ukraine).

Introduction

This work examines issues related to the structure, substructure and submicroporosity of metal coatings with face-centered cubic lattices – Cu following condensation under the conditions of space flight of orbital stations and under Earth-based conditions. As described by Cheremskoy et al [1], one major issue in the development of new materials for aerospace engineering applications is the porosity problem, which has significant effects on the performance properties of these materials. To control the parameters of porous structures and predict their stability during operation in the presence of multifactorial external inputs (for example, in open space), the origin, mechanisms and kinetics of processes used to develop porous materials must be subjected to systematic testing and data analysis. Previously [2], we introduced a theoretical model of pore formation in solids based on thermodynamic considerations. Note that in [4] we conducted an experimental survey of the impact of space on thermostatic metal coatings of black aluminium.

Experimental Section

These experiments were conducted on films of Cu condensed on the OS "SALUT –6" and on board the "MIR" orbital station. Small-angle X-ray scattering (SAXS) was conducted according to the previously described technique [3].

Results and Discussion

After the channels are filled and the entire film has formed a significant amount of macro-, micro- and submicropores (SMP) remain, which form through several mechanisms: diffusion-vacancy, the shadow effect, non-compact coalescence and joining of the structural elements, uneven growth, gas absorption and micro-contraction. Which mechanism predominates is determined by the physical and

chemical conditions of evaporation and condensation processes. This comparison of the porosity features of space and Earth-based samples is extremely important for the analysis of the impact of orbital station flight conditions on the mechanism of porosity formation.

For Cu films of different thicknesses, the total porosity measured based on the absorption of monochromatic radiation reaches several per cent.

Most of the porosity of space and Earth-based samples is constituted of micron-sized macro-pores, which cannot be revealed by SAXS. However, the quantity of SMPs is several times greater than the quantity of macro-pores. The observed small-angle X-ray scattering mostly results from SMP's.

The analysis of SAXS indicatrix asymptotes recorded on an incline reveal that Cu films mostly contain SMPs, the orientation and anisometry of which are mostly determined by aligning the motion of molecular flow during condensation.

The pores of Earth-based samples of Cu films are in prolate form, and due to their large size, are aligned in a direction close to the molecular flow direction. However, in space, SMP samples are almost equiaxial.

TF-6-Or-4

Structural, Compositional and Electronic Transport Properties of Magnetron Sputtered Hydrogen-Aluminium Co-doped ZnO and ZnMgO Films

T14 Thin Films

#TF-6-Or-4

A. Bikowski, K. Ellmer, D. Zajac.

Helmholtz-Zentrum Berlin für Materialien und Energie GmbH - Berlin (Germany).

ZnO:Al and Zn_{1-x}Mg_xO:Al belong to the class of transparent conductive oxides. These materials have a high transparency accompanied by a low resistivity and are used in various fields of application like flat panel displays, thin film solar cells, low emissivity glass, etc. [1]. From experiment and theory, it is known that hydrogen acts as a shallow donor in ZnO [2,3]. Since hydrogen is present in almost all deposition processes, it is vital to understand the influence of hydrogen on the electrical properties of ZnO. However, the electrical properties are strongly determined by structural properties like grain size, density of dopants and defects, inclusion of other phases, etc., which requires a combination of analytical methods to obtain comprehensive information about the relation between doping and electrical and structural properties.

The ZnO:Al and Zn_{1-x}Mg_xO:Al ($x \approx 0.12$) films were deposited by magnetron sputtering from ceramic targets at substrate temperatures of 300°C as well as at room temperature (without intentional heating). We studied the influence of adding up to 10% hydrogen to the sputtering gas in comparison to films without (intentional) introduction of hydrogen. Secondary ion mass spectrometry (SIMS), elastic recoil detection analysis (ERDA) and Rutherford backscattering spectrometry (RBS) were used to determine the chemical composition of our samples. X-ray diffraction measurements in the Bragg-Brentano geometry revealed the crystalline quality, while

conductivity and Hall measurements were used to determine the carrier concentration and the Hall mobility as a function of the temperature, respectively.

We found, that the hydrogen in the ZnO films acts as a donor only under certain conditions. The effect of the hydrogen on the electrical properties of the films strongly depends on the deposition temperature. For $T_{\text{sub}}=300^{\circ}\text{C}$, the resistivity of the films increased significantly owing to a decrease of the free carrier concentration and the Hall mobility of the carriers. This effect is attributed to the formation of H_2 molecules in the films [4]. For depositions at room temperature, however, the film resistivity could be reduced by up to 2 orders of magnitude by the addition of hydrogen to the sputtering gas. In this case the hydrogen is incorporated in an electrically active way, most probably in the bond-center configuration [5]. This reduction of the resistivity (caused by increasing mobility and carrier concentration) occurred despite the fact, that the films became X-ray amorphous with increasing amount of hydrogen incorporated. This effect has been further investigated by transmission electron microscopy (TEM) and X-ray absorption spectroscopy (XAS), which allow to obtain a detailed picture of the local atomic structure of the samples. Our investigation showed, that in many ways, these X-ray amorphous ZnO:Al and $\text{Zn}_{1-x}\text{Mg}_x\text{O:Al}$ films resemble the amorphous transparent oxides, which are used in transparent thin film transistors.

SE/TF-1-Or-1

Structure and corrosion properties of TiN films deposited by combined HIPIMS-UBM process

T14 Thin Films

#SE/TF-1-Or-1

P. Hovsepian, A. Sugumaran, P. Mandal, A. Ehasarian.

Sheffield Hallam University - Sheffield (United kingdom).

TiN films were deposited using four cathode HTC 1000-4 Hauzer coating system equipped with Huettinger Electronic Sp.z.o.o power supplies for High Power Impulse Magnetron Sputtering (HIPIMS) and power supplies for standard Unbalanced Magnetron Sputtering (UBMS). In this study, the coatings were produced using different combinations of HIPIMS and standard magnetron sputtering sources. Increasing the number of HIPIMS sources involved in the combined process proved to be an effective tool to manipulate the ionisation degree in the plasma. Optical emission spectroscopy revealed that the intensity ratio of Ti¹⁺:Ti⁰ in the plasma increased with increasing the number of HIPIMS sources involved in the process from 0.09 to 1.93 for pure UBMS and pure HIPIMS respectively.

TiN coatings phase composition, microstructure texture as well as residual stress, and corrosion properties were studied by number of surface analyses techniques such as X-Ray Diffraction (XRD), Fracture Cross Sectional Scanning Electron Microscopy, (XSEM), Transmission Electron Microscopy, (TEM) as well as RAMAN spectroscopy.

It was revealed that in mixed HIPIMS - UBMS processes the residual stress can be controlled in wide range from -0.21 GPa to -11.35 GPa by smart selection of the degree of HIPIMS utilisation, strength of the electromagnetic field of the unbalancing coils of the machine as well as the bias voltage applied to the substrate.

XSEM analyses revealed that the fracture morphology changes from open columnar to dense almost glassy morphology when the number of HIPIMS sources in the process increases due to the higher ionisation and therefore higher mobility of the condensing species. Furthermore, higher ionisation with HIPIMS dominated processes leads to change in preferred film orientation from (111) to (200).

Significant improvement in corrosion performance was achieved by increasing the number of the HIPIMS sources involved in the process. Raman spectroscopy was used to analyse the nature of the corrosion products as well as to estimate the extent

of the corrosion damage. When polarised around E_{corr} values (-1 V to + 200 mV), pure UBM and 1 HIPIMS + 3 UBMS coatings exhibited iron and chromium oxide (Fe_2O_3 , Cr_2O_3) peaks at $\sim 495 \text{ cm}^{-1}$ and $\sim 550 \text{ cm}^{-1}$ in the spectra indicating that the corrosion has reached the substrate. No corrosion products were found in the above potential range for 2 HIPIMS + 2 UBMS and pure HIPIMS coatings demonstrating the advantages of the denser structures. Mixing HIPIMS with UBMS is also seen as an effective tool for improving the productivity of the deposition process.

TF-P2-22

Hybrid Orientation Structure of CeO₂(100) and (110) Regions on Si(100) Substrates Formed by Orientation Selective Epitaxial Growth

T14 Thin Films

#TF-P2-22

T. Inoue, S. Shida.

Iwaki Meisei University - Iwaki (Japan).

Cerium dioxide (CeO₂) has many advantageous properties for various applications; such as high dielectric constant of 26, chemical stability, transmission in visible and infrared regions and high efficient ultra-violet absorption. For application to silicon technology, especially hybrid orientation technology, we are studying a spatially orientation varied epitaxial growth of thin CeO₂(100) and (110) layers on Si(100) substrates using reactive dc magnetron sputtering. It has been found that the epitaxial CeO₂ layer with (100) or (110) orientation is selectively grown by controlling substrate surface potential, which we call orientation selective epitaxial (OSE) growth. There are two ways for the surface potential control; substrate bias application [1] and charged particle irradiation [2]. The latter gives a way to the spatially controlled OSE growth, which will lead to a hybrid orientation structure (HOS) formation.[3]

This paper describes the experimental results on the HOS formation using electron beam irradiation during reactive sputtering. Fig. 1 shows a schematic diagram of the HOS formation: CeO₂(100) grows in the high potential area due to irradiated electron beams, whereas CeO₂(110) grows in the low potential area. Spatially controlled HOS samples were made on Si substrates with various resistivities. We obtained the lateral orientation profiles within the sample surfaces by X-ray diffraction measurements. It was found that the existence of the transition region containing both (100) and (110) components in between the (100) and (110) areas. It is clarified that the transition region width decreases proportionally with the

logarithm of Si substrate resistivity. This can be explained by a potential model. Here, we propose a new way for perfect separation of the two orientation regions using silicon on insulator (SOI) substrates having lithographically isolated Si islands. Preliminary experiments showed that the orientation components vary stepwise from island to island. In order to realize perfect isolation, we are making efforts to optimize the experimental parameters. This work was supported by KAKENHI (20560024). A part of this work was conducted at the AIST nano-Processing Facility, supported by "Nanotechnology Network Japan" of the MEXT, Japan.

Stress and structure evolution of nanocomposite TiZrAlN protective coatings under ion irradiation

T14 Thin Films

#SE/TF-1-Or-2

G. Abadias ¹, I. Saladukhin ², V. Uglov ², A. Michel ¹, P. Djemia ³, S. Dub ⁴, G. Tolmachova ⁵.

¹Institut P' - Poitiers (France), ²Belarusian State University - Minsk (Belarus), ³LSPM - Paris 13 (France), ⁴Institute of Superhard Materials - Kiev (Ukraine), ⁵Kharkov Institute of Physics and Technology - Kiev (Ukraine).

Quaternary TiZrAlN coatings, deposited by reactive magnetron co-sputtering, have been shown to possess unique microstructure and mechanical properties when increasing the Al content from 0 to 18 at.%. In particular, the formation of hard (H ~ 24-27 GPa) coatings is revealed for Al content between 4.5 and 8 at.%, corresponding to the formation of a nanocomposite structure consisting of cubic TiZr(Al)N nanosized-grains embedded in a highly disordered matrix [1]. For higher Al content, the films tend to be 'X-ray amorphous'. The typical microstructural evolution with increasing Al content is schematically shown in fig.1

The objective of the present work is to investigate the stability and performance behavior of these nanostructured TiZrAlN films under irradiation, as they constitute potential candidates for **radiation-tolerant nanocomposites** [2]. For this purpose, the phase stability and structural evolution upon ion irradiation (Xe²⁺, 180 keV) is studied using X-ray Diffraction, while the evolution of hardness and elastic properties is obtained by Nanoindentation and Brillouin Light Scattering experiments. Complementary measurements were obtained by XRD using sin²ψ method to determine the stress state of irradiated films. Interestingly, an amorphous-to-crystalline phase transformation is observed for Al contents close to 10 at.%, as

shown in fig.2. Several ion fluences, in the range 1×10^{15} to 5×10^{17} cm⁻², were investigated to obtain insights on the ion irradiation induced crystallization process. The results are discussed based on inverse Kirkendall effect, and related Al redistribution at the grain boundary.

Thin Film Metallic Glasses: Current Status and Future Trends

T14 Thin Films

#TF-4-In-1

J. Chu.

Department of Materials Science and Engineering, National Taiwan University of Science and Technology - Taipei 10607 (Taiwan, republic of china).

Amorphous alloys, or metallic glasses (MGs), are non-crystalline metals with lack of long-range atomic periodicity because they are generally formed with fast quench rates for the retention of the glassy state from the melt. MGs are considered as non-equilibrium materials with important characteristics of the glass transition and crystallization when heated towards the liquid state. Due to the disordered atomic structure and the absence of grain boundaries, MGs have many excellent properties including good soft magnetic properties and exceptional mechanical properties of high specific strength, large elastic limits (~2%), high resistance to corrosion and wear. Thus, they have been a subject of interest for scientific research and engineering application for decades. The pioneer works by Klement et al., Chen and Turnbull, and Chen in 1960s and 1970s reported the first MG samples based on binary Au-Si and ternary Pd-Si-X (X= Ag, Cu or Au) and Pd-Y-Si (Y= Ni, Co or Fe) systems, using rapid solidification methods such as splat quenching. MGs at that time were limited to relatively small sizes, typically in μm , in order to achieve fast quench rates. The recent advent of MGs with relatively high thermal stability and low critical cooling rates, mainly through multi-component composition design, has led to significant improvements in the characteristic specimen sizes. As a result, many MGs (e.g. Zr-, Cu-, Ti-, Fe-, Pd-, Pt- and Au-based systems) with sizes in excess of 1 mm (or so-called bulk metallic glasses, BMGs) have been reported. These BMG systems in general have good glass-forming ability (GFA) such that rapid solidification is unnecessary and BMGs thus have become obtainable with conventional casting methods.

Increasing interest in developing and understanding this new family of materials has also led to making thin film metallic glass (TFMG) processing possible, which was not readily achieved in the past when MGs were available only as powder or ribbon. To make use of great properties, TFMGs with good GFA are evolving as alternative film materials which are potentially useful for many applications such as micro-electro-mechanical system (MEMS) devices. While MGs and BMGs are considered as

newcomers, there are already many succinct and thorough articles reviewing various topics from the science of glass forming, atomic structure to mechanical properties [1-4]. It is thus important for this presentation [5] to summarize and discuss the progress made in this area of TFMG over the past ten years or so and several challenging subjects will be proposed for future research.

Evaluation of time-dependent compound layer formation and removal at target surface by model calculation of mass balance change in reactive sputtering

T14 Thin Films

#TF/SE-1-Or-1

E. Kusano, M. Sakamoto.

Kanazawa Institute of Technology - Hakusan (Japan).

To discuss effects of pumping speed and discharge current on time-dependent mass balance change in Ti-O₂ reactive sputtering, formation and removal of a compound layer on target surface is evaluated by a time-increment model based on a previously proposed dynamic mechanism model on target surface condition change¹⁾. In Ti-O₂ reactive sputtering, the following O₂ mass balance change is kept;

$$Q_{in} + Q_{sputtered} = P_{O_2}(S_{gettering} + S_{oxidization} + S_{pump}) + Q_{residing},$$

where Q_{in} is the amount of O₂ gas introduced in the chamber, $Q_{sputtered}$ is the amount of O₂ gas sputtered from the target, P_{O_2} is O₂ partial pressure, $S_{gettering}$ is gettering pumping speed for O₂ gas by depositing Ti, $S_{oxidization}$ is O₂ gas consumption speed by target surface oxidization, S_{pump} is vacuum pump pumping speed, and $Q_{residing}$ is the amount of O₂ gas residing in the chamber as an increase in O₂ partial pressure. At a steady state $Q_{in} = Q_{gettering} + Q_{pumped}$, because the compound layer formation and removal at the target are balanced. In the model calculation, mass-balance shown in the equation is calculated for a step of a time-increment and $Q_{residing}$ is given as a result of an increase or decrease in O₂ partial pressure between two sequential time steps. In Fig.1 and 2, results of time-dependent formation and removal of a target surface oxide layer for various Q_{in} are shown as a function of time elapsed after discharge ignition for S_{pump} of 0.20 and 0.40 m³/s, respectively. The results well show time-dependent oxide formation and removal at the target surface for sequential change in Q_{in} . The changes in coverage θ for S_{pump} of 0.20 m³/s are faster than those for S_{pump} of 0.40 m³/s, indicating the difference in process stability for the difference in pumping speed. The model well yields information on time-dependent process change in reactive sputtering.

Fig.1 and 2 Formation and removal of target oxide layer for various O_2 flow rates, Q_{in} , as a function of time elapsed after discharge ignition for vacuum pump pumping speed of 0.20 and 0.40 m^3/s , respectively.

TF-P3-08

Calculating Models for Film Thickness Distribution on Inner Surface of Semispherical Work-pieces by Circular Planar Target Sputtering

T14 Thin Films

#TF-P3-08

S. Zhang, W.H. Zhang, Y.H. Xie.

School of Mechanical Engineering and Automation, Northeastern University - Shenyang (China).

In the vacuum coating production, film coatings on the inner surface of semispherical work-pieces are sometimes in demand. When the sputtering coating method has to be adopted to coat the functional films under certain conditions, obtaining uniform film thickness on the inner surface of semispherical work-pieces has great difficulty due to the limitation of sputtering target shape.

In order to solve this problem, the circular planar magnetron sputtering target is chosen in this paper to coat films on the inner surface of semispherical work-pieces. Three arrangement modes of target-substrate systems are proposed: For the small semispherical work-pieces whose diameters are close to the normal sputtering target – substrate distance, the circular planar target is centrally placed relative to the semispherical work-piece; For the larger size work-pieces, or requiring space to arrange for ion source, the target is eccentrically placed outside, as shown in Fig. 1; For those work-pieces whose diameters are far greater than the normal target-substrate distance, the target is eccentrically and aslant placed in the semispherical work-pieces.

Aiming at above arrangement modes, three models are respectively established and the film thickness distributions are calculated. Based on the assumptions of particle cosine emission and straight line flight as well as simplified circular sputtering line, calculation formulas for film thickness distribution on semispherical work-piece inner surface are deduced and the results are illustrated as shown in Fig. 2. By comparison and analysis of calculation data, the optimal structure parameters are obtained. The optimization result can provide reference for relative engineering and technical personnel in the design of coating equipment structure and evaluation of

film performance.

WATER PURIFICATION USING AN HYBRID SYSTEM MEMBRANES / PHOTO-CATALYSIS

T14 Thin Films

#TF-P2-12

O. Arous.

USTHB / CRAPC - Algiers (Algeria).

Abstract:

In this work, we have developed a novel class of polymeric inclusion membranes (PIMs) for the cations separations. The membrane is made up of cellulose triacetate modified by polyelectrolytes using 2-nitrophenyl-pentyl ether (NPPE) incorporated into the polymer as plasticizer. Different (PIMs) are synthesised and characterised by the Fourier Transform Infra-Red, X-ray diffraction, thermal analysis and scanning electron microscopy. The influence of the membrane nature is studied using supports with different physical characteristics (porosity, thickness, hydrophobia). As application, the transport of Pb^{2+} using PIMs coupled with photo-electrodes is investigated.

The photo-catalytic results indicate that the combined system $p-CuCrO_2$ /membrane/ $n-Sr_2Fe_2O_5$ enhances considerably the electrons transfer toward the delafossite $CuCrO_2$.

The position of the conduction band of $CuCrO_2$ is looked to be the key issue for the photo electrochemical Pb^{2+} reduction.

Key words: Membrane; Cellulose; Triacetate; Polyelectrolyte; delafossite $CuCrO_2$; photo electrochemical.

Switchable Mirror Device with Adhesive Electrolyte

T14 Thin Films

#TF-P3-01

K. Tajima, M. Shimoike, Y. Yamada, M. Okada, K. Yoshimura.

National Institute of Advanced Industrial Science and Technology - Nagoya (Japan).

In order to reduce the environmental load in houses and buildings, windows having a functional coating on the glass are being developed and becoming widespread as energy-saving windows. Our developed switchable mirror glass will be expected for application in new energy-saving windows since they can reflect solar radiation effectively in the reflective state, which results in a reduction in the cost for air conditioning [1-3].

A typical switchable mirror has a multilayer of Mg-based alloy thin film (40 nm)/Pd/Ta₂O₅/H_xWO₃/indium tin oxide (ITO) on a transparent substrate. The layers act as an optical switching, a proton injector, a solid electrolyte, an ion-storage layer and a transparent conductor, respectively. changes its state followed by electrochromic (EC) principle. When a voltage is applied to the mirror, the protons in the ion-storage layer move to the optical switching layer and the layer is hydrogenated, thus resulting in the transparent state [3, 4].

In our conventional fabrication method, the layers were deposited on the substrate by only magnetron sputtering method. In this method, a long fabrication time might be required and it may be difficult to fabricate a large size sample because our sputtering chambers are small. In this research, we focused on the fabrication method of electrolyte layer, and tried to develop a new fabrication method by using adhesive electrolyte to obtain large sample [5].

A part of this work was supported by Industrial Technology Research Grant Program in 2009 (Project No.09B36002a) from NEDO of Japan.

Effects of target grain size and density on properties of rf sputtered aluminium oxide thin film

T14 Thin Films

#TF-3-Or-1

M. Sakamoto, E. Kusano.

Kanazawa Institute of Technology - Hakusan (Japan).

It is well known that impurities in a sputtering chamber and a target affect properties of deposited thin films¹⁾. To establish a steady, reproducible deposition process of high-quality aluminium oxide (Al_2O_3) insulating thin film by sputtering, the relationship between thin film properties and target properties were investigated. Al_2O_3 thin films were deposited by rf magnetron sputtering using initial condition or pre-sputtered (discharged for 4.5 kWh) target on borosilicate glass substrate with or without indium-tin-oxide coating. The thin film properties were studied in terms of the target parameters such as target purity, target density and grain size. The surface roughness of the films were analyzed by atomic force microscopy and the refractive index was calculated from UV/Vis/NIR spectra. A precision impedance analyzer was used to measure dielectric constant at 1 MHz. Dielectric breakdown was determined by I-V measurement using an electrochemical analyzer. In Fig. 1, the relationship between dielectric constant of deposited thin films and density and grain size of the targets is shown. The dielectric constant is increased with decreasing grain size of the target. Additionally, the refractive index and the dielectric breakdown show the same trend. Fig. 2 shows the correlation between surface roughness of thin films using initial condition target and that of using pre-sputtered target. The correlation coefficient is 0.95, indicating that the film properties would not be affected by impurities derived from the sputtering chamber, but by target properties. It is concluded that the dielectric constant and other properties of the Al_2O_3 thin films are influenced by grain size and density of the sputtering targets.

Metal layers on polymer substrates are used in a wide range of applications, such as micro- and nanoelectromechanical systems (MEMS and NEMS), sensors, catalytic activity, bioengineering, and more recently, new developments emerged in electronic textiles. In all these applications, material properties such as mechanical and electrical resistivity, surface morphology and optical reflectivity are affected by the grain growth of the metal deposit.^[1]

Thin gold (Au) and silver (Ag) films in the thickness range of 5 to 200 nm were prepared on Si wafers and polyethylene terephthalate (PET) surfaces by pulsed DC sputtering at different pressure and power levels. The variation of deposition pressure and power influences the directionality and the energy flux onto the deposited film.^[2] The grain growth, morphology and film properties of Au and Ag layers were investigated on PET foils and compared to films grown on Si wafers. The grain growth of both metals was identified as a monomodal columnar growth from scanning electron microscopy (SEM) and atomic force microscopy (AFM) investigations. X-ray diffraction and AFM investigations showed on both substrates presence of spherical grains with a preferred (111) orientation almost independent of the metal and film thickness. The number of grains per unit area was extracted from AFM data. In the early stage of film growth a strong decrease of the number of grains per unit area was observed for thickness values between 5 and 100 nm, indicating competitive grain growth. For Au films the steady-state grain density of around 500 grains per μm^2 was reached at a film thickness of 60 nm for Au films. In comparison showed Ag coatings larger grain size and lower grain densities due to their higher surface diffusion coefficient.

The optical properties were studied by UV-VIS-NIR spectroscopy as a function of film thickness. Anomalies in optical transmission spectra indicate the conversion from discontinuous to continuous film growth. Optimized optical and adhesive properties can finally be established with films below 100 nm.

Recently, thin films of rare-earth (RE) oxides, including Gd₂O₃, Er₂O₃, and Lu₂O₃ [1], are considered for SiO₂ replacement in ultra-large scale integration technologies due to their high dielectric constants, large bandgap energies, high resistivities, and low interface trap densities. The biggest issue when using RE films is moisture absorption to degrade their permittivity through the formation of low-permittivity hydroxides [2]. To solve this problem, the incorporation of Ti or TiO₂ into the RE dielectric films can cause improved electrical properties [3]. The sensing characteristics of the Gd₂Ti₂O₇, Er₂TiO₅ and Lu₂Ti₂O₇ sensing films in electrolyte-insulator-semiconductor (EIS) device is not clear to date. In this paper, the sensing properties of the Gd₂Ti₂O₇, Er₂TiO₅ and Lu₂Ti₂O₇ films deposited on a Si substrate were studied. Fig. 1 shows the sensing characteristics of the EIS devices using different sensing films immersed in different pH solutions. To evaluate the sensing performance, we recorded a set of capacitance–voltage (C–V) curves. In the pH sensing of an EIS device, the change in the pH of the solution caused a shift in the flatband voltage of the C–V curves. The Lu₂Ti₂O₇ EIS device exhibited a better sensitivity of 59.32 mV/pH than other EIS devices. This result could be attributed to the higher surface roughness. Fig. 2 revealed the drift characteristics and the stability of the EIS pH sensors with different sensing films. The Er₂TiO₅ EIS device exhibited a better long-term stability (slope = 0.29 mV/hr) in comparison with the other EIS sensors.

TF-3-Or-2

Reactive layer assisted deposition mechanism and properties of silver nano-crystals embedded titanium oxide film as a model photo-catalyst

T14 Thin Films

#TF-3-Or-2

L. Zilberberg, M. Asscher.

The Hebrew University - Jerusalem (Israel).

Titanium oxide (TiO_2) is used for various environmental applications such as solar light harvesting in photovoltaic applications, self-cleaning surfaces and sterilization due to its ability to degrade organic compounds, and become super hydrophilic under UV light illumination. All these applications derive from the unique photo-catalytic activity of TiO_2 . However, TiO_2 has a wide band gap which limits its efficiency under solar irradiation, therefore an important challenge is to widen its optical activity into the visible spectrum.

The growth mechanism of TiO_2 films and their morphology are being studied using Reactive Layer Assisted Deposition (RLAD) method under ultra high vacuum conditions. The oxide film formation involves Ti atoms deposition on top of amorphous solid water (ASW) condensed on a $\text{SiO}_2/\text{Si}(100)$ support at 90K. Subsequent annealing leads to desorption of all non-reacted buffer molecules, and at the same time forming and depositing the titanium oxide film. Employing mass spectrometry and using D_2O as buffer, evolution of deuterium molecules has been detected during titanium atoms deposition. A solid state sol-gel-like formation mechanism of titanium oxide is proposed based on these observations. This is the first demonstration of a cold, solid-state sol-gel like oxide film formation. The morphology of the oxide films has been characterized by ex-situ AFM as a rather uniform amorphous film less than a nanometer thick at room temperature. Upon further vacuum-annealing above 750K, crystallization of the titanium oxide film has set-in coinciding with a dewetting process of the oxide layer, information obtained from similar growth procedure on amorphous carbon and Si_3N_4 covered TEM grids. It was shown that these films are rather insensitive to the under laying substrate at temperature below 500K.

The second part of this work addressed the possibility to improve the photocatalytic

activity of TiO_2 , via resonant surface plasmons excitation in the visible by growing Ag nano-particles embedded in the TiO_2 nano-film. The method of growing the silver nanoclusters was, in vacuum, Buffer Layer Assisted Growth (BLAG).

The effect of the silver nanoparticles and the titanium oxide composition on the intensity of surface plasmon resonance was studied. It was found that the optical excitation of the embedded silver nano crystals is significantly more stable over time than the absorption of bare silver particles. Namely, the TiO_2 thin film served as a protection layer against oxidation of the silver particles.

The future research plans include preparation of various composites by using different metal oxides, and different metals and alloys. Eventually, we intend to study the photocatalytic activity of these composites at the gas and at the liquid phases.

Facile Preparation and Physical Properties of CdS Thin Films

T14 Thin Films

#TF-P3-05

H. Moualkia, A. Mahdjoub, L. Hadjeris, L. Remache, L. Herissi.

Laboratoire des Matériaux et Structure des Systèmes Electromécaniques et leur Fiabilité, Faculté des Sciences et de la Technologie, Université Larbi Ben M'Hidi, Oum El Bouaghi, Algérie - Oum El Bouaghi (Algeria).

Extensive research has been carried out on the deposition and characterization of cadmium sulfide (CdS) semiconducting thin films because of their potential application in the area of electronic and optoelectronic devices [1-4]. Cadmium sulfide which is a material with a direct and wide band gap (2.42 eV), can provide good matching between the lattice and absorption layer, which favors the stability of copper-indium-gallium-diselenide (CIGS) solar cells. The highest conversion efficiency of CIGS solar cells that has been reported to date is 20.3% [5]. Among various techniques for preparing cadmium sulfide, chemical bath deposition (CBD) is a simple and low cost method that produces uniform and adherent thin films for solar related applications. One of the advantages of the CBD CdS layers in photovoltaic devices is deposition of very thin layers (< 50 nm) in a conformal manner on the substrate surface. These characteristics produce an increase in the device photocurrent by enhancing the solar cell absorption spectra in the UV-range. In this work, we report on the preparation of CdS thin films by CBD as a function of deposition time. The influence of deposition time on the optical, morphological and structural properties of chemical bath-deposited CdS thin films has been studied. The optical transmittance is made using Shimadzu 1650 PC UV-visible spectrophotometer in the wavelength range 300–1100 nm. Layers thickness (d) is measured by fitting the transmittance. The photoluminescence measurements are carried out using Perkin-Elmer LS 50B luminescence spectrometer. The photoluminescence (PL) spectra are recorded with the excitation wavelength of 457 nm. Surface morphology is performed by atomic force microscopy (AFM) (Pacific Nanotechnology). The latter technique offers digital images which allow quantitative measurements of surface features, such as root mean square (RMS). The crystalline structure is analysed using a BRUKER D8 Advance X-ray diffractometer with line (wavelength: 1.54Å). The optical measurements show that the elaborated thin films have high optical transmission (85%). The band gap presents a maximum value of

about 2.4 eV at deposition time of 45 minutes corresponding to lower disorder. The deposition rate, deduced from the transmittance spectra, lower than 6.5 nm/min, indicates that ion by ion dominates the deposition process and as a result a much smaller grain size and thinner films are obtain. The AFM images display homogeneous and continuous thin layers with small rounded grains and surface roughness RMS of about 22 nm. X-ray diffraction analysis reveals that the deposition films have a cubic structure and the grain size varies between 13 and 35 nm.

From nano-layers to large area neutron supermirrors.

T14 Thin Films

#TF-1-Or-10

T. Bigault, V. Gaignon, G. Delphin, A. Vittoz, P. Courtois.

Institut Laue Langevin - Grenoble (France).

Neutron supermirrors are multilayer stacks of two different materials deposited alternatively with varying thicknesses, up to thousands of individual layers. The principle is analogous to interferential optical coatings, or to Bragg diffraction by crystals with a varying inter-atomic distance, with a working range restricted to grazing incidence angles. These coatings, performed on rather large area substrates (several tens of square centimetres), are used as optical elements on instruments using neutron beams. In particular, when one of the materials is magnetic, these mirrors can reflect or transmit selectively neutrons according to their spin state. Thus neutron beam spin-polarisers and spin-analysers can be produced by using supermirrors [1]. At the world-leading European neutron source ILL, such polarising supermirrors are developed and produced on a large scale by magnetron sputtering, based on Co/Ti and Fe/Si material pairs [2]. A few examples of recent supermirror production projects for ILL instruments will be given.

Optimizing the performance of polarising supermirrors requires tailoring the microstructure and magnetic properties of these complex multilayer stacks [3]. Some challenges linked to this optimization will be presented, together with recent progress in this domain.

Ni nanoparticles (NPs) attract lot of interest as catalyst for carbon nanotube growth, as particles forming interacting or noninteracting ensembles, optoelectronic entities, etc. We have produced self-ordered Ni NPs either on surface or embedded into the alumina or silica matrix starting from three types of nickel and alumina multilayered structures prepared by magnetron sputtering. The structure and morphology of the prepared materials have been examined by grazing-incidence small-angle scattering (GISAXS), wide-angle X-ray scattering (WAXS), atomic force microscopy (AFM), and transmission electron microscopy (TEM), while magnetic properties were measured by SQUID magnetometer.

Thin Ni films deposited onto dielectric's surface exhibit markedly different particle size distribution at room temperature and at elevated temperatures. The effect of temperature on NP formation has been employed for formation of 3-dim arrays of Ni NPs in dielectric matrix. Two types of precursor materials have been used: a) multilayers consisting of alternating pure Ni and pure alumina layers, and b) multilayers consisting of alternating mixed Ni+alumina and pure alumina layers. Both types of precursor material were deposited at room temperature and at elevated temperature, and subsequently annealed. The size of the Ni NPs and their average lateral distance was controlled

by the amount of Ni in the Ni-containing layer, while their cross-layer interaction was governed by the thickness of intervening dielectric spacer. That way, the magnetic properties could be controlled, as well.

An example of the effects of alumina dielectric spacer thickness (6 & 2 nm) and annealing temperature (RT & 500°C) upon Ni NPs sizes and spatial distribution is shown in composite GISAXS Fig. 1.

The size and spatial distributions of Ni NPs govern the supermagnetic properties of such an ensemble. An example of the blocking phenomena of superparamagnets is shown in Fig. 2 for Ni NP array in silica.

Nanopatterned thin films prepared by the evaporation-induced self-assembly (EISA) process have up to now been limited to a few transition metal oxides (i.e. Al_2O_3 , TiO_2 and ZrO_2)¹. Here we describe for the first time the formation of zinc titanate nanopatterned thin films with different Zn/Ti ratios using the dipcoating process. Atomic force microscopy and scanning electron microscopy reveal that the structure consists of well-ordered pseudo-hexagonal nanopatterns in the range of 30 nm in diameter separated by 25 nm wide metal oxide ridges, while the film thickness is close to 2 nm (Figure 1). For films with a zinc precursor content up to 50 mol-%, the well-organized structure of the thin film can be maintained, while at higher Zn contents the nanostructure is gradually becoming more disordered. Grazing incidence x-ray diffraction measurements on the films calcined at 700 °C indicate that the anatase phase of the pure TiO_2 films is gradually consumed at the expense of a newly formed $\text{Zn}_2\text{Ti}_3\text{O}_8$ phase² upon increasing the Zn/Ti ratio in the starting precursor solution (Figure 2). To the best of our knowledge, this is the first demonstration of the preparation of ternary metal oxide nanopatterned thin films using the EISA approach and the unique combination of the nanostructure with the zinc titanate composition grants these films significant application prospects in for instance optics and catalysis.

Metallic nanoclusters have found numerous applications in heterogeneous catalysis (effluent treatments, sensors, energy storage and conversion, etc.). Costly and strategic metals from the platinum group are required. There is thus a real interest to obtain the highest catalytic surface area from a low metal weight, in particular for fuel cell electrodes for achieving highest performance.

Here, different techniques of physical vapor deposition have been developed for the synthesis of Pt catalytic nanoclusters. We can distinguish sputtering techniques where the nucleation and the growth clusters occur on the substrate (conventional DC magnetron sputtering – DCMS) from those where the nucleation and the growth happen in the gas phase (low energy cluster beam deposition, LECBD).

In this work, well defined platinum nanoclusters are produced by DCMS/LECBD on perfluoropolymer membranes (Nafion® used as ion conductive electrolyte in fuel cell) and on microporous carbon substrates (Sigracet® carbon used as cathode in fuel cell). Platinum acts as catalyst for oxygen reduction at the cathode-membrane interface. The physical and the electrochemical properties of the Pt nanoclusters have been investigated as a function of the deposition technique and of the deposition parameters. The catalyst coated membrane (CCM) and the catalyst coated backing (CCB) are tested in a proton exchange membrane fuel cell station. The maximum power densities reach 0.7 and 0.50 W cm⁻², respectively. The

performance is compared to those obtained with commercial fuel cell where the Pt nanoclusters are grown by chemical routes.

The second generation of gravitational wave detectors will aim at improving by an order of magnitude their sensitivity versus the present ones (LIGO and VIRGO) [1]. These detectors are based on long-baseline Michelson interferometers @ 1064 nm with high finesse Fabry-Perrot cavity in the arms and have strong requirements on the optics. These large low-losses mirrors (340 mm in diameter, 200 mm thick) must have a near perfect flatness. The coating process shall not add surface figure Zernike terms higher than second order with amplitude >0.5 nm over the central 160 mm diameter. The limits for absorption and scattering losses are respectively 0.5 and 5 ppm. For each optic the maximum loss budget due to the surface figure error should be smaller than 20 ppm. Moreover the transmission matching between the two input mirrors must be better than 99%.

Coatings are done using Ion Beam Sputtering (IBS) technique in a large chamber specially developed for this purpose. Low losses optics with very high reflection value ($R > 99.999\%$) were obtained by multilayer dielectric coating based on a stack of alternate Titanium doped Tantalum pentoxide (Ti:Ta₂O₅) layers and silica layers. The total coating thickness is 2.8 μm for the Input mirrors and 5.2 μm for the End Mirrors.

We describe the different configurations that were explored in order to respect all these requirements.

The two first configurations based on a single rotation motion for the substrates combined or not with uniformity masks allow obtaining uniformity around 0.2 % rms on 160 mm diameter [2]. But this is not sufficient to meet all the specifications. A planetary motion completed by masking technique has been studied. With simulated values the loss budget is below 20 ppm, better than the requirements. Experimental results obtained with the planetary system will be presented.

The electronic properties of the interfaces between transition metal oxides, and in particular the discovery of 2D conductivity in heterostructures composed of LaAlO₃ (LAO) and SrTiO₃ (STO) band insulators [1], have generated new paradigms, challenges, and opportunities [2] in condensed matter physics. Recently, a universal surface metallic state was also found on bare STO(001) crystals [3,4,5], raising important questions concerning the role of the LAO overlayer and the effective differences between STO/vacuum and LAO/STO interfaces [6,7]. Here, by using pulsed laser deposition (PLD) coupled in situ with angle-resolved photoemission spectroscopy (ARPES), we show the evolution from the metallic state on STO to the one found in LAO/STO. While the character and size of the Fermi surfaces in all these systems are qualitatively similar, LAO/STO interfaces exhibit a sign of 2×1 reconstruction when the LAO layer matches or exceeds the conventional critical thickness of 4 unit cells (uc). In addition, LAO/STO interfaces show a similar response to irradiation as previously reported for bare STO [4]. We interpret these findings within the framework that the low-dimensional metals in STO surfaces and interfaces originate from a polar lattice distortion that can be triggered in multiple ways – e.g., directly by photons, or indirectly through coupling to a secondary deformation driven by polarity, diluted defects and/or strain effects.

TF/SE-P3-01

Formation of hydrated oxide thin films by reactive sputtering in H₂O atmosphere and their electrical properties

T14 Thin Films

#TF/SE-P3-01

Y. Abe, N. Li, K. Nishimoto, M. Kawamura, K.H. Kim, T. Suzuki.

Kitami Institute of Technology - Kitami (Japan).

Proton conducting hydrated oxide thin films have been attracted attentions as a solid electrolyte layer of electrochromic devices and switchable mirrors. (1,2) To prepare hydrated oxide thin films, our group has developed a new reactive sputtering technique using H₂O as a reactive gas. OH radicals and atomic hydrogen formed in the H₂O plasma were incorporated into the growing films and hydrated oxide films were deposited. (3,4)

In this study, metal targets of Ti and Y were reactively sputtered in H₂O atmosphere at substrate temperatures from -30 to +130°C, and hydrated TiO₂, and YOOH thin films were formed. Infrared spectra of all the films indicated that the absorption peak intensity due to OH bonds, which corresponds to the amount of hydrogen in the films, increased with decreasing substrate temperature. The electrical conductivities of the films were estimated by AC impedance measurements in a frequency range from 10 mHz to 1 MHz at room temperature. The conductivities of the TiO₂ and YOOH films with a thickness of about 1 micrometer are plotted in Fig. 1 as a function of substrate temperature. The conductivities of the Ta₂O₅ and ZrO₂ films (3,4) are also plotted in the figure for comparison. The conductivities of the Ta₂O₅, ZrO₂, and YOOH films increased with decreasing substrate temperature, and maximum conductivities of about 10⁻⁵ S/m were obtained at the lowest substrate temperature of -30°C. The increase of the conductivity corresponds well with the increase of the absorption peak intensity due to OH bonds. These results suggest strongly that the electrical conduction of the Ta₂O₅, ZrO₂, and YOOH films are caused by proton conduction. In contrast, the conductivity of the TiO₂ films increased with increasing substrate temperature. It is considered that the electrical conduction of the TiO₂ films is caused by electron

transport. N-type semiconducting TiO_2 is thought to be formed by the incorporation of hydrogen.

Introduction

Metallic nanohole arrays have been widely investigated due to their potential application to chemical- and bio-sensing, metamaterials, photovoltaic cells as well as for scientific interests in their unique optical responses. Their useful and also intriguing optical characteristic is the asymmetric resonance originating from the inter-hole coupling through supported bonding- surface plasmons (SPs). In most past research the nanoholes have been fabricated in a single thick layer more than 10 nm using noble metals. In this study, we fabricate nanoholes in ultrathin Al/AlN multilayers with their optical resonance adjusted in the Vis-NIR range. In this system, it is possible to deposit metallic and dielectric films as thin as a few nanometers with atomically smooth interfaces.

Method

100nm colloid particles were deposited on glass substrates and multilayers of Al and AlN were sputter-deposited on the colloid-masked substrates. The colloid particles were then removed to create nanohole arrays. The fabricated samples were evaluated by SEM, AFM and transmission spectroscopy, and analyzed by comparing with the dispersion relation of the multilayer systems. Vacuum annealing up to 400°C was also performed to test the thermal stability.

Results

The created nanoholes, as shown in the AFM image of Fig.1, have a short range order with characteristic spacing. The radial distribution function of the nanoholes exhibits a clear peak around 200 nm corresponding to the characteristic hole-hole

distance. Propagating SPs interfere between nanoholes resulting in the resonance.[1] SP modes can be calculated by solving the dispersion relation. The optical spectra of multilayers, consisting of three 2.3nm AlN and two 5.0/2.5nm Al layers, are shown in Fig.2. The asymmetric resonance shape is characterized by the dip and peak at the higher wavelength, which are here tuned to Vis/NIR.

Molecular dynamics study of the growth of various crystalline phases of TiO₂ and Al₂O₃

T14 Thin Films

#TF-2-Or-2

J. Houska ¹, S. Mraz ², J.M. Schneider ².

¹University of West Bohemia - NTIS - Plzen (Czech republic), ²RWTH Aachen University - Aachen (Germany).

Thin films of crystalline transition metal oxides are of high interest due to a wide range of functional properties. Previously, their preparation has been described in terms of extrinsic process parameters, such as total pressure, oxygen partial pressure or substrate bias potential. We study the growth of individual phases of TiO₂ (rutile x anatase) and Al₂O₃ (α x γ) using a combined approach of magnetron sputtering and atom-by-atom molecular dynamics (MD) simulations (>=3000 deposited atoms per simulation). We focus on the effect of intrinsic process parameters including particle energy, growth temperature and growth template. We report a significant methodological progress: while most of the structures of various materials obtained (predicted) previously by classical MD simulations are amorphous, we study the growth of multiple competing crystalline phases described by a single interaction potential. A particular advantage of these simulations is a disentanglement of the nucleation and the growth. We identify which classes of interaction potentials allow such simulations and which do not.

In the case of TiO₂, experiments indicate that the deposition of rutile requires higher temperatures and/or energies compared to anatase. However, MD simulations [1] show that the growth of (previously nucleated) rutile can take place in a wider range of process parameters (at lower temperatures and especially both at lower and up to higher energies per film-forming atom) compared to anatase. Growth of distorted rutile is observed even on (110) and (111) anatase, in a slightly narrower range of process parameters compared to the undistorted rutile growth.

In the case of Al₂O₃, MD simulations allow us to identify that an energy of 35-50 eV is ideal for the growth of (previously nucleated) α-Al₂O₃. The crystals (i) quickly

amorphize if the energy per film-forming atom is lower and (ii) slowly amorphize if the energy per film-forming atom is higher (especially at small crystal size). The aforementioned ideal energy value slowly decreases with increasing growth temperature. On the contrary, we show that (previously nucleated) γ - Al_2O_3 grows in a very wide range of process parameters.

In all cases, the crystal growth is supported (the amorphization is slowed down) if the crystal (column) is sufficiently wide compared to the thermal spike size. In such a case, the undamaged crystalline cells support "healing" of the damaged neighboring cells.

Phenomena observed experimentally are in agreement with the MD results. Collectively, the results provide an insight into the complex relationships between process parameters and deposited film structures. Consequently, they allow one to tailor the synthesis pathways for the production of TiO_2 and Al_2O_3 thin films, considering conditions for nucleation and different conditions for growth. The phenomena shown (e.g. the fact that the phase which more easily nucleates is not necessarily the same which more easily grows) may be tested for even wider range of materials.

TF-P2-02

In-situ time-resolved microGISAXS investigation of the growth kinetics of Ag-PTFE nanocomposites prepared by sputter deposition

T14 Thin Films

#TF-P2-02

G. Santoro, S. Yu, A. Buffet, M. Schwartzkopf, S. Koyiloth Vayalil, S. Bommel, G. Herzog, B. Heidmann, J. Perlich, S. Roth.

HASYLAB at DESY, Notkestr. 85, D-22607 - Hamburg (Germany).

Polymer metal nanocomposites are interesting materials because of the extraordinary physical properties they show. They are used in advanced optical, electrical and medical applications, as well as for data storage and catalytical applications [1]. Among the different methods used to prepare such nanocomposites, sputter deposition is a widely employed technique in industry and research, presenting a major advantage in comparison with wet chemical approaches that is the absence of residual solvents in the prepared thin films. RF sputter deposition allows to extend this technique to depositing insulating materials, such as polymers. Thereby one can especially use the co-sputter deposition of the metal and the organic materials at the same time to create tailored nanostructures.

Ag-polytetrafluoroethylene (Ag-PTFE) nanocomposites prepared by sputter deposition has been shown to exhibit excellent properties that can be exploited for applications such as antibacterial coatings, plasmonic devices or sensors [2]. Nevertheless, in order to fully control the desired final properties of the nanocomposites, that are very sensitive to the size and shape of the nanoparticles as well as to the arrangement of the metal nanoclusters inside the polymeric matrix, it is mandatory to achieve a profound understanding of the growth kinetics of the nanocomposites. In this sense, micro Grazing Incidence Small Angle X-ray Scattering (μ GISAXS) [3] is a very powerful and valuable tool for the in-situ characterization of the growth kinetics allowing to extract morphological information of the surfaces that are developing with time resolution on the order of the millisecond [4].

In this work we present important μ GISAXS results concerning the time evolution of the structures developed during the RF-sputtering of PTFE/Ag nanocomposites by the co-sputtering of Ag and PTFE. A portable in-situ RF-sputter deposition chamber [5] that can be couple to the P03 beamline (MiNaXS beamline) at the PETRA III storage ring (DESY, Hamburg) has been designed and manufactured (Fig. 1).

KMC approach to simulations of mosaic phase formation on the Si(111) surface

T14 Thin Films

#TF-2-Or-3

P. Kocán, P. Sobotík, I. Ošťádal, P. Matvija.

Charles University - Prague (Czech republic).

Deposition of metals on the Si(111) surface together with an appropriate thermal activation results in re-organizing of surface atoms to variety of ordered structures, often with interesting properties. A special attention has been paid to mosaic phases

of 2D alloys with $\sqrt{3} \times \sqrt{3}$ symmetry. These structures are usually induced by desorption of metal atoms (Pb, Sn, Tl) together with substitution by Si atoms.

We use configuration-based kinetic Monte Carlo (KMC) model to explain important features related to the mosaic structure formation: 1) the zeroth order of desorption surprisingly observed in the case of Pb/Si(111) system [1-3], 2) mechanism of substitution by Si adatoms and 3) ordering of the 2D metal/Si alloy into the mosaic phase by means of effective repulsive interaction [4].

The zeroth-like order desorption spectra are simulated by means of first-order desorption processes with enhanced desorption from domain boundaries. For the substitution of desorbed metal atoms by Si adatoms, fast diffusion of adatoms on top

1×1 layer is proposed as the most probable. In the case of the mosaic ordering similar to the 2D antiferromagnetic Ising system on a triangular lattice, a new mechanism of ordering induced by selective desorption is provided and tested.

The model was successfully applied on the examples of Tl [5] and Pb [1-3] desorption.

Magnetron sputtering of ZrB₂ films on 4H-SiC(0001) and Si(100) substrates

T14 Thin Films

#TF-4-Or-2

L. Tengdelius¹, M. Samuelsson², J. Jensen¹, J. Lu¹, U. Forsberg³, L. Hultman¹, E. Janzén³, H. Högberg¹.

¹Thin Film Physics Division, Department of Physics, Chemistry, and Biology (IFM), Linköping University, SE-581 83 - Linköping (Sweden), ²Impact Coatings AB, Westmansgatan 29, SE-582 16 - Linköping (Sweden), ³Semiconductor Materials Division, Department of Physics, Chemistry, and Biology (IFM), Linköping University, SE-581 83 - Linköping (Sweden).

Zirconium diboride, ZrB₂, combines typical ceramic properties such as high hardness and high melting point with a low resistivity. Moreover, ZrB₂ exhibits a lattice mismatch to 4H-SiC(0001) of only 3.8%, which is favorable for heteroepitaxial growth. This makes ZrB₂ interesting as a thin film contact material in e.g. microelectronics. It is known that the electrical properties of ZrB₂ are influenced by film structure, composition, as well as the level of contaminants. These properties, in turn, can be influenced by process parameters such as growth temperature and bias voltage.

In this study the effect of deposition temperature and applied bias voltage on the electronic properties of ZrB₂ thin films was investigated under industrial conditions. The ZrB₂ films were deposited by direct current magnetron sputtering from a ZrB₂ compound target in an industrial scale high vacuum system on 4H-SiC(0001) and Si(100) substrates. The base pressure of the system was ~0.13 mPa – 1.3 mPa, depending on the growth temperature. A high deposition rate (~30 Å/s), in combination with short deposition times (100 s) minimized the influence of the residual gas. Films were grown at three different temperatures (without intentional heating (RT), 400°C and 550°C), and at a range of substrate bias voltages between -20 V and -80 V. Scanning electron microscopy showed that the films exhibit a columnar appearance. All films showed a B/Zr ratio close to, or slightly below 2 (stoichiometry), and low levels of contaminations (O content < 1 at%), as determined by time-of-flight energy elastic recoil detection analysis. X-ray diffraction and selected area electron diffraction patterns (SAED from TEM, see Fig. 1), showed that with

increasing deposition temperature, the crystallographic structure changed from a (0001) fiber texture to a random orientation. Moreover, increasing the growth temperature in combination with increasing the substrate bias caused the relative metallic content in the films to increase somewhat, yielding B/Zr ratios close to 1.84. Transmission electron microscopy showed an amorphous layer at the interface between the film and substrate for films deposited at RT (see Fig. 1), whereas such a layer was not present in films grown at high temperature. Upon increasing substrate bias voltage as well as the growth temperature, it was found that the electrical resistivity decreased from 200 to $\sim 100 \mu\Omega\text{cm}$. Furthermore, results from ex-situ annealing experiments – an attempt to increase crystallinity and further improve the electrical properties – will be presented.

Fig 1. TEM image and SAED pattern of a film deposited at RT with a substrate bias of -80 V showing an amorphous layer at the substrate interface.

TF-P2-23

Formation and structure of Au and Pt epitaxial clusters supported by tungsten oxide

T14 Thin Films

#TF-P2-23

J. Polášek, K. Mašek, J. Beran, P. Blumentrit, M. Vorokhta, N. Tsud, V. Matolín.

Charles University, Faculty of Mathematics and Physics, Department of Surface and Plasma Sciences - Prague (Czech republic).

Tungsten oxide surface was prepared by radio - frequency (RF) plasma oxidation of (110) tungsten single crystal surface followed by annealing at the high temperature. This process led to the formation of pseudocubic WO₃ thin film having (111) surface orientation [1]. Au and Pt were deposited at different substrate temperatures by thermal evaporation. Surface structure, composition and electronic properties were investigated using reflection high energy electron diffraction (RHEED) and synchrotron radiation photoelectron spectroscopy (SRPES).

Deposition of Au or Pt at the substrate temperature of 570 K led to the formation of epitaxial clusters having (111) surface plane. Strong metal - substrate interaction (SMSI) between Pt and tungsten oxide surface was observed leading to the encapsulation of Pt clusters at the temperatures above 570 K. Encapsulation was proven by CO adsorption. Only a weak interaction between Au and substrate was found.

Formation of Au - Pt bimetallic clusters was investigated at the temperature range of 160 K - 870 K. It was found that detailed cluster structure depends on the substrate temperature and order of deposited materials. If Pt is deposited first, Pt particles serve as nucleation sites for the growth of bimetallic clusters. In the case of Pt deposition on Au predeposited surface, bimetallic clusters grows preferentially, but lower Pt mobility leads to formation of pure Pt clusters on the bare tungsten oxide surface [2]. Deposition at low temperature (160 K) and subsequent annealing showed that at the temperatures higher than room temperature, metallic atoms can diffuse on the tungsten oxide surface and pure Pt particles are covered by Au. At the temperature of 500 K, interdiffusion of Pt and Au takes place resulting in formation of Pt - Au alloy at the metals interface. At the temperatures around 570 K, the clusters

are composed of Pt core and Pt-Au alloy shell enriched by Au on the surface due to the segregation of Au into the near surface region (fig. 1). Strong interaction between Au and Pt led to the weakening of SMSI of Pt and tungsten oxide, limiting the encapsulation process. Further annealing showed that temperature above 770 K leads to the reduction of tungsten oxide and strong interaction between metallic W and Pt atoms leads to decomposition of Au - Pt alloy clusters and formation of Pt - W alloy. These findings can explain the physical and chemical properties of Pt/WO_x, Au/WO_x and Pt - Au/WO_x catalysts and gas sensors.

The tribological properties of Zr-C:H coatings sliding against various normal loading, wear mode and counterbody

T14 Thin Films

#TF-P2-13

W. Kao.

Professor - Chang Hua.

Diamond-like carbon is an ideal surface coating material since it possesses exceptional properties, including high fatigue life, high hardness, high chemical inertness, low friction and high wear resistance under sliding conditions [1-7]. In this study, Zr-C:H-x coatings are deposited on AISI M2 substrates using a closed field unbalanced magnetron sputtering system with pulsed-direct current (pulsed-DC) power frequencies in the range 30 kHz to 110 kHz (the x in the term Zr-C:H-x is the power frequencies in the deposition process). The study investigates the tribological properties of the coatings under ball-on-disk point and cylinder-on-disk line contact wear modes using an oscillation friction and wear tester. We discuss the tribological behaviour of various wear pairs based on hardness (H), elastic modulus (E), adhesion property, initial Hertzian pressure and transferred layer on various contact surfaces of wear pairs. The experimental results display the Zr-C:H-110 coating with the good adhesion property, the lowest initial Hertzian pressure and the lowest friction coefficient possesses excellent wear resistance under point contact wear mode, while the Zr-C:H-70 coating with the maximum hardness and plastic deformation resistance (H^3/E^2) displays excellent wear resistance under line contact wear mode.

Calcium-phosphate slurry processing: A novel chemical treatment technique to activate osteogenesis on titanium

T14 Thin Films

#SE/PST/TF/BI-2-Or-6

N. Ohtsu, M. Hirano, H. Arai.

Kitami Institute of Technology - Kitami (Japan).

Titanium (Ti) implants have become essential medical products in surgery and dentistry as substitutes for hard tissues. However, it is difficult to achieve a strong mechanical interface between the implant and the surrounding hard tissue because osteogenesis does not progress easily on Ti. This paper presents a novel chemical treatment technique, called calcium-phosphate slurry processing, to activate osteogenesis on Ti substrate, developed by our research group¹⁻³). The calcium-phosphate slurry processing is a simple technique, and it involves burying a Ti substrate in calcium phosphate slurry prepared by mixing calcium phosphate powder with distilled water and then heated at 973 K in air. This process induces the substrate to react with the reagent efficiently and crystallizes the surface layer in one step. By treating with the slurry prepared by mixing 1 g of tribasic calcium phosphate ($3\text{Ca}_3(\text{PO}_4)_2 \cdot \text{Ca}(\text{OH})_2$) powder with 1.5 mL of distilled water, a composite coating comprising calcium phosphate and titanium dioxide (TiO_2) was fabricated on a Ti substrate. The thickness of the coating, estimated from a transition electron microscopic (TEM) image, was approximately 300 nm, and the average roughness (Ra) of the treated surface, calculated from the scanning probe microscopic (SPM) image, was slightly increased as compared to that of a non-treated surface. After the sterilization, osteoblast-like MC3T3-E1 cells were seeded on the treated and non-treated Ti substrates and then cultured for 3 d. There was no difference in the attached cell numbers between the non-treated and treated substrates, indicating that the treated Ti surface will not show the cytotoxicity. The cells were thereafter differentiation-induced on the substrates. The calcifications of the cells at 27 d after differentiation-incubation are shown in Fig. 1. The calcified deposits were stained by alizarin red S. The clustered deposits were observed only on the treated Ti substrate. This result indicates that osteogenesis on Ti is activated by treating with calcium-phosphate slurry. On the basis of these experimental results, we propose that

calcium-phosphate slurry processing is one of the hopeful surface treatment techniques to activate osteogenesis of Ti implants.

Perpendicular magnetic anisotropy and perpendicular exchange bias in sputter-deposited CoO/CoPt multilayers

T14 Thin Films

#TF-8-Or-1

J. Shi, J. Wang, T. Sannomiya, Y. Nakamura.

Department of Metallurgy and Ceramics Science, Tokyo Institute of Technology
- Tokyo (Japan).

Recently, interests in perpendicular exchange biased (PEB) spin valves for spintronics and magnetoelectronics have been dramatically increased due to their high magnetic stability and low device operating current density. In this study, the structural and magnetic properties of room temperature sputter deposited CoO/CoPt multilayer were investigated. In Fig.1(a), the as deposited multilayer shows strong perpendicular magnetic anisotropy (PMA) at room temperature. Moreover, after perpendicular field cooling, the multilayer with AF/FM interfaces exhibits a large shift (PEB) as indicated in Fig.1(b). Furthermore, the PMA of the multilayer after field cooling is also enhanced. This is considered due to the strong interfacial exchange coupling between the CoPt and CoO layers. Unlike the CoPt/AlN multilayer we reported before¹, which show PMA after thermal annealing, the multilayers studied here with relatively thick FM layer surprisingly show strong PMA at in the as-deposited state (Fig.1(a)). Therefore, the PMA found in AF/FM multilayer may be partially attributed to the interfacial AF-FM exchange coupling. On the other hand, XRD result indicates a well-defined layered structure and strong (111) texture for CoPt layers (Fig.2). Lattice fringes in TEM image (Inset of Fig.2) support the results of XRD and confirm that both of the CoPt and CoO layer show (111) texture. It seems that CoO layer here serves as a good seed layer for the growth of textured CoPt layer. As [111] is one of the easy axes for the fcc CoPt, the (111) texture should also benefit the PMA. To our knowledge, this is the first time to prove that PMA can be established with metal/oxide interface. With the remarkable PEB, the CoPt/CoO multilayer show great application potential for magnetoelectronic devices.

Abstract:

Gallium doped zinc oxide (GZO) thin films were prepared using the simple spray pyrolysis technique. The molar ratio of Ga in the spray solution was changed in the range of 0–5 at. % in steps of 1 at. %. The films were characterized by various methods to understand their structural, morphological, optical and electrical properties. The X-ray diffraction analysis revealed that the films were polycrystalline in nature having a hexagonal wurtzite type crystal structure with a preferred grain orientation in the (0 0 2) direction [1]. The scanning electron microscopy (SEM) measurements revealed that the surface morphology of the as-deposited ZnO films is greatly affected and a decrease in the grain size [2] with increased doping concentration was observed. The optical band gap was found to increase from 3.25 to 3.58 eV with increase in Ga-doping level [3]. All the films showed good transparency in the entire visible region from 80 to 92 %. A blue shift of the optical band gap was observed with an increase in Ga-doping. The electrical characterization was performed using two-probe press contact method. The electrical resistivity was found to vary from $8.02 \times 10^{-4} \Omega\text{-cm}$ to $5.43 \times 10^{-4} \Omega\text{-cm}$ with increasing doping level [4].

Monitoring the exhaust ammonia in conventional plasma nitriding process for closed loop control of compound layer formation

T14 Thin Films

#PST/SE/TF-3-Or-11

H. Klümper-Westkamp.

Stiftung Institut für Werkstofftechnik - Bremen (Germany).

Plasma nitriding and nitrocarburizing has been established in industrial production since many years. This thermochemical surface treatment is applied to various steel components in order to enhance wear resistance, corrosion resistance and fatigue resistance. The process is done at the state of art in a pulsed discharge technique in the region of anomalous glow discharge in a conventional heated furnace. By adjusting the gas composition and plasma parameters different compound layers with different thickness, composition, hardness and morphology can be produced. Up to now applications run under constant gas and plasma parameters, which have to be investigated and evaluated before. A lot of expert knowledge and experience is necessary to get the right parameters for the production of the intended compound layer specification and to secure the reproducibility. Further influencing aspects on the compound layer formation as batch size, batch surface, batch cleanliness, jigging, temperature distribution, cleanliness and leak rate of the plant are difficult to take into account and can cause large deviations.

To overcome these disadvantages a new concept for controlled processing is developed. Investigations in analyzing the exhaust gas of the plasma nitriding process gas showed a significant amount of ammonia, although no ammonia is added to the process. The ammonia is obviously produced in the plasma nitriding process as a reaction product of hydrogen with nitrogen in the glow discharge. Varying the inlet gas ratio of hydrogen to nitrogen, temperature and batch size leads to different ammonia content in the exhaust, as shown in figure 1. Based on this information and further gas measurements a closed loop control is build up to regulate the compound layer formation. First results are shown.

Based on these results as well as results of literature [1, 2, 3, 4], a new and more complete model to describe the mechanisms of plasma nitriding is introduced.

Development of innovative surfaces by plasma technologies on metallic substrates according industrial specifications

T14 Thin Films

#SE/PST/TF/BI-2-Or-7

A. Daniel, C. Archambeau.

CRM Group - AC&CS (Advanced Coatings & Construction Solutions) - Liège (Belgium).

The achievement of functionalized surfaces industrialization relies on various critical parameters that must be considered from the beginning and all along the product developments. Indeed the implementation of a surface functionality generally cannot be only limited to the validation of basic properties at lab scale, but must take into account the use in real conditions according customers' specifications as well as constraints related to associated production technologies, shaping and commercialization.

Taking into account the whole package of requirements we have to study, besides the desired functionality, other aspects such as durability of the function in various environments, aesthetic, forming ability, cost and specific tests if needed.

This approach allows a selection of most promising products and deposition technologies from the first experiments at lab scale.

We propose to illustrate this through a few examples of surface functionalization developed within the CRM Group.

The first example concerns the deposition of an hydrophilic easy-to-clean and anti-staining transparent thin layer on prepainted steel for outdoor building application.

Thin films are based on silicon and/or titanium oxides deposited by reactive magnetron sputtering or Plasma Enhanced Chemical Vapor Deposition (PECVD).

The end-user specifications are described and some differences in anti-staining and easy-cleaning properties are highlighted between flat substrates and shaped samples showing the importance to study the surface properties as close as possible to the real application. Finally the up-scaling of the functionality is described from lab experiments to industrial production line.

A second example deals with the development of an antibacterial coating on steel.

Thin films based on silver/copper containing oxide matrices are deposited by reactive magnetron sputtering and PECVD. In this case the product requirements are detailed in connection with the associated markets showing that developed antibacterial coating materials have to be adapted depending on the final use.

Magnetic canting at the interfaces of Fe/ MgO(001) and Fe/Al₂O₃(0001)

T14 Thin Films

#TF-8-Or-3

T. Kawauchi ¹, X. Zhang ², K. Fukutani ¹.

¹Institute of Industrial Science, The University of Tokyo - Tokyo (Japan),

²Institute of Materials Structure Science, High Energy Accelerator Research Organization - Ibaraki (Japan).

Magnetization of magnetic films is of considerable interest and importance in recent years. Because of the symmetry breaking at surfaces and interface, ultrathin magnetic films often reveal particular magnetic properties. The magnetization direction of magnetic films has usually been assumed to have a particular direction as an entire film. However, we have recently demonstrated that the magnetization cants only at the surface of Fe films in the surface normal direction [1]. In this paper, we have studied interface magnetization of Fe/MgO(001) and Fe/Al₂O₃(0001) by means of the quantum beat spectroscopy due to nuclear-resonant scattering with synchrotron radiation (SR).

The samples were prepared by evaporating Fe films with the electron bombardment on MgO(001) and Al₂O₃(0001) substrates at room temperature in UHV with a base pressure of 1×10^{-8} Pa. As the nuclear-resonant scattering is sensitive to only ⁵⁷Fe isotope, stacked structures of ⁵⁶Fe(20nm)/⁵⁷Fe(1nm)/Substrate and ⁵⁶Fe(10nm)/⁵⁷Fe(1nm)/⁵⁶Fe(10nm)/Substrate were fabricated on MgO(001) and Al₂O₃(0001). From the analysis of the RHEED pattern, we confirmed that Fe(001) was epitaxially grown on MgO(001) with Fe[100]//MgO[110] and Fe[110]//MgO[100]. Although Fe(110) was epitaxially grown on Al₂O₃(0001), on the other hand, the azimuthal direction of the film was found to be random. After transportation of the samples in the air, the nuclear-resonant-scattering experiment was performed in the grazing condition at the PF-AR NE1 beamline of High Energy Accelerator Research Organization.

The time spectra of the nuclear-resonant scattering taken for these samples revealed a clear quantum beat structure reflecting the Zeeman splitting of the ⁵⁷Fe nuclear level, which definitely showed the films are ferromagnetic. For ⁵⁶Fe(20nm)/⁵⁷Fe(1nm)/MgO(001), a quantum beat frequency of only 72 MHz was observed independent of the azimuthal direction of the SR incidence. Considering the polarization direction of SR, the results indicate that the magnetization of ⁵⁷Fe at

the interface is perpendicular to the interface. On the other hand, the time spectra taken for $^{56}\text{Fe}(10\text{nm})/^{57}\text{Fe}(1\text{nm})/^{56}\text{Fe}(10\text{nm})/\text{MgO}(001)$ showed two beat frequencies of 72 and 124 MHz depending on the azimuthal direction of SR, indicating that the magnetization direction at the middle of the iron film is different from that at the interface. From the analysis of the spectra taking account of the SR polarization, the magnetization has a uniaxially in-plane component in the direction of $\text{Fe}[100]/\text{MgO}[110]$. In contrast to $\text{Fe}/\text{MgO}(001)$, the magnetization direction of $\text{Fe}/\text{Al}_2\text{O}_3(0001)$ was found to be mostly in the parallel direction in the entire film, although the direction of the parallel component is $\text{Al}_2\text{O}_3[11-20]$ at the interface and $\text{Al}_2\text{O}_3[1-100]$ in the film. From the temperature dependence of the beat frequency, the internal magnetic field (B_{IN}) was evaluated, which exhibited a gradual decrease with increasing temperature. With a fit of the formula $B_{IN}=B_0(1-T/T_C)^\beta$, the critical exponent of $\beta=0.093\pm 0.053$ was obtained, which is similar to the value of $\beta=0.125$ expected for the 2-D ising model.

Pulsed Laser Deposition of Sub-Stoichiometric Tungsten Oxide Films: Growth and Structure

T14 Thin Films

#TF-3-Or-4

A. Caruana, M. Cropper.

Loughborough University Physics Department - Loughborough (United Kingdom).

Tungsten oxide has attracted vast interest in recent years due to its electrochromic and gas sensing properties (1,2). However, these phenomena tend to occur only in the material in thin film form (2). For example the increased surface area of a thin film greatly enhances the gas sensing properties of tungsten oxide. Reactive pulsed laser deposition (PLD) is being used increasingly in the deposition of oxides, due to the relative ease in which multi component materials can be deposited under relatively high gas process pressures (3). Consequently, work has been done on the influence of deposition pressure (1), and deposition temperature (4) on the film properties and structure, but to our knowledge, very little work has concentrated on the effect of laser fluence on the film structure (5).

In the work reported here, sub stoichiometric films of tungsten oxide deposited by PLD under different laser fluences are investigated. Tungsten oxide films have been deposited onto single crystal Si (100) and SrTiO₃ substrates by irradiation of a stoichiometric tungsten oxide target, using a frequency doubled Nd:YAG laser at a repetition rate of 10 Hz. All films were deposited at 500°C under a constant O₂ background pressure of 2.5×10^{-2} mbar. The films have been characterised by X-Ray diffraction, X-Ray reflectivity (XRR) and X-Ray photoelectron spectroscopy.

A predominant [001] texture was observed in all films, indicating preferential c-axis orientated growth. Films grown on SrTiO₃ exhibited a stronger degree of crystallisation in comparison to those grown on Si. The X-Ray diffraction patterns for the SrTiO₃ films showed over an order of magnitude increase in intensity for the [001] texture than was observed at equivalent fluence values on Si substrates. XRR scans revealed that the surface and interface roughness was far greater for films deposited on Si; further indicating that the films grown on SrTiO₃ were of better quality. The

deposition rate stayed relatively constant with increasing fluence up until a critical value of 8.9 J cm^{-2} , where the deposition rate approximately doubled. At this critical fluence the FWHM of the [001] texture on the SrTiO_3 films reduced significantly, indicating a decreased variation in crystallite orientation and suggesting a greater degree of crystallisation.

Atomic processes and crystal structures in Cr₂AlC films at high temperatures

T14 Thin Films

#TF-4-Or-8

V. Vishnyakov ¹, S. Haigh ², A. Gholinia ², U. Bangert ², J. Colligon ¹.

¹Dalton Research Institute, Manchester Metropolitan University - Manchester (United kingdom), ²Manchester Materials Science Centre, University of Manchester - Manchester (United kingdom).

A Dual Ion Beam deposition system was used to create thin films of Cr₂AlC. The films were deposited onto Silicon, Stainless Steel and Superalloy substrates at substrate temperatures ranging from room temperature to 700 K. Energy Dispersive and Wave Dispersive X-Ray analysis was used to determine the precise film composition, while High Resolution Transmission Electron Microscopy (TEM) coupled with Electron Energy Loss Spectroscopy and Electron Backscatter Diffraction (EBSD-like) mapping in the TEM was used to access for the first time local structural information and phase relationships of crystals on internal and external interfaces in as-deposited and annealed films.

The degree of crystallinity and the size of the crystallites within the film increases with deposition and/or annealing temperature and is also positively linked to the presence of a small surplus of Al above the stoichiometric level. A highly crystalline structure has been observed by EBSD in the TEM after annealing at 973K as shown on Fig.1. The film consists of predominantly the Cr₂AlC MAX phase structure with small traces of other binary phases. The dependence of crystal growth on annealing conditions will be discussed.

From a technical point of view the film's high temperature oxidation behaviour weakly depends on the initial deposition conditions and substrate temperature. We have observed that these films develop a dense protective Cr- and Al-rich surface oxide and that there is also some ingress of oxygen into the film bulk. The overall film oxidation and oxygen uptake appear to be lower for the films with smaller crystals and higher proportion of amorphous phase and we speculate that this can be linked to a slightly higher initial film density

Fig. 1. Electron Backscatter Diffraction-like mapping of a cross section through a Cr_2AlC thin film sample annealed at 973K, showing from left to right, crystal orientation map and structural image.

Mechanical characterization of AlTiN-coatings processed by different PVD techniques

T14 Thin Films

#SE/TF-1-Or-6

F. Lomello ¹, M. Arab Pour Yazdi ², A. Besnard ³, F. Sanchette ⁴, F. Schuster ⁵, A. Billard ².

¹LRC CEA-IRTES-LERMPS, site de Montbéliard, UTBM - Belfort (France), ²IRTES-LERMPS, site de Montbéliard, UTBM - Belfort (France), ³LaBoMaP (EA 3633) - Equipe MAT, Ecole Nationale Supérieure d'Arts et Métiers - Cluny (France), ⁴LRC CEA-ICD LASMIS, Nogent International Center for CVD Innovation (Nicci), UTT Antenne de Nogent, pôle technologique de haute Champagne - Nogent (France), ⁵CEA Cross-Cutting program on Advanced Materials - Saclay (France).

In this study, AlTiN coatings were deposited by means of two high energetic deposition techniques such as cathodic-arc deposition and high-power impulse magnetron sputtering (HIPIMS) [1,2].

Recently, the application of single layer AlTiN synthesized by physical vapor deposition (PVD) in cutting applications increased due to their improved tribological and high oxidation temperature (up to 800°C) if compared with a single-phase nitrides [3].

A correlation between these techniques and the resulting morphological-mechanical properties was established. Firstly, a physico-chemical characterization was conducted by means of X-ray diffraction (XRD), transmission electron microscopy (TEM), scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS), glow discharge optical emission spectroscopy (GDOES) techniques.

Subsequently, the mechanical-tribological characterization allowed comparing these properties to the chemical-morphological properties. The resulting properties were strongly depending on the processing routes. For instance, the differences in terms of surface roughness strongly affected the final tribological properties. The

tribological tests were performed at both low- and high-temperature regimes up to 800°C.

Moreover, the higher droplets' density strongly affected the built-up of material at the edge of the wear tracks after ball-on-disc tests. Indeed, the better surface state in the case of HIPIMS leads reducing the coefficient of friction (COF). It is well known that macroparticles emission creates defects (droplets) in non-filtered cathodic-arc evaporation processes.

These droplets act as cutting edges increasing the COF as already reported in the literature [4]. Nowadays, HIPIMS has few industrial applications for this reason a final aspect concerning the industrial up-scaling feasibility was investigated. The developed approach included several aspects such as the deposition parameters and the measured final properties.

MODEL OF RELAXATION AND CRYSTALLIZATION KINETICS OF AMORPHOUS Al-(Mo, W) THIN FILMS UNDER ISOCHRONAL HEATING

T14 Thin Films

#TF-P2-03

T. Car ¹, J. Ivkov ², N. Radic ¹, M. Jercinovic ¹.

¹Rudjer Boskovic Institute - Zagreb (Croatia), ²Institute for Physics - Zagreb (Croatia).

Relaxation processes and crystallization kinetics of Al-(Mo, W) amorphous thin films under isochronal conditions was examined by continuous *in situ* electrical resistance measurements in vacuum. For the isochronal heating, it was observed that the relaxation effects decreased with an increase of the heating rate and decreased with the content of molybdenum and tungsten in the film. The crystallization temperature decreased with an increase of aluminum content. Assuming the linear dependence of resistivity with temperature, the linear $\rho(T)$ contribution is extracted from the relaxation effects. Adopted experimental function of $\rho(T)$ is fitted to a modified Bloch-Gruneisen formula with excellent agreement of experimental data and fitting function. The adaptation of the JMAK model to the non-isothermal kinetics was used for calculation of crystallization kinetic parameter n and activation energy for crystallization E_c . The unified model for both processes is examined and discussed.

Molecular Dynamics simulations of plasma sputtered Zr_xCu_{1-x} amorphous metallic glass thin film growth. Effects of composition and kinetic energy

T14 Thin Films

#TF/SE-1-Or-7

P. Brault, L. Xie, A.L. Thomann.

GREMI UMR7344 CNRS-Université d'Orléans - Orleans (France).

Recently, there has been a huge interest in the atomic-level structure and structure-property relationship in metallic glasses (MGs). These materials have been studied for 40 years because of their promising properties belonging to both metals (electron, heat conductivity, ductility...) and glasses (hardness...). To stabilize an amorphous phase in metallic alloys, atomic diffusion must be prevented. This could be achieved by playing with the chemical composition (mixing of elements with different atomic sizes) or by freezing low ordered phases during the synthesis process. It has been shown that deposition of thin films by condensation onto substrates, even at ambient temperature, allows to synthesize metallic glasses even in binary systems. In this work, we employed classical molecular dynamics simulations model to study Zr_xCu_{100-x} ($3 \leq x \leq 95$) metallic alloy films deposited on a silicon (100) substrate. Input data were chosen to fit with typical experimental operating conditions of magnetron sputter deposition process. The evolution is monitored with variable compositions of deposited atoms. The Zr-Zr, Cu-Cu and Zr-Cu interactions are modelled with the Embedded Atom Method (EAM), the Si-Si interaction with Tersoff potential, the Zr-Si and Cu-Si interactions with Lennard-Jones (12-6) potentials. Snapshots are created for visualization purposes. X-Ray Diffraction patterns and Radial Distribution Functions are calculated for direct comparison with sputter deposition experiments. Different film morphologies and structures are evidenced when the Zr/Cu composition ratio and the argon sputtering gas pressure are varied. Varying the argon sputtering pressure results in the variation of the Zr and Cu kinetic energies which in turn modifies the input parameters for carrying out the MD simulations. The results are compared with X-Ray Diffraction and Scanning Electron Microscopy analyses of experimentally deposited thin films by magnetron co-sputter deposition. Both simulation and experimental results show that the structure of the Zr_xCu_{100-x} film

varies from crystalline to amorphous depending on the Zr concentration. The kinetic energy affects the layer morphology : below a threshold kinetic energy the film is nanostructured and above it becomes continuous.

Recently, we demonstrated that the group 4 metal Zr can form 111-oriented δ -ZrH₂ films when deposited on Si(100) substrates by reactive high power impulse magnetron sputtering (HiPIMS) and direct current magnetron sputtering (dcMS) [1]. X-ray diffraction (XRD) patterns recorded from films grown in mixed Ar and H₂ plasmas containing: 2.5, 5, 10, 15, and 20% H₂ as seen from the resulting total pressure show that the phase is obtained by both techniques. Time-of-flight energy elastic recoil detection analysis (ToF E ERDA) shows that the films contain up to 61 at.% hydrogen and are very pure with oxygen contents less than 0.2 at.%. Scanning electron microscopy (SEM) images show that the δ -ZrH₂ film deposited by HiPIMS exhibits a glass-like microstructure and a smooth surface structure, while the dcMS film shows a more columnar growth behavior, see Fig. 1; both Zr reference films display a rougher surface and a ductile behavior when fractured for analysis with SEM. Four point probe measurements yield typical resistivity values of about 90-120 $\mu\Omega\text{cm}$. Mechanical properties investigations, as obtained by nanoindentation gives hardness values of 6-7 GPa, and reciprocating tribological tests gives a friction coefficient of ~ 0.15 for both deposition methods. In contrast, for the group 6 metal Cr, we find a different behavior as ToF E ERDA reveals that no hydrogen (< 0.5 at.%) is incorporated into the films even at the highest investigated H₂ partial pressure (20%). However, the resulting film oxygen content is notably low (≤ 0.1 at%), in particular when hydrogen is added to the plasma. XRD shows that all Cr films are 110 oriented, and SEM shows that the films grown by dcMS exhibit a columnar microstructure while those deposited by HiPIMS

display a more glass-like microstructure. Nanoindentation shows hardness values of about 16 to 19 GPa for films grown by both techniques irrespectively of hydrogen presence in the plasma. Four-point-probe measurements show resistivity values of $\sim 30 \mu\Omega\text{cm}$ for all films, i.e. approximately twice the value for bulk Cr ($\sim 13 \mu\Omega\text{cm}$). In addition, results from reactive sputtering of the group 5 element Ta in H_2 will be presented.

We report on thin RF-sputtered Ga-doped ZnO layers on gallium phosphide (GaP) substrate and GaP nanowires (NWs); the latter were grown by metal organic vapour phase epitaxy (MOVPE) on the GaP (111)B substrate. The RF-sputtering conditions were adjusted to deposit very thin ZnO layers with defined electrical parameters onto the GaP NWs and substrate, hereby forming a core-shell GaP/ZnO NW surface structure. We studied the properties of planar ZnO layers and core-shell GaP/ZnO NWs using scanning electron microscopy (SEM), transmission electron microscopy (TEM), atomic force microscopy (AFM), and electrical and photocurrent measurement.

Detailed TEM observation showed that ZnO shell consists of multilayered system of ZnO nanocrystallites (grains). This behaviour was observed even the thinnest shell layers (10nm thick) too. Detailed description of the ZnO shell structure is in our previous work [1]. The longitudinal TEM view showed that ZnO deposited on the GaP NWs has a columnar morphology. The columns are inclined at a positive angle close to 70 ° with respect to the GaP core axis; all columns we observed were tilted at this angle to the growth direction. Although we did not observe ZnO columns tilted at 109.5 ° to the growth direction, this possibility cannot be excluded at this stage. One can suppose that ZnO nanocrystallites grew preferentially on the {111}B GaP NW facets.

The polycrystalline character of the ZnO layer, inferred from the TEM images, was confirmed in the XRD pattern. The size of crystallites evaluated from XRD measurements (application of Scherrer's formula) was in agreement with the size of nanocrystals observed in TEM (an order of nanometers). It is known that thin ZnO films grow preferentially along the c-axis because of anisotropy in growth rate, as its various crystallographic planes differ in surface energy. In addition, the NWs had defects formed in them during the deposition of ZnO because they were bombarded at high energies by oxygen species from ZnO and Ga₂O₃. The crystallographic quality of the NWs can be improved by thermal annealing [2,3]. Our samples of ZnO:Ga thin films were annealed in vacuum and in

forming gas at temperatures from RT to 500 °C. The changes of XRD patterns before and after annealing process will be presented. The width of the (002) peak decreased noticeably after annealing. Its full width at the half maximum (FWHM) decreases from 0.795 degrees to 0.57 degrees. Furthermore, the intensity of the peaks increased by a factor of 1.95. Both these observations indicate the increase of the quality of the nanocrystalline ZnO with possible increase of the grain size.

Thermally stable Ag thin films with various surface nanolayers

T14 Thin Films

#TF-P2-04

M. Kawamura, Z. Zhang, Y. Abe, K.H. Kim.

Kitami Institute of Technology - Kitami (Japan).

Silver (Ag) has long been of interest for use as a low-resistivity electrode material, but the problem of agglomeration caused by annealing must be resolved.(1) As a solution, introduction of surface layer and/or interface layer has been reported instead of a solution by alloying Ag.(2-4) In this study, we have investigated usefulness of various metals for surface nanolayers. 60 nm thick films of Ag, Pd, Ni, W, Ti, Nb were deposited on thermally oxidized Si substrate by RF sputtering method. The films were annealed under vacuum at 600 °C for 1 hour. Figure 1 shows surface morphology of all the samples by SEM observation. The roughness values were obtained by AFM observation. Severe agglomeration is confirmed for Ag film (a) where substrate is largely revealed. Pd film (b) and Ni film (c) show surface roughening with many small voids. On the other hand, W (d), Ti (e) and Nb (f) films have very smooth surface. Thus, we have confirmed that these three metals are hardly agglomerated by annealing under vacuum. W and Nb have high cohesive energy in common.(5) That of Ti is not very high, but fast oxide formation at its surface is considered to be useful for film stability. Next, we introduced 5 nm thick surface metal (Pd, Ni, W, Ti or Nb) layer on 100 nm thick Ag thin film deposited on thermally oxidized Si substrate, followed by vacuum annealing at 600 °C. As a result, surface morphology was largely different. Namely, with Pd or Ni surface layer, surface was rough and roughness was over 10 nm. On the other hand, smooth surface with 2 nm of roughness was obtained with W, Ti or Nb surface layer. In conclusion, we have found that W, Ti and Nb, which have high morphological stability on annealing, are appropriate for surface nanolayer to prepare thermally stable Ag thin films.

Cerium oxide is very attractive material due to its catalytic activity. It is widely used in catalysts and solid oxide fuel cell nowadays. Its catalytic activity is based on relative

easy change of cerium oxidation state via the reversible reaction $2\text{CeO}_2 \rightleftharpoons \text{Ce}_2\text{O}_3 + 1/2 \text{O}_2$. Changes from oxidized Ce⁴⁺ to reduced Ce³⁺ are accompanied by the formation of mobile oxygen vacancies. While ordered stoichiometric layers of model CeO₂ catalyst are commonly prepared, cerium oxide with vacancies is restricted mainly on disordered systems.

In this work, we prepared very thin ordered continuous layer of CeO_x by cerium evaporation onto the oxygen precovered Cu(110) surface. X-ray photoelectron spectroscopy (XPS), low energy electron diffraction (LEED), ion scattering spectroscopy (ISS) and scanning tunneling microscopy (STM) were used for the characterization of prepared systems. The mix of (2x1) and c(6x2) surface reconstruction was formed by oxygen exposure at 300 °C. Cerium was deposited on this surface also at 300 °C. Afterwards temperature stability of this system to 700°C was studied. At first the formation of hexagonal Ce₂O₃(0001) continuous epitaxial film was observed, accompanied by the creation of large hundreds nm long smooth band structures in the [1-10] direction. After annealing to higher temperature the cerium oxide film became gradually discontinuous and oxidation state of cerium significant changed from Ce³⁺ to Ce⁴⁺. The formation of CeO₂ regions with saw-tooth relief with the (1,5x1,5) periodicity with respect to the substrate on facets was observed, accompanied by disappearance of Ce₂O₃(0001) areas. Subsequent oxidation caused the change of morphology and formation of CeO₂ regions with the (1,5x2) periodicity with respect to the substrate.

Cerium oxide thin film catalysts with different thickness were prepared by magnetron sputtering technique on graphite foil. Scanning electron microscopy (SEM), atomic force microscopy (AFM) and transmission electron microscopy (TEM) were used for investigation of surface morphology of the films. Chemical composition of the catalyst was investigated by using photoelectron spectroscopy (XPS) and electron energy loss spectroscopy (EELS).

It was found that magnetron sputtering of ceria led to the formation of nanostructured high surface area catalyst when deposited on carbon substrate. The mechanism of the formation of such structure was explained through simultaneous deposit growth and oxygen plasma etching of carbon substrate. It was also found that thickness had a crucial influence on the structure and morphology of thin films. Hence, we are able to tune the morphology, i.e. active surface area, and stoichiometry of sputtered ceria films by simply changing the deposition time which makes this method promising for production of thin film catalysts. It opened the way to preparation of novel planar catalytic micro-reactors by using planar technology techniques.

The growth of thin films depends on the characteristic of the species impinging on the substrate. And these are ruled by the deposition conditions and the process. Taking them into account makes simulated results closer to experimental ones.

In this study, we developed a strategy based on three different tools to simulate the three-dimensional growth of thin films.

- SRIM [1], which takes into account the power applied to the chromium target and simulates the sputtered particles flux.
- SIMTRA [2], which considers the deposition conditions (working pressures, dimensions of the chamber, target-to-substrate distance, target material...) and gives the impinging particles flux on the substrate.
- Simul3D [4], which simulate the growth of the films, taking into account the process conditions and allow obtaining physical information (roughness, density...)

One of the main challenges is to determine the behavior of an atom impinging on the film, in particular sticking and diffusion phenomenon.

This strategy is use in the case of Cr/CrN_x periodic multilayers. They were deposited by reactive magnetron sputtering with a pulsing gas process [4], which alternates reactive and metallic sputtering modes. The duty cycle α between nitrogen injection and non-injection time (t_{on} and t_{off} respectively) was fixed at 50% of the pulsing period T using a square signal. The period T was systematically changed from 10 to 320 s for a same film thickness (± 50 nm).

The deposition conditions and the process are monitored and then used in the simulations tools. The results obtain by simulation are studied at each steps of the strategy. The simulated films are then compared to the experimental characterizations.

Metallic (Me) oxynitrides (MeN_xO_y) are an attractive class of materials of emerging interest due to a unique set of versatile properties in different technological domains such as protective applications (wear, diffusion and corrosion-resistance), decorative coatings for high-quality consumer products, gas barriers, microelectronics, optoelectronics, solar cells, etc. Among the group of already studied oxynitrides, aluminium oxynitride (AlN_xO_y) presents some interesting characteristics to be used in different technological fields, since it may combine the behaviour of metallic aluminium, and those of the base binary systems: aluminium nitride, known for its semiconducting and piezoelectric properties and aluminium oxide, for its protective and insulating performance. In this work, thin films of AlN_xO_y were prepared by reactive DC magnetron sputtering, using a pure Al target and an $\text{Ar}/(\text{N}_2, \text{O}_2)$ gas mixture. The particular stoichiometry, structure and morphology of the films leads to the formation of a nanocomposite-like material, with Al nanoparticles randomly dispersed in an AlN_xO_y matrix, forming a percolating network. This fact induced a

wide variation in the electrical properties [1], such as a gradual transition from positive to negative temperature coefficients of resistance (TCR) as the non-metallic/Al atomic ratio increases; as well as distinct optical responses [2], such as an unusual large broadband absorption for some stoichiometries. The nanocomposite films are also very stable in terms of their microstructure and resistance to chemical degradation, even immersed for several weeks in typical solutions such as NaCl. This set of properties opens a wide range of possible applications in the electrical-driven application and in optical coatings such as those used in concentrated solar power systems.

Cerium oxide thin films supported by sputtered a-C and CNx films on silicon for the use as a catalyst in micro fuel cells

T14 Thin Films

#TF-P2-25

M. Dubau, I. Matolínová.

faculty of mathematics and physics, Charles University Prague - Prague (Czech republic).

Cerium oxide has received much attention due to its promising catalytic properties for a variety of reactions [1-2]. The main goal of our research activity is focused on the fabrication of catalytically active (e. g. for methanol oxidation) cerium oxide based thin films on silicon with large surface for the application as a catalyst for on-chip micro fuel cells. It was shown in an earlier study, that cerium oxide based thin films exhibit a porous structure on glassy carbon [3]. Furthermore, it was shown that partial oxygen plasma etching of the glassy carbon substrate during cerium oxide film deposition is very likely the driving force for the formation of the observed porous structure of cerium oxide. In this contribution we will show to what extent it is possible to achieve similar results on silicon substrates using sputtered amorphous carbon films (a-C) and nitrogenated amorphous carbon films (CNx) as an interlayer. Amorphous carbon and CNx films have been deposited via magnetron sputtering on silicon and studied with respect to their morphological and structural properties. In the second step of this study the behavior of these films in oxygen plasma has been investigated. It was found out, that oxygen plasma treatment leads to a morphological and structural modification of the a-C and CNx film. Besides, CNx films exhibit a significantly lower resistance against oxygen plasma leading to a higher etching rate compared to a-C films. The third part of the study covers the investigation of the morphology and structure of cerium oxide films supported by an a-C or CNx film on silicon depending on cerium oxide film thickness. Investigation with SEM revealed that cerium oxide exhibits a highly porous structure on CNx, while the a-C supported cerium oxide film has a fine grainy surface structure. Investigation with XPS showed that the CNx supported cerium oxide film contains a significantly higher fraction of the Ce³⁺ oxidation state at the interface compared to the a-C

supported film. Together with the porous surface structure of the CNx supported cerium oxide film these results promise a high catalytic activity of the cerium oxide film.

¹Institute of Metal Research Chinese Academy of Sciences - Shenyang (China),
²Key Lab of Material Processing and Mould Technology - Wenzhou (China).

Hard nanocomposite Ti-Cu-N films were deposited on high-speed-steel (HSS) substrates by pulse biased arc ion plating with a TiCu (88:12 at. %) single multi-component target. The effects of pulse bias duty cycle of elemental content, structure and mechanical properties of the films were investigated. The Cu atomic content of Ti-Cu-N films was examined by Electron Probe Micro-Analyzer (EPMA). The structure was determined by X-ray diffraction (XRD). Hardness and elastic modulus were determined by nanoindenter. The results showed that the content of Cu appeared to decrease with the duty cycle increasing from 10 to 50 % under the pulse bias voltage of -300 and -600 V. The XPS spectra of Cu 2p of the Ti-Cu-N films showed that there is only pure metallic Cu in the films. The diffraction peak of TiN in preferred orientation (111) was observed when the pulse duty cycle increased to 30 and 50% under the pulse bias voltage of -300V, whereas the corresponding peak changed to preferential orientation (220) when duty cycle increased to 30 and 50% under the pulse bias voltage of -600 V. And no obvious sign of metal copper phase was observed in the XRD patterns. The value of hardness under pulse bias voltage of both -300 and -600 V firstly increased and then decreased with duty cycle increasing from 10 to 50 %. Hardness enhancement was observed, the maximum value of the hardness, 31.5 GPa, was obtained with duty cycle 30 % under -600 V, corresponding to Cu content of 1.75 at.%. The hardness enhancement was discussed.

Gold/yttria-stabilized zirconia nanocomposite films at the nanoscale

T14 Thin Films

#TF-1-Or-5

D. Horwat, J. Ghanbaja, S. Migot, J.F. Pierson.

Institut Jean Lamour - Nancy (France).

Microstructural and chemical analyses are routine characterizations in materials science. Information at the atomic scale (coordination, oxidation states) is particularly relevant to understand the physical and chemical properties of materials. The local interaction of noble metals and oxides can generate specific local chemical and structural states, which is particularly true when an element can diffuse at the metal/oxide interface [1, 2].

In this communication we treat the case of gold/yttria-stabilized zirconia nanocomposite thin films relevant for the fields of low friction, plasmonics and catalysis. We use local analytical methods available with high resolution transmission electron microscopy (HRTEM) for structural investigation and elemental mapping at the nanometer and atomic scales. X-ray photoelectron spectroscopy (XPS) was used to determine the metal oxidation state. Spectrophotometry has been used for the detection of localized surface plasmon resonance (LSPR), which the results are compared to the literature [3]. Electrical investigations were conducted by "4 point" probe, which are in line with the local chemistry. A special attention was paid to the oxidation state of the metal atoms in relation to the size of the nanoparticles. The size is controlled by the synthesis parameters and the gold content. The influence of the local state on the plasmonic, electrical and catalytic properties is demonstrated.

Tokyo Institute of Technology - Tokyo (Japan).

Perpendicular magnetic anisotropy (PMA), which can result in preferentially magnetization in the direction perpendicular to the film plane, has long been a research interest. PMA has been found in layered structures consisting of magnetic metals and noble metals, for example Co/Pd, Co/Pt,¹ and CoPt/AlN layered structures.² In this work we study the magnetic anisotropy of another metal alloy/nitride layered structure, FePt/AlN layered structure.

The M-H loops of sputter-deposited $[\text{Fe}_{0.4}\text{Pt}_{0.6}(2 \text{ nm}) / \text{AlN}(20 \text{ nm})]_5$ layered structures are shown in Fig. 1. It is clear that the as-deposited film (Fig.1a) show in-plane magnetic anisotropy. However, the anisotropy of the layered structures can be altered through annealing. As shown in Figs. 1(b)–1(f), the easy axis of magnetization turn from in-plane to out-of-plane direction with increasing annealing temperature.

In order to understand the change of magnetic property, the structure of the layered structures was characterized by XRD, and the results are shown in Fig. 2. The layered structures show preferred orientations of FePt [111] and AlN [001] parallel to the growth direction. When annealing at temperatures above 500°C, highly symmetrical satellite peaks can be seen clearly superimposing the FePt 111 peak, indicating the sharpness and flatness of interface are enhanced by annealing. Another phenomenon needed to mention is that the peak position of FePt 111 shifts to higher angles with the increasing of annealing temperature. This suggests the change of internal stress inside the FePt layers.

It is considered that transition of the magnetic anisotropy with increasing annealing temperature is due to the improvement of interface quality between FePt and AlN layers and the evolution of internal stress.

b: Department of Physics, Rajarshi Shahu Mahavidyalaya - Latur-413512, India.

Abstract:

A simple and inexpensive chemical bath deposition technique is employed for the deposition of Cd_{1-x}Pb_xS ($0 \leq x \leq 1$) thin films. Cadmium sulphate, lead sulphate and thiourea were used as the basic starting materials. TEA was used as complexing agent. For good quality deposits the various preparative parameters such as deposition temperature, time, speed of substrate rotation and pH of the reaction mixture were optimized to 80 °C, 60 min., 65 rpm and 10.5±0.1 respectively. The 'as-grown' samples were characterized through structural, surface morphological, compositional, optical, electrical and thermoelectric studies. The color of 'as-grown' samples changed from orange yellow to black as x changed from 0 to 1. The X-ray diffractograms of 'as-grown' samples exhibited polycrystalline nature with presence of cubic phases for CdS and PbS and hexagonal phase for CdS alone [1]. The crystal size determined from XRD and SEM micrographs is observed to increase with 'x' up to 0.175 and later on it decreased. The energy dispersive analysis by X-rays (EDAX) revealed that films are cadmium rich. The optical study at room temperature revealed high coefficient of absorption (10^4 cm^{-1}) with a direct allowed type of transition with band gap energy decreasing continuously from 2.47 eV to 0.49 eV with varying composition parameter 'x'. The electrical resistivity measurements revealed semiconducting nature of the film and it is found that the resistivity of the film decreases with increase in 'x' up to 0.175 and further it increases up to x = 1 [2]. The n-type conduction was observed in film from TEP studies [3-4].

Keywords: Chemical bath deposition, Cd_{1-x}Pb_xS thin films, XRD, EDAX, SEM.

Stabilisation of α and β phases of Ta thin films grown by magnetron sputtering

T14 Thin Films

#TF-1-Or-6

A. Michel, J.J. Colin, G. Abadias, C. Jaouen.

Institut Pprime, CNRS- Université de Poitiers- ENSMA, Département de Physique et Mécanique des Matériaux - Poitiers (France).

Considerable research has been carried out in the recent years on the growth of Ta thin films using sputter deposition techniques [1,2]. The technological interest in such films arises from a wide range of potential applications: Ta films can be used in fields spanning from diffusion barriers in micro-electronic devices to protective hard coatings. However, in most of these applications, the physical properties of Ta that are sought are based on the electrical and mechanical properties of the well-known cubic α phase. Therefore, the occurrence of either the α or β -Ta phase plays a key role since, indeed, the metastable β phase, characterised by high electrical resistivity and ill-known mechanical properties, often appears during thin film growth, as dynamic growth processes sometimes oppose thermodynamic equilibrium-based predictions.

In the presented work, Ta thin films were grown using a magnetron sputtering chamber equipped with a multiple beam optical stress sensor (kSA-MOSS system) that allows a real-time *in-situ* monitoring of the stress state of the film. Special attention is given to the control of all parameters during the growth, in order to separate the effects of temperature on the one hand and energy of deposition due to the sputtered species on the other hand. Additionally, the effect of different buffer layers on the film structure was examined. *Ex-situ* investigation techniques (X-Ray diffraction, X-ray reflectivity, electron microscopy, AFM, ...), were used in order to obtain as much as possible information on structure, defects and microstructure of the deposited thin films.

It is shown that the β -Ta phase is favoured during RT growth on neutral substrates such as amorphous Si, however the nucleation occurs only after the formation of an

initial amorphous layer (2-3 nm thick). This β -Ta phase formation is extremely stable concerning the energy deposition involved during growth (pressure during deposition ranging from 0.1 to 0.8 Pa, bias voltage applied to the substrate reaching 200 V). However, when the substrate temperature is increased, nucleation of α -Ta phase becomes possible; therefore, a temperature region of coexistence of the two allotropic phases was determined, pure α -Ta films were obtained at higher temperatures ($T > 550$ K).

An analysis based on the minimisation of the surface/interface energy versus volume energy shows that all results can be interpreted by the nucleation-and-growth approach. The lower surface energy of the (002) textured β -Ta phase then acts as the driving force for low temperature phase stabilisation, whereas at higher temperatures, the increasing difference in Gibbs energy of the respective α and β phases turns, in terms of nucleation, to the advantage of the α -Ta phase.

Study of Sheath in Multicomponent Plasmas

T14 Thin Films

#PST/SE/TF-P1-08

S. Novak, P. Cerny, P. Bruna, R. Hrach.

J. E. Purkinje University - Usti Nad Labem (Czech republic).

A detailed description of physico-chemical processes taking place during an interaction of plasmas with solid surfaces is rather difficult, especially at higher pressures and/or in chemically active plasmas, and thus a combination of experimental and computational approaches is used. Negative ions in such plasmas influence the transport of charged species from the plasma to the immersed solids [1]. First results have been obtained in a 1D approximation [2].

Two different techniques of computational physics were used. First, the particle simulation approach based on the self-consistent PIC-MCC technique was used for study of the interaction between the low-temperature multicomponent plasma and the surface immersed. An effective particle model is used. As input the concentrations of the basic charged species obtained from the following model were used.

The macroscopic kinetic approach was chosen for a study of chemical processes in the chemically active plasma. The kinetic scheme contained more than one hundred reactions between neutral, charged, and excited species in oxygen and argon. The chemical reactions and corresponding rate coefficients were obtained from both the literature and the calculations with help of the ELENDF program. The time dependencies of concentrations of the neutral, excited, and charged species were obtained for various discharge parameters in a DC glow discharge in Ar/O₂ mixture.

Results of the 2D computer simulations describing the interaction between the low-temperature multicomponent plasma and the immersed metal substrate are presented and compared to the experimental data. The potential distributions in the sheath and presheath were calculated and concentrations of all kinds of charged particles were determined in the dependence on plasma parameters, especially on plasma pressure. The simulations were performed both in the static and dynamic regimes.

For the detailed plasma characterization, the multicomponent plasma consisting of more types of positive and negative species was used. The concentrations of the most important species in oxygen plasma were obtained by the macroscopic kinetic approach [3]. These concentrations were used as input data for the particle simulations. An example of the particle simulation results derived in static case for higher pressure can be found in Fig. 1.

Numerical simulation of porosity development kinetics into multy-layer media

T14 Thin Films

#TF-P2-09

A. Bondareva, G. Zmievsckaya.

M.V. Keldysh institute of applied mathematics RA - Moscow (Russian federation).

Numerical simulation of the porosity in the thin layers may be applied to the technological mirror production, EUV-lithography applications, plasma engine wall erosion study, semiconductor devices and others. The generalized program system Stosh-An-1 had been developed for simulation of blistering in metals and dielectrics to apply it for models of radiation flow interaction with multilayered media with boundary condition variation between layers by consideration of the crystal lattice vacancies role in the formation of blisters under inert gas flow. The processes of chemically active gases collisions with pore walls are included in the model. Hibbs energy model of pore nucleation is complemented by considering the stress in the crystalline lattice caused by parameter mismatch of layer lattices. The model of Brownian movement of defects based on previously developed methods of accounting the long-range potential of elastic interaction of defects by excitation of acoustic phonons in lattice matrix and Frenkel oscillations of electron density is complemented by taking into account the orientation of crystallographic planes of body-centered lattices of sample material relative to the flow. The numerical investigation has been conducted according to the model of blister (vacancy-gas pores) merging into defect structures on the characteristic times of the fluctuation stage of phase transition "vacancy (gas) in lattice - pores". The structure sizes (the number of blisters in the structure) are defined. Using the distribution function of blisters by sizes and placement in the layers the porosity of sample layers and the contribution of pressure contrasts on the bubble boundaries to layer stress are determined. Further stressing of the elongated defect structures may lead to crack formation. The diffuse shuffle of atoms and chemical composition formation on the interlayer surface (in the limits of several monolayers) should be modeled separately. In the current simulations the arising roughness of the layer boundary surface is modeled using the initial fractal distribution of interlayer surface areas and deviations

of their depth relative to the disturbance source. The prospects of the interlayer surface flattening under Xe^{++} radiations are investigated. The method of boundary projection of the elongated defect structures onto the crystallographic planes of layer materials is developed, including the ones perpendicular to the incident flow (crystallographic plane 001) and parallel to it (crystallographic plane (100) and (010)) at bilayer sample temperatures from 0.4 to 0.6 of Molibden melting point, radiation level from 10^{14} to 10^{18} cm^{-2} , ion energy from 1 to 10 keV. Their sizes had been determined. The contribution of radiation defects in Silicon Carbide coating to the stressed layer condition is comparable to the contribution of the lattice parameter mismatch in the "metal-semiconductor" bilayer under the assumption of coherent state of the interlayer boundary. It has been discovered that the average blister sizes in the both layers of the substrate (in both metal and semiconductor) depend nonlinearly on the temperature. Work is partially supported by the RFBR grants 11-01-00282-a, 12-01-00490-a and 12-01-00708-a).

¹Institut de Chimie de Clermont-Ferrand, Clermont Université, Université Blaise Pascal, BP 10448, F-63000 - Clermont-Ferrand (France), ²Institut de Chimie de Clermont-Ferrand, Clermont Université, Université Blaise Pascal - Clermont-Ferrand (France), ³Institut de Chimie de Clermont-Ferrand, Clermont Université, Université Blaise Pascal, - Clermont-Ferrand (France), ⁴Institut Pascal, Clermont Université, Université Blaise Pascal, BP 80026, F-63171 AUBIERE - Clermont-Ferrand (France), ⁵Institut Pascal, Clermont Université, Université Blaise Pascal, - Clermont-Ferrand (France).

Although the market for photovoltaic products is evolving rapidly, photovoltaic developers are concerned about the price. The optimization of the electrical properties of the active layers is progressing. However, the optical properties of the entire device have also to be optimized, especially for thin Si-based film solar cells. In order to capture the maximum of photons, and so to ensure the highest photovoltaic yield, antireflective layers should be very efficient.

Our challenge is to explore powerful and economical routes using radio-frequency magnetron sputtering, a cheaper and a well-controlled industrial process to develop complex antireflective systems. We are focused on the control of the deposited thin film optical properties through their composition by tuning the deposition parameters (target, gas flows, cathode power, pressure, substrate temperature...). With a refractive index tunable between 1.46 for pure silicon oxide to 2.03 for silicon nitride [1], silicon oxynitrides are interesting candidates for antireflective thin films. Their deposition was carried out using an argon, oxygen and nitrogen gas mixture from a silicon target. In a first step of our work, Argon and nitrogen were introduced at constant gas flows,

whereas oxygen gas was pulsed in order to adjust films' chemical composition over a large range [2]. For constant T_{on} and T_{off} pulse durations, we get a specific composition of SiO_xN_y with a specific refractive index. Then, by changing the O_2 gas flow pulse durations during the deposition steps, we predict a gradient of composition which leads also to a controlled refractive index gradient. It is a way to improve Si thin film photovoltaic yield with an economical process. The plasma analysis has been carried on by time-resolved Optical Emission Spectroscopy to identify the generated species in the plasma, and to follow their evolution during the deposition steps. The film composition is investigated by Rutherford Backscattering Spectroscopy, and their structural properties by Fourier Transform Infrared Spectroscopy. The optical properties have also been studied by spectroscopic ellipsometry and by UV-visible absorption spectroscopy. In addition, to optimize the performance [3] of the realized structures and for a better understanding of their optical properties, an electromagnetic nanostructure model has been established.

TF-4-Or-7

The effect of substrate temperature and direct current bias on the properties of titanium oxide thin films elaborated by pulsed filtered cathodic arc technique.

T14 Thin Films

#TF-4-Or-7

F. El Ghoulbzouri, M.P. Delplancke.

Princ - Brussel (Belgium).

Titanium dioxide thin films were deposited on silicon wafer (100) by pulsed cathodic arc technique in an oxygen atmosphere. We studied the effect of substrate temperature and the DC substrate bias on the properties of the elaborated thin films. The crystalline structure, mechanical properties, topography and microstructure were characterized by X-ray diffraction, Raman spectroscopy, nano-indentation, Atomic Force microscopy and Transmission electron microscopy. Without a substrate bias, a transition from amorphous to rutile phase was observed at a temperature of 673 K. The crystalline thin films do not exhibit a preferential orientation. By applying a DC bias of -200 V, we could decrease the temperature at which the crystalline phase occurs to 473 K. In fact, at this temperature, XRD patterns and Raman spectroscopy data showed a formation of Ti_2O_3 thin film. The transition to rutile phase was observed at a substrate temperature of 673 K. All the elaborated crystalline thin films at -200 V DC-bias exhibit a preferential orientation due to the combination effect of substrate heating and bias, allowing to promote the thin film growth according to the lowest energy state. Cross section TEM micrograph (Fig. 1) revealed a columnar growth for the crystalline layer, the grain diameter could be estimated in order of 20 nm. Unfortunately, the application of a DC bias on the substrate over a range of -100 V to -400 V at room temperature was not enough to promote the formation of a crystalline phase. The hardness and the reduced Young modulus of the amorphous/rutile TiO_2 coatings were respectively in order of 8 GPa /19 GPa and 90 GPa/200 GPa. The root mean square roughness measured on a scanned area of $1 \times 1 \mu m^2$ was in the range of 1 nm to 2 nm.

TEM cross section of TiO_2 thin film deposited at a substrate temperature of 873 K and a DC substrate bias of -200 V.

Performance evaluation of h-BN coatings prepared on titanium via polymer pyrolysis in RTA furnace

T14 Thin Films

#SE/TF-1-Or-4

B. Toury ¹, Y. Sheng ², S. Benyoun ².

¹Université de Lyon - Villeurbanne (France), ²Ecole Centrale de Lyon - Ecully (France).

Today, the aeronautic industry requires the use of titanium alloys-based mechanical tools or components in more and more severe conditions (i.e. high temperature, corrosive and oxidative atmospheres), imposing to coat the solicited piece with a protective coating. Hexagonal boron nitride (h-BN) is known to be eco-friendly, thermally and chemically stable and especially self-lubricant. Thus, shaped as coating, it represents an environmentally acceptable solution to fight against galling and/or wearing solicitations and thus increase the life-time of those metal parts. h-BN coatings have been prepared through the Polymer Derived Ceramics (PDCs) route and annealed via infra-red irradiation performed by Rapid Thermal Annealing (RTA). Resulting coatings have been demonstrated as crack-free, recovering and homogenous films. Chemical analyses performed on samples annealed at least at 1350 °C under nitrogen or argon; show the presence of a TiN layer recovered by the expected h-BN. Adherence and friction coefficient measurements were carried-out by means of scratch-tests, calo-tests and tribological tests. Results exhibit a weaker friction coefficient for nitrogen-pyrolized samples, which can be explained by a thinner TiN interphase. However, all the samples display a good adhesion between the substrate and the coating, explained by the formation of Ti-B-N bonds at the interface. Hardness was also estimated by micro-indentation, different behaviour was observed between samples annealed under Ar ou N₂ probably due to different chemical composition of the coatings. Finally, the effect of ceramic charges and metallic nano-particles loaded in the coating during the synthesis process will also be investigated.

Structural and dielectric characterization of perovskite oxide and oxynitride lanthanum titanium films deposited by reactive sputtering deposition

T14 Thin Films

#TF/SE-1-Or-8

C. Le Paven ¹, Y. Lu ¹, H. Nguyen ², R. Benzerga ¹, L. Le Gendre ¹, A. Sharaiha ¹, C. Delaveaud ³, F. Tessier ⁴, F. Cheviré ⁴.

¹IETR - Saint Briec (France), ²IETR / CEA Leti - Saint Briec (France), ³CEA Leti - Grenoble (France), ⁴ISCR - Rennes (France).

In the field of microwaves, the needs of materials with high performances drive the research on perovskite type structure compounds which present attractive dielectric and ferroelectric properties. Our contribution is related to the development of lanthanum titanium perovskite oxide (LTO) and oxynitride films (LTON), for which the substitution between oxygen and nitrogen atoms allows to tune the dielectric properties. Single layers, mixed films and multilayers have been deposited by reactive RF magnetron sputtering using an oxide $\text{La}_2\text{Ti}_2\text{O}_7$ or an oxynitride LaTiO_2N homemade target. Depending on the reactive gas and the nature of substrate, various chemical composition and crystalline textures of films have been evidenced. The dielectric measurements were performed on MIM devices at low and high frequencies. The LTO oxide films present a moderate dielectric constant ($\epsilon = 60$) with very low dielectric loss ($\tan\delta = 0.011$) at 10 GHz, with no variation of ϵ under the application of DC electric fields. The dielectric constant of LTON oxynitride films is higher, with values of few hundred but with substantial dielectric loss. The LTON films show a variation of ϵ , but only in low frequency ranges (up to 1 MHz), for example the tunability is 8 % at 100 kHz with a maximum applied field of 16.7 kV/cm. LTO/LTON bilayers exhibit improved values compared to "pure" oxynitride films, for example a maximum applied field of 44 kV/cm with a tunability of 15 % (Figure 1). The absence of tunability of oxynitride films in high frequencies, as well as the observed dispersed results, suggests that the LaTiO_2N compound does

not behave as a ferroelectric material. In accordance with literature, its nonlinear dielectric properties may be related to polar nano-regions, coming from a local ordering of oxygen and nitrogen ions in the perovskite structure.

Figure 1. Evolution of the dielectric constant (a) and the dielectric loss (b) depending on a DC bias at 100 kHz of a LTO/LTON bilayer deposited by reactive sputtering with a $\text{La}_2\text{Ti}_2\text{O}_7$ oxide target.

Phase transformation of amorphous TiO₂ films to anatase / rutile crystalline structure

T14 Thin Films

#TF-P2-26

J. Bruncko ¹, M. Netrvalova ², A. Vincze ¹, P. Sutta ².

¹International Laser Centre - Bratislava (Slovakia), ²New Technology Research Centre West Bohemian University - Plzen (Czech republic).

TiO₂ is one of the most studied transition metal oxide that exists at two main polymorphs – anatase and rutile. The increasing application interest (sensor applications, solar cells, photo-catalytic materials, etc.) demands preparation of nanostructured TiO₂ films with controlled phase structure. Phase composition of the functional structures impacts on their performance and efficiency. Both phases crystallises in tetragonal crystal structure but in different space groups which implies that they have different physical properties and chemical behaviour. The contribution deals with TiO₂ films prepared by pulsed laser deposition (PLD). According to deposition conditions the resulted structure can be amorphous, anatase, rutile or mixed. PLD at room temperature usually lead to amorphous films. We propose an enhanced version of PLD with deposition on substrates cooled below room temperature. Films deposited by such manner exhibited highly porous nature assembled in a very fine hierarchical (like fractal) dendritic arrangement of nanoparticles smaller than 10 nm. Fig. 1 shows a pair of SEM records of TiO₂ films. Fig. 1a represents the sample deposited on cooled Si (100) substrate while the sample shown in Fig. 1b was grown at room temperature. This example shows that despite the same property – both films are amorphous; they differ in porosity and surface morphology.

Phase transformation of amorphous TiO₂ to crystalline permitted controlling of phase composition in dependence on annealing process parameters and initial morphology. The films were investigated by various analytical methods (scanning electron microscopy, X-ray diffraction, optical emission spectroscopy, micro-Raman spectroscopy) and experimental results revealed that transformed films consist of 100% anatase up to 600 °C. They preserved high porosity (typical grain size around 10 - 20 nm) which is desirable property for sensor and photo-catalytic applications.

Fig. 1 The comparison of SEM images of TiO₂ films in as-deposited state prepared at different temperatures on Si (100) substrate (a – substrate temperature near 77 K; b - substrate at RT).

TF/SE-1-Or-11

Yttria-Stabilized Zirconia thin films as oxygen ion conductor for solid oxide fuel cells

T14 Thin Films

#TF/SE-1-Or-11

J. Lamas, W.P. Leroy, D. Depla.

Research group DRAFT - Ghent University - Ghent (Belgium).

Yttria-stabilized zirconia (YSZ) is one of the most popular materials chosen as electrolyte for solid oxide fuel cells. Due to its mechanical strength, chemical stability, high ionic conductivity, low electrical conductivity, good radiation-resistance and low cost, YSZ has also become a popular material in different applications, e.g., as buffer, oxygen sensors, nuclear applications and thermal barriers coatings. Current studies aim to lower the process temperature of the SOFC by reducing the thickness of the electrolyte. However, reducing the thickness might change the properties of the electrolyte in comparison to the bulk properties of these materials. The fundamental aspects of the oxygen ion conduction, for example, change due to the occurrence of nano-effects. That is why, the good understanding of the microstructure and crystallinity opens the possibility to manipulate the ionic conductivity.

A good approach for understanding the microstructure is the study of YSZ thin films ranging in composition by varying the deposition conditions. The variation of deposition conditions, such as pressure and Y target-substrate distance enables us to modify the film morphology and texture. In this work, YSZ thin films were deposited by the dual reactive magnetron sputtering technique. The analysis of these films were performed in two steps: first, it involves the characterization of the film in a crystallographic way using X-ray diffraction (theta-2theta configuration), pole figures and cross section images via scanning electron microscopy and transmission electron microscopy. The preferential orientation of these films were studied and correlated with an extended structure zone model of the growing material. The columnar microstructure present in those films was fitted in a quantitative model where the columnar angle is related to the variation of composition along the sample and its correspondent grain size. Secondly, it is based on the ionic conductivity of YSZ at different yttrium composition levels using electron impedance spectroscopy. Correlating both approaches allows us to identify the compositional and

crystallographic influences on the ionic conductivity and to unravel the oxygen ion conduction mechanism of the YSZ thin film solid state electrolytes.

Sputter yield amplification upon reactive serial co-sputtering of doped TiO₂

T14 Thin Films

#TF-9-Or-7

R. Schmidt ¹, T. Kubart ², M. Austgen ¹, A. Pflug ³, T. Nyberg ², S. Berg ², M. Wuttig ¹.

¹Institute of Physics, RWTH Aachen University - Aachen (Germany), ²Solid State Electronics, The Ångström Laboratory, Uppsala University - Uppsala (Sweden), ³Fraunhofer IST - Braunschweig (Germany).

TiO₂ plays a prominent role in several applications such as anti-reflective coatings [1] or self-cleaning surfaces [2]. Most frequently this material is deposited by reactive magnetron sputtering. Unfortunately TiO₂ suffers from a comparatively low deposition rate. To increase the deposition rate, Sputter Yield Amplification (SYA) can be used through recoil of the sputtering species at implanted heavy dopants below the target surface [3,4,5]. Here we present experimental results for different dopants using a dedicated sputter deposition tool which enables systematic studies of SYA. In this study the rate increase by SYA is investigated for different heavy dopants (e.g. Hf, Ta, W, Bi, etc.). Our experiments show that the rate increase of TiO₂ by some dopants (e.g. Bi) is surprisingly low, whereas other dopants, which are even slightly lighter, result in a large rate increase of up to 250%. This behavior demonstrates that sputter yield amplification does not only require a high mass of recoil atoms but also necessitates high surface binding energies. TRIDYN [6] simulations employing a model optimized for serial co-sputtering [5] confirm and explain the experimentally determined deposition rates.

Zinc oxide has been attracting particular interest because of its high optical transparency combined with an excellent electrical conductivity [1]. We incorporate wide band-gap p-GaP/n-ZnO nanowires (NWs) junction to increase solar cell efficiency to shift the absorption edge more to the blue part of the solar spectrum (350-480 nm) for an enhanced photon capture. The GaP NWs were prepared in an AIX 200 MOVPE low-pressure reactor by a vapour-liquid-solid method from 30 nm BBI colloidal Au particles from a water-based colloidal solution [2]. We discuss the deposition of ZnO thin layers on positioned GaP substrate and GaP nanowires by RF magnetron sputtering at different ZnO:Al target-substrate geometry. We selected the tilting angles (0°, 45° and 82°) of substrate normal to the target center-substrate center flow line, see Fig. 1. The surface morphologies of ZnO films and core-shell GaP/ZnO NWs were examined by AFM, SEM and TEM. TEM images of a GaP/ZnO NWs revealed that GaP nanowire has zinc blende crystal structure and growth axis [111], see Fig. 2. ZnO polycrystalline layer formed nano-crystals with wurtzite columnar structure. The positioning of the substrate to the target and its rotating has beneficial influence in the suppression of shadowing effect and provide more homogenized films. We simulated the influence of residual stress on bending of GaP/ZnO NWs using ANSYS software, results of calculations will be compared with experimental observations. The results revealed the ability to utilize p-GaP/n-ZnO NWs in the solar cells development and will be subjected for future electrical and optical properties investigation.

The work is supported by grant of Science and Technology Assistance Agency "GRONA" no. APVV-0301-10, and VEGA projects 1/1106/12, 1/0534 and 1/0439/13.

L. Nittler, Y. Busby, J.J. Pireaux.

University of Namur, Centre de Recherche en Physique de la Matière et du Rayonnement (PMR), Laboratoire Interdisciplinaire de Spectroscopie Electronique (LISE), rue de Bruxelles 61 - Namur (Belgium).

Nanoparticles (NPs) are not only of great scientific interest because they constitute a kind of a link between bulk materials and atomic or molecular structures, but also because they present a wide variety of potential applications in biomedical, optical, and electronic fields, to cite only a few of them. But in order to enhance optical or electronic performance for example, a control of size, shape and spatial distribution of the NPs is required.

Although the chemical synthesis of gold NPs (AuNPs) allows controlling their size and shape, the control of their spatial distribution over a surface or in a bulk is still a challenge. This is especially true for organic material substrates, where the interaction between solvent and the organic surface cannot be neglected.

In this study the deposition of well-defined Au nanoparticles is performed by the aerosol technique, which consists in an injection of a colloidal solution through a high pressure carrier gas pulse into a low pressure plasma reactor. The main advantage of this technique is to control independently the NP size and density for the deposition on nearly all kind of sample substrates under a controlled (eventually reactive) atmosphere.

We study the spatial distribution of AuNPs as a function of the deposition conditions. The main parameters which influence the NP deposition are the pulsing condition of

the aerosol technique, the carrier gas as well as the pretreatment of the polymer surface.

We will compare the deposition and coalescence of AuNPs on different sample surfaces by electron microscopy and AFM. Furthermore we will present preliminary results of the aerosol-AuNPs/polymer chemical interaction by high resolution XPS.

SE/TF-4-Or-5

Annealing effects on Raman spectra of nitrogen doped ZnO thin films produced by N₂-reactive sputtering

T14 Thin Films

#SE/TF-4-Or-5

O. Debieu, J. Cellier, A. Bousquet.

Institut de Chimie de Clermont-Ferrand, UMR 6296, Université Blaise Pascal, Campus des Cézeaux, 24 avenue des Landais, BP 80026, 63171 AUBIERE Cedex - Clermont-Ferrand (France).

ZnO has recently received particular attention because of its transparency and electrical conductivity which are interesting for future applications in optoelectronics. However, although n-type semiconductor material is now attainable, the reproducibility and the stability over time of p-type ZnO remain a barrier for the realization of p-n junction diodes. Nitrogen is one of the most promising candidates as acceptor dopants in ZnO since the N-incorporation by substitution of N atoms for O sites is facilitated by the similar atomic radius of N with O. However, the N-content and annealing treatment effects on the mechanisms of the generation of acceptors in ZnO are still unclear and need to be more extensively investigated through the combined analysis of the structural, optical, and electrical properties of N-doped ZnO. In this work, N-doped ZnO thin layers were produced by N₂-reactive magnetron sputtering. The films were deposited on Si wafer and fused silica substrates at various temperatures ranging from 50 to 400°C using Ar as the main sputtering gas. The doping concentration was set by the N₂ gas flow and monitored through the analysis of the plasma composition by optical emission spectroscopy. The film composition was investigated by Rutherford backscattering spectrometry and by X-ray photon spectroscopy. The optical properties were investigated by means of UV-visible absorption, photoluminescence, and spectroscopic ellipsometry. The carrier density and mobility were determined by Hall effects measurements. The film structure was investigated by X-ray diffraction, by electron paramagnetic resonance, by energy dispersive X-ray analysis, by high resolution transmission electron microscopy, and by Raman spectroscopy. Raman spectroscopy is particularly suitable for the analysis of the effect of the N content on the ZnO structure because of the coexistence of the anomalous (275 cm⁻¹), E₂-high (437 cm⁻¹), and A₁-LO (580 cm⁻¹) Raman modes which are related to the

substitution of N for O site, the wurzite crystalline structure quality, and the generation of defects, respectively. Besides, we compared the effect of conventional annealing and laser annealing on the Raman spectra in order to optimize the electrical and optical properties.

TF-4-Or-5

Asymmetrical diffusion at interface of Mg-based multilayer films

T14 Thin Films

Multilayer mirrors have been widely used as reflective element in the extreme ultra-violet (EUV) and soft x-ray regions. Interfacial diffusion is one of the most efficient defects that will reduce the reflectance. However interfacial diffusion in these nanoscale multilayers is a phenomenon not as well understood as diffusion in bulk materials. In this report, interface structure of Mg-based multilayer films as EUV reflectors has been studied. We deposited a series of multilayers with the structure of $[X_1/Mg/X_2] \times 5$ ($X_{1,2} = \text{SiC}, \text{Si}, \text{and C}$). The nominal thickness of Mg is 5.0 nm and that of $X_{1,2}$ is 2.5 nm. All multilayers were deposited onto polished Si (001) wafer at ambient temperature by direct current magnetron sputtering. The pressure of residual gas before deposition was 5.0×10^{-5} Pa and that of sputtering gas Ar was 0.13 Pa. X-ray grazing reflectivity (XRR) measurements were made for each sample using Cu K α source ($\lambda = 0.154$ nm) to determine the multilayer structure (Fig.1). The measured curves were fitted to obtain the interface width. X-ray photoelectron spectroscopy measurements were carried out for the three $[X/Mg/X]$ multilayer samples. Depth-profiles were obtained by Ar etching. Transmission electron microscopy (TEM) measurements were carried out for another three $[X/Mg/X]$ multilayer samples having the same structure with the period repeat number $N=80$. The cross-section samples for TEM were prepared by focused ion beam etching. X-ray diffraction measurements in the symmetric ($\theta-2\theta$) geometry were performed using Cu K α source ($\lambda = 0.154$ nm). The experimental results show that asymmetry is found on the interlayer thickness at all three interfaces. The thickness of the interlayer at Mg-on-Si (>7 nm) and Mg-on-C (>5 nm) is larger than that at Si-on-Mg (3 nm) and C-on-Mg (2.5–3 nm). In the Mg/SiC multilayer, opposite asymmetry is found as the thickness of the interlayer at Mg-on-SiC (1 nm) is smaller than SiC-on-Mg (2.5 nm). Based on XRD, XPS and TEM measurement results, different mechanisms for interfacial diffusion are proposed. These results are not only of fundamental importance in understanding the nanoscale interfacial diffusion but are also beneficial for improving the performance of Mg/SiC multilayers as EUV reflector by means of inserting diffusion barrier layers.

²Fraunhofer-Institut für Werkstoffmechanik IWM - Halle (Germany).

The application of energetic nitrogen ions, which possess hyperthermal kinetic energies instead of the thermal atomic nitrogen usually used in conventional molecular beam epitaxy (MBE) of GaN, introduces additional growth parameters to this already complex heteroepitaxial growth system. In analogy to conventional MBE of GaN, the ratio of the impinging hyperthermal nitrogen ion flux to the flux of the incoming Ga atoms (ion to atom ratio I/A) was observed to be one crucial parameter in ion-beam assisted molecular beam epitaxy (IBA-MBE), amongst others like the kinetic energy of the ions [1]. A window of suitable ion energies, where no ion collision induced defects are created below the surface, but instead only at the surface is used (for details see Ref. [2]). This provokes a rearrangement of surface atoms that can be interpreted as ballistically enhanced adatom mobility. Aim of the present study is to determine the influence of the hyperthermal ion irradiation on the nucleation, on the formation and growth of islands, as well as on the structural properties, the morphology and surface topography of the growing ultra-thin GaN films.

Ultra-thin GaN films were grown on 6H-SiC(0001) substrates by deposition of gallium and simultaneous irradiation with low-energy nitrogen ions (energy < 25 eV) delivered by a constricted glow-discharge ion source [3]. The GaN film formation at a constant substrate temperature of 700°C was studied in situ by reflection high energy diffraction (RHEED) during the deposition process and the surface topography of the deposited GaN islands and films on the SiC substrate surfaces was analyzed without interruption of the ultra-high vacuum by scanning tunnelling microscopy (STM). The crystalline structure and quality of the GaN films was studied by x-ray diffraction (XRD). Transmission electron microscopy (TEM) was applied to characterize the film microstructure. The results show that ultra-thin epitaxial GaN films can be obtained by ion-beam assisted molecular beam epitaxy [4]. The I/A ratio at constant nitrogen

ion flux and at constant substrate temperature has a major impact on the properties of the resulting ultra-thin GaN films. The growth mode, the surface roughness, the degree of GaN coverage of the substrate and the polytype mixture depend notably on the I/A ratio. Determined by the I/A ratio, the growth mode changes from three-dimensional (3D) to two-dimensional (2D) growth. At an I/A ratio ≤ 1.6 the formation of islands develops through rapid coalescence into 2D growth. 3D island growth is favoured at an I/A ratio > 1.6 . An increase of the island diameter to island height ratio with increasing I/A ratio is observed indicating an enhancement of the lateral growth. In the 2D growth mode, which leads to relatively smooth films of high crystalline quality, the formation of the zincblende polytype of GaN is detected that is absent in 3D grown films. The results are discussed taking into account the influence of the impinging hyperthermal ions on the growing film.

The integration of antireflective coatings in optical applications has made an important improvement in their performance. The simplest antireflective coating consists of a single layer of transparent material with an optimum refractive index. The efficiency is improved by a multilayer structure formed by a succession of layers with graded refractive indices. These films are the essential component of electroluminescent devices used particularly in lighting applications (panel backlighting to liquid crystal displays) providing good illumination by consuming relatively little electric power, and frequently used as protective and antireflection coating in eyeglass lenses and solar panels.

In view of these considerations, we investigated the potential of the use of Tantalum oxynitride thin films in the field of optics. Indeed, Tantalum pentoxide (Ta_2O_5) can be used as gate dielectric in electronics, optical devices and in antireflective coatings due to its high transparency, high dielectric constant, large band gap and its large refractive index (~2.3 at 632.8 nm). Tantalum nitride (TaN) is a hard material, resistant to corrosion and chemically inert. It is used for hard and wear resistant coatings, as diffusion barrier, as well as film resistors since its electrical resistance is very stable and it possesses metallic behaviour. Combining the useful properties of oxide and nitride allows obtaining all the qualities in oxynitride material supervised by controlling the process parameters. That's why, Tantalum oxynitride films are promising candidates for applications in electroluminescent devices and antireflective coatings due to the wide range of variation of their refractive index between 2.3 and 3.8.

In this work we deposited TaOxNy thin films by reactive magnetron sputtering from a pure tantalum target with Ar/O₂/N₂ plasma. This process was chosen because of its low working temperatures allowing depositing optical and electrical structures on

sensitive substrates. The possibility of variation of several deposition parameters such as pressure, gas flows, target, power, etc. allows obtaining a wide range of film stoichiometry.

The main goal of this study is about a perfect knowledge of the structure of the deposited films versus the parameters used. From this one, the optical behaviour could be understood.

For that, chemical composition was investigated by ion beam (Rutherford Backscattered Spectroscopy). The structural and microstructural properties of films were investigated using X-ray diffraction technique (Xpert Pro Diffractometer, Cu $K\alpha_{1,2}$) in terms of crystal orientation, lattice parameter, and coherent domain size. To estimate the optical band gap and Urbach energy, UV-visible spectrometer was used. The results were completed with phase modulation spectroscopic ellipsometry measurements obtained using a Jobin-Yvon UVISEL instrument in 248-2000 nm (0.6 - 5.0 eV) spectral range.

We report on the properties of ZnO:Ga thin films deposited on glass and sapphire substrates by rf diode sputtering and then implanted with nitrogen to achieve a p-type semiconductor. After the N implantation, the films were annealed under O₂ and N₂ ambient. The effects of the implantation parameters (energy, dose) and the annealing parameters on the films' properties will be discussed. Ion implantation is an important technique for controllable doping in semiconductors and there have been reports for obtaining a p-type ZnO via N implantation [1]. In our earlier experiments, p-type doping with N₂ was done during sputtering and we reported p-type ZnO:Ga:N films with maximum hole concentration of $2.6 \times 10^{18} \text{ cm}^{-3}$ [2]. Recently, we have started investigating the p-type doping in ZnO:Ga via N implantation. SIMS measurements showed that the distribution of the complex $^{30}\text{NO}^-$ ions is Gaussian in the films implanted with 180 keV N⁺ ions (a dose range of $1 \times 10^{15} \div 2 \times 10^{16} \text{ cm}^{-2}$), and it is uniform when performing two implants at 40 keV and 80 keV with doses of 1×10^{15} and $1 \times 10^{16} \text{ cm}^{-2}$ (Fig. 1). Annealing at temperatures above 400°C resulted in n-type films with electron concentrations $10^{18} \text{--} 10^{20} \text{ cm}^{-3}$. A conversion of n-type into unstable p-type (hole concentrations $10^{17} \text{--} 10^{19} \text{ cm}^{-3}$) was observed in some samples after annealing in O₂/200°C and in N₂/400°C. The resistivity of the N₂ annealed films at 200°C is 4.2 Ωcm, almost 2 times lower than that of the O₂ annealed films, and it decreases to 10^{-1} Ωcm with increasing the annealing temperature (Fig. 2). An average transmittance higher than 80 % in the wavelength range of 390-1100 nm proved that N-implanted ZnO:Ga films were highly transparent. Annealing caused the transmittance increase and the band gap widening (3.19-3.3 eV).

The ZnO attracts large interest in research activities for its potential application mainly in UV and VIS optoelectronics with native n-type conductivity, excellent electrical, optical, piezoelectric and mechanical properties [1,2]. The pulsed laser deposition (PLD) allows to prepare various kinds of ZnO layers by two different ways, either by sputtering Zn target in O₂ atmosphere or by sputtering ZnO target onto substrate with a high power pulsed laser [3]. The contribution deals with multilayered samples grown by Nd:YAG laser at 355 nm, 5 Pa pressure of ambient O₂, substrate temperature at 400°C and combination of ablating pulses for ZnO target and Al target. Annealing process were done in O₂ ambient at temperature range 400-800°C. Beside the surface characterisation SIMS and AES depth profiles were done in order to characterize the Al incorporation, Fig 1. After the annealing, the Al level in the SIMS depth profile was changed, Fig 1a. This can be explained by the higher dynamics in Al migration and also by the differences in recrystallization kinetics. The decomposition of the metastable structure to thermodynamically stable wurtzite serves as an efficient diffusion booster supporting the migration of Al atoms. This observation indicates that recrystallization gives a more positive base for the homogenization annealing [4]. The AES depth profile shows similar chemical element's profile, Fig.1b.

This work has been supported by projects from the International Laser Centre VEGA 1/0907/13 and APVV 0424-10.

Silicon carbonitride thin films have been drawing a lot of attention in the past 20 years. This stems from their many tunable properties useful in various fields such as microelectronics, solar energy[1] or optoelectronics[2]. Silicon carbonitrides allow different complex compositions and structures. Several synthesis ways exist for SiCN thin films and their characteristics are dependent on the parameters of the chosen elaboration technique. For example, precursor compounds are determinant because of pre-existing bonds in their structure which are likely to end up in the thin films. While silane is a commonly used precursor gas, its manipulation requires a highly secured process as it is explosive and toxic. Hence, using organosilicon compounds is less dangerous and can lead to interesting properties as well as ease the formation of some phase, but can also hinder the versatility of the process.

We worked with a PE-CVD (Plasma Enhanced Chemical Vapor Deposition) method: thin films were synthesized with an H₂/N₂/Ar/hexamethyldisilazane microwave plasma and deposited on Si(100) substrates. Although we have used an organosilicon precursor, our process has been exhibiting significant flexibility. Optical band gap E_g and refractive index n could be tuned with a low addition of N₂ in the gas

mixture ($3,0 < E_g < 5,0$ eV ; $1,8 < n < 2$)[3]. Looking at bonding in the films with XPS measurements, we noticed that a very low N_2 content was necessary to operate a changeover between Si-C and Si-N bond density. In fact, thin films appeared to be a nanocomposite material consisting in 2H-SiC nanocrystallites embedded in an amorphous SiCN matrix. The crystallinity of the film was monitored via FTIR measurements and the decomposition of the signal into an amorphous signal and a crystalline signal corresponding to the SiC phase[4]. From XRD measurements, we could deduce that while the substrate temperature increased, so did the nanocrystallites size. Substrate temperature and N_2 contents in the gas mixture seem to be crucial parameters. Consequently, the study of the influence of those two parameters enables us to gain more control over SiCN thin films characteristics, especially SiC crystallites size. Besides, controlling film composition, bonding and crystallite sizes is decisive when it comes to photoluminescence properties.

Concentrating solar power (CSP) systems use solar absorbers to convert sunlight into electrical power. The direct way to use solar energy is solar thermal conversion method using solar absorbers which are coated with solar selective absorbing coatings. Solar selective absorbing coatings, as a key part in the CSP systems, are used to convert sunlight into thermal energy, so they need to work at high temperature in a vacuum ($T \geq 400^\circ\text{C}$) for a long time. Consequently, not only an excellent solar spectrally selective absorption property, but also the chemical and thermal stability of film are very important for practical application. The ideal spectrally selective absorbing coating would be cheap, with simple structure and convenient manufacture, require high absorptance (α) in the wavelength range of 300 nm-2500 nm and low emittance (ϵ) in the infrared region of 2500 nm–30 μm as well. According to the double interference absorptive theory, the film structure of solar selective absorbing coating from substrate to surface consists of an IR-reflective metallic layer, a high metal volume fraction (HMVF) cermet layer and a low metal volume fraction (LMVF) layer (as the double interference absorption layers), and a transparent ceramic antireflection (AR) layer.

Through the previous work it was found that niobium alloys (such as NbTi, NbZr and NbCr etc., their nitride and oxynitride coatings) could have enhanced properties, such as chemical stability and thermal stability. Based on this reason, a new solar selective absorbing coating with the film structure of Al/NbCrN(H)/NbCrON(L)/Si₃N₄ will be designed and deposited on copper substrate by reactive magnetron

sputtering.

In this study, we present the influence of composition and thickness on the optical properties of the cermet NbCrON coatings. By using Cr-Nb target, the NbCrON thin films were deposited with various Ar-O₂-N₂ gas atmospheres. The layer composition and morphology were investigated by Rutherford Back Scattering (RBS) and Scanning Electronic Microscopy (SEM), respectively. Moreover, the UV-Vis spectrophotometer and the spectroscopic ellipsometry were used to confirm the optical properties in term of refractive index and optical gap. The spectral properties were also determined to find the highest α and the lowest ε . It is shown that the thickness of HMVF and LMVF cermets for a given composition affects the solar selectivity (α/ε). At the optimum thickness in the range of 100-400 nm, the coating can achieve a high solar selectivity. On the other hand, argon plasma was used to improve the absorptance of the NbCrON cermet films without antireflective coating by significantly changing the roughness of the films. All the results indicate that this material is a promising coating for concentrating solar power systems.

Correlation between microstructural and electrical properties of heat treated Ti/Pt layers

T14 Thin Films

#TF-P1-02

D. Resnik.

University of Ljubljana - Ljubljana (Slovenia).

Investigation of DC sputtered Ti/Pt thin film layers on SiO₂/n+Si substrate is presented. The main objective of this work was to determine the influence of heat treatment on the morphology and microstructure of Ti (20-50 nm)/Pt (180-250 nm) resistive layers and to correlate them with electrical properties such as Ti/Pt layer resistance and temperature dependency of resistance (TCR) of fabricated temperature sensors. Depth profiles and interdiffusion of individual layers were studied by AES for samples annealed between 300-700 °C.

AES depth profile of the sample annealed between 400-700 °C showed significant diffusion of Ti throughout the Pt layer toward surface, accompanied with oxygen incorporation, keeping rather constant TiO_x composition throughout the structure (Fig.1) [1]. AFM surface analyses showed that Pt grain size was almost temperature independent up to 400 °C, while at 500 °C, slightly larger grains were observed. Above this temperature sudden increase of grain size was determined (Fig. 2). At 700 °C, grains have typically diameter of 300-400 nm compared to as-deposited grain diameter which was in the range of 10-30 nm.

Consequently, also electrical properties of the deposited resistive layer change significantly around 400 °C what complies with AES analyses. The correlation of surface roughness and electrical resistance is roughly inversely proportional (Fig. 2). The resistance of the temperature sensors showed linear dependency of R vs. T ($\pm 0.5\%$). The reproducibility of the TCR within the same run was within 10%, mostly due to the nonlinearity of measured resistance at lower temperatures [2]. It was further determined that by increasing the annealing temperature from 300 °C to 700 °C, gradual increase of TCR from 1500 ppm up to 2900 ppm was obtained, respectively, which is a significant value when implementing Ti/Pt layers as a temperature sensing device.

Nanocomposite structures composed of crystalline and (or) amorphous phases are of rapidly growing interest. Combination of pure carbon-based thin films with metallic nanoparticles for example will result in a material with enhanced physical properties. Such structures can be obtained by addition of different metals, e.g. Ni, Cu, Ag, Cr, and Ti. Understanding the structural background of mechanical characteristics and atomic mechanism of the development of surface morphology in novel materials is significant because the demands to mechanical and surface properties may be different for different applications.

The main aim of this work is the development of different carbon-metal (Ti) coatings by relatively easy and cheap technology; magnetron sputtering. These films will be applied as self-cleaning protective or hard coatings for multifunctional applications. 500 nm thick films were deposited on oxidized silicon substrates by DC magnetron sputtering of Ti and C targets in argon at 25°C, using different Ti target powers. The structure of the samples was studied by transmission electron microscopy (TEM) and atomic force microscopy (AFM). The layers were found to be consisting TiC nanocrystals of a few nanometres in size embedded in carbon matrix. Auger Electron Spectroscopy (AES) and Raman Spectroscopy were used to characterize the amorphous matrix found to be dependent on the Ti sputtering power. Nano-indentation was used to measure the mechanical properties of the nanocomposites. The measured hardness values were between 35 and 60 GPa, modulus of elasticity between 235–401 GPa depending on Ti content.

Our results show strong relationship between the evolving structure and the mechanical properties of C-Ti films.

While the production capacity of dispersed carbon nanotubes is booming [1], the coming of industrial production of vertically aligned carbon nanotubes carpets/arrays/forests (VACNT) is still at its first stages. but represents the second generation of carbon nanotubes based products. From an industrial point of view, The main challenge is the control of carbon nanotubes characteristics in terms of length, density, cleanness, diameter and structure through a low cost process applicable to large surfaces. In this context, amongst the different methods reported for the growth of aligned CNT [2] Catalytic Chemical Vapour Deposition (CCVD) appears as a versatile process with great potential. CCVD process using catalyst pre-deposition and gaseous precursors, succeeded in controlling CNT morphology and size.

In this paper we focus our work on the co-injection aerosol-assisted Pressure CCVD process [3][4] we developed, that offers a rapid, never-ending and a continuous growth of aligned multiwall CNTs by injecting simultaneously carbon (liquid hydrocarbons) and catalyst precursors (ferrocene). We present the specificity of such a process and its ability to be upscaled for industrial production of VACNT. We demonstrated in small furnace configurations that by adjusting operating conditions nanotubes characteristics such as length, density, catalyst content or nanotubes diameters can be controlled within a large range [6] an deposited directly on various substrates (flat substrates: silicon, quartz, carbon, metals; porous substrates: fibers [5]). By designing a new furnace, we were able to up-scale the process over large surface while reaching the same versatility process for both flat substrates and especially for fibers where pre-deposition of a protective layer is necessary. This pilot

is seen as a new step towards safer large scale and low cost in-line aligned carbon nanotubes production by aerosol-assisted CCVD.

ITO thin films fabricated by a hybrid facing-target sputtering system

T14 Thin Films

#TF-P3-11

S. Morohashi, K. Usui, F. Takaki, T. Murata, K. Kishimoto, N. Harada.

Yamaguchi University - Ube (Japan).

A hybrid facing-target sputtering system has been newly devised. The magnetic field distribution between facing targets can be easily changed by moving a inner rod magnet without breaking the vacuum. By changing the magnetic field distribution between facing targets, Indium-Tin Oxide thin films have been deposited on glass substrates with controlled Ar/O₂ gas mixture and with DC power.

Figure 1 shows the schematic diagram of a facing-cathode, with moving rod magnets that change a magnetic field distribution between facing-target in a hybrid facing-target sputtering system and the plasma discharge state in ITO film deposition. This sputtering system has devised to realize high-speed deposition for improved throughput, while satisfying the requirements for low damage during deposition. The sputtering can be achieved under different magnetic field distribution between facing-target, where the magnetic field distribution is controlled with a moving rod magnet without breaking the vacuum^{1,2}). The polarity of the fixed facing outer cylindrical magnets is opposite. The inner rod magnets are moving magnets. The polarity between the cylindrical magnet and the moving magnet is opposite, and the polarity between the facing inner rod magnets is opposite. With such a magnet arrangement, three magnetic field distributions are created between the facing-targets: (1) a magnetic field distribution due to the facing cylindrical magnets; (2) a magnetic field distribution due to the facing moving rod magnets, which directed oppositely to the magnetic field created by the cylindrical magnets; and (3) a magnetic field distribution created between the stationary cylindrical magnet and the moving rod magnet at the back of each target. The hybrid magnetic field distributions between the facing-target can be controlled by the positions of the moving rod magnets without breaking the vacuum. The magnetic field distribution is shown schematically for the two cases in Figure 1. Figure 1(a) shows the case where the magnetic field distribution of (1) is strong, and Figure 1(b) shows the case where the magnetic field distributions of (2) and (3) are added to the distribution of (1).

Without both substrate heating and post annealing processes, the resistivity of as-

grown ITO film with 200 nm thickness was $7.3 \times 10^{-4} \Omega\text{-cm}$. The deposition rate of ITO films was 142 nm/min and the substrate temperature rise during deposition was 90 °C or less.

Exploring the effects of Co and (Co,Mo) doping on the properties of TiO₂ semiconductor thin films

T14 Thin Films

#TF-8-Or-5

A. Silvestre ¹, S. Rout ², S. Dalui ², O. Conde ².

¹Instituto Superior de Engenharia de Lisboa, Área Departamental de Física and ICEMS, 1959-007 Lisboa, Portugal - Lisboa (Portugal), ²Universidade de Lisboa, Faculdade de Ciências, Departamento de Física and ICEMS, 1749-016 Lisboa, Portugal - Lisboa (Portugal).

Here we report on the effect of Co and (Co,Mo) doping on the structural, optical and electrical properties of TiO₂ thin films. Undoped TiO₂, Co and (Co,Mo) doped TiO₂ films (5 at.% Co, 1 and 3 at.% Mo) were grown by pulsed laser deposition onto Al₂O₃(0001) substrates, using a Ar background pressure of 8×10^{-2} Pa and a substrate temperature of 350 °C. Films' thicknesses are in the range of 100-140 nm. XRD analyses shows that all films are anatase single phase with (112) orientation. Crystallite sizes in the range of 7-17 nm were inferred depending on the doping. The broad Raman peaks presented by all films are in line with the smallness of the coherent diffraction domains determined by XRD. Optical measurements show that the band gap values of doped films are red shifted when compared to the undoped TiO₂ films. Urbach energies of 784.6, 458.4 and 428.7 meV were estimated for the Ti_{0.95}Co_{0.05}O₂, Ti_{0.94}Co_{0.05}Mo_{0.01}O₂ and Ti_{0.93}Co_{0.05}Mo_{0.03}O₂ films, respectively, which seems to support that Co doping is effective in introducing additional localized states into the band gap whereas Mo doping affects reversely. All the films show weak ferromagnetic semiconductor behavior at room temperature. The nature of the carriers is currently being studied by Hall effect measurements. The role of oxygen vacancies and doping elements on the optical, electrical and magnetic properties of the films are discussed.

Cermet coating deposition by DC reactive co-sputtering process controlled by voltage

T14 Thin Films

#TF-7-Or-5

J. Rodrigo ¹, B. Navarcorena ¹, G. García Fuentes ¹, J.A. García ¹, R. Escobar ², C. Prieto ², J.A. Sánchez ², E. Céspedes ², J.M. Albella ².

Cermet-type coatings are drawing full attention as solar selective coatings for concentrated solar power (CSP) applications [1]. For this application, high melting point transition elements, as for instance Mo, Ni, Pt or Cr, are used as the metallic component of the cermet. This elements are usually inside a dielectrical matrix of SiO₂, Al₂O₃, Si₃N₄ or AlN.

Insulating ceramic compounds deposition by physical vapor deposition (PVD) is typically done by RF assisted sputtering processes. However, due to the low deposition rate achieved by this deposition technique, there is being progressively more used pulsed DC or DC reactive sputtering deposition technique [2].

In DC reactive deposition of insulating ceramic compounds there are two operation modes: metallic mode and reactive mode [3]. The metallic mode is characterized by a low gas partial pressure and a high deposition rate. In the other hand, the reactive mode has a high gas partial pressure and a low deposition rate. The transition between both modes is quite steep with a slight change in the reactive gas. In addition, the transition takes place at different reactive gas rates depending on the direction of the transition, a hysteresis cycle rules the stability of the process.

One of the most important parameters to control in the deposition is the target voltage. Not only for having under control the deposition rate, but also for mandating over the deposited oxide stoichiometry during the reactive sputtering process [4].

In this work the co-deposition of a Mo-SiO₂ coating has been studied. The process was carried out in a DC reactive environment with two targets of silicon and

molybdenum. Process parameters are highly influenced by the deposition strategy. In this case, in one hand we must deposit silicon oxide as matrix and in the other hand we have to deposit metallic molybdenum as dopant in order to achieve LMVF and HMVF required values. Moreover, we should control both cathodes voltage very precisely, managed by a PID controller, in order to avoid undesired transitions between metallic and reactive sputtering modes.

Roughness and thickness of the coatings have been measured, they have been also characterized by GDOES and UV-VIS-nIR and FTIR spectroscopy. The study shows the different absorption and emission coating properties achievable depending on the process parameters. The optical characterization of the coating, with the n and k parameters, allows us to predict the final emission and absorption properties of the complete stack with the help of a coating simulation software.

Coloration Mechanism and Optimized Performance of Electrochromic Nickel Oxide

T14 Thin Films

#TF-6-Or-12

Y. Ren ¹, S.Y. Chiam ¹, J. Liu ².

¹Institute of Materials Research and Engineering, A*star - Singapore (Singapore), ²Department of Chemistry, National University of Singapore - Singapore (Singapore).

Electrochromic (EC) materials are important for enabling technologies such as smart windows and non-volatile displays. The stability of the open-circuit memory can be translated to possible energy savings in integrated windows application for indoor comfort. Nickel oxide (NiO) is a common high-performance anodic EC material. In this presentation, we will introduce solution-based deposition methods of thin film NiO for low-cost and large-scale fabrication, followed by examining the coloration and EC mechanism of NiO. The role of ions is especially important in aqueous electrolyte. Apart from the commonly reported contribution from hydrogen ion (H^+), hydroxyl ions (OH^-) can also play a role. The presence of OH^- ions can lead to existence of different phases for both bleached and colored states and even multiple chemical reactions during the aqueous electrolyte cycling. We show that while H^+ ions are important to give rise to the coloration, initial OH^- ions incorporation in a dehydrated NiO enhance the EC property of the film by increasing inter-layer spacing that allows more H^+ ions movements. Later stages of OH^- ions incorporation results in intercalated H_2O that inhibits further H^+ ions diffusion. This understanding of the role of ions shown in the figure will therefore be crucial in the optimal control of hydroxyl ions for both efficiency and durability of the EC devices. Since one key enabling feature of initial OH^- incorporation is to increase interlayer spacing, a substitution of aqueous electrolyte with non-aqueous electrolyte (Li-PC or solid electrolyte) during cycling will prevent degradation through intercalated water molecules. The optimally hydrated NiO will also need to be well passivated to retain its interlayer spacing. Here, we propose tantalum oxide as a suitable candidate for the solid electrolyte. On the other hand, the coloration mechanism of EC NiO remains controversial and a detailed understanding of the electronic structure evolution has yet to be reported. We show here a detailed study of filled and empty electronic states of the bleach and

color states of NiO thin film. We use X-ray photoelectron spectroscopy (XPS) to show that the removal of H^+ ions give rise to holes that resides in a $p-d$ hybridized state of mainly oxygen p -character. This can be determined from the slight change in near-valence band edge states from the fitted XPS data. While the valence band edge is not significantly affected, the presence of these ligand holes drastically change the empty state in the conduction band investigated by X-ray absorption spectroscopy. This spectrum weight transfer is believed to be brought by split-off state with primarily O_p -character and effectively reduces the optical band gap to below 2eV for visible light absorption.

Low-Cost High-Performance Zinc Antimonide Thin Films for Thermoelectric Applications

T14 Thin Films

#TF-7-Or-6

Y. Sun ¹, M. Christensen ², S. Johnsen ², B.B. Iversen ².

¹School of Science, Harbin Institute of Technology; Center for Materials Crystallography, Department of Chemistry and iNANO, Aarhus University - Harbin (China), ²Center for Materials Crystallography, Department of Chemistry and iNANO, Aarhus University - Aarhus (Denmark).

Rising demand on energy efficiency and green solutions has made global interest in thermoelectric (TE) devices explode. However, TE power generation still has few commercial applications since no cheap, stable, non-toxic and high performing materials made of abundant elements are known. Recently, low power applications of TE thin films has attracted intense attention. Extremely high TE figures of merit have been reported for superlattices [1,2], yet their complicated and expensive production makes commercialization problematic. Zn_4Sb_3 and ZnSb are cheap, promising p-type TE bulk materials in the intermediate temperature range (473-673 K). Here, we report on the synthesis and characterization of stable, phase pure Zn_4Sb_3 and ZnSb thin films with outstanding TE properties [3]. ZnSb films as well as two completely new meta-stable crystalline phases of zinc antimonide were directly deposited on silica substrates by a co-sputtering method. After post-annealing treatments at 573 K, the two new phases transformed into Zn_4Sb_3+ZnSb and single phase Zn_4Sb_3 films, respectively. Thermoelectric characterization along the in-plane direction revealed that these Zn_4Sb_3 and ZnSb films exhibit very large PF values, which are comparable to the best reported results of the bulk materials [4,5], but unlike the bulk materials, they also have good thermal stability up to 573 K. These thin films fulfill all the key material requirements for commercial TE application, and have significant potential to be used in TE sensors, coolers or self-powered micro-devices.

Titanium oxynitride coatings deposited by the reactive magnetron sputtering: structure and physicochemical properties

T14 Thin Films

#SE/PST/TF/BI-P1-07

V. Pichugin, M. Konishchev, N. Morozova, O. Kuzmin, A. Pustovalova.

Tomsk Polytechnic University - Tomsk (Russian federation).

Titanium oxynitride films are perspective materials for different applications. TiN_xO_y films have been deposited on substrates using reactive magnetron sputtering technique. The deposition process was carried out with pulsing frequencies 60 kHz and duty cycles in the range 50–90%. The method of time-resolved optical emission spectroscopy used to characterize the pulsed magnetron plasma. The experiments were carried out at total pressures in the range 0.1–0.6 Pa in either pure O_2 (“oxide” mode) or in O_2 – N_2 mixtures. The surface morphology and topography of the films were studied by different techniques (EDX, ESEM, XRD, IR spectroscopy). The results show that deposited coating has character of nanocomposite with two-phase amorphous-crystalline structure with high part of interphase boundary. The adhesion strength of the coatings was in order to 40 MPa. The film has nanocrystalline structure with average grain size equals 13.83 nm. High enough Young’s modulus value (11 GPa) is evidence of high mechanical strength and good elastic properties of coatings. Obtained films possess the properties which allow to use they as coatings for medical grafts applied in implantology.

Reactive Magnetron Sputtering of AgFeO₂ Compounds with the Delafossite Structure

T14 Thin Films

#TF-3-Or-6

F. Mao, T. Nyberg, U. Jansson.

Uppsala University - Uppsala (Sweden).

Delafossites AMO₂ (A=Ag, Cu, Pd, Pt; M=Fe, Co, Ni, Cr, Al, Mn, etc) have received considerable attention due to their potential applications as transparent conducting oxides, photocatalysts, batteries and thermoelectric materials [1]. Recently, high temperature superconductivity was also suggested for doped members of this type of oxide compounds [2]. Many of the interesting properties of delafossites are related to the crystal structure where linear O-A-O bonds connect layers of slightly distorted edge-sharing MO₆ octahedra. Consequently, the delafossites can be described as natural nanolaminates of MO₂ layers separated by A atoms.

Delafossite materials, especially copper compounds, have been studied intensely through synthesis of high temperature solid-state reaction, sol-gel methods, hydrothermal synthesis methods, cation exchange reaction methods and in a few cases reactive sputtering [3]. To our knowledge, however, very few studies have previously been published on silver-based delafossite films deposited by sputtering.

In this work we demonstrated the deposition of single-phase delafossite AgFeO₂ thin films using pulsed-dc co-sputtering of silver and iron targets in a reactive Ar-O₂ mixture atmosphere. The effect of O₂ flow rate, substrate temperature, deposition pressure, pulse frequency of sputtering power on the formation of delafossite AgFeO₂ were investigated. XPS, XRF, XRD and Raman Spectroscopy were employed to determine the chemical composition and phase structure. Film thickness and morphology were studied by SEM. Optical and electrical properties were also investigated.

Our results showed the possibility of depositing single-phase AgFeO₂ films without post-annealing, however, the process window is very narrow and strongly dependent on oxygen flow rate, pulse frequencies, pressure and temperature. In general, high

pulse frequencies above 300 kHz, medium oxygen flow rate (around 15 sccm) and a deposition pressure of 10 mTorr were required. The most critical parameter was the temperature with an optimal deposition temperature at 400 °C. Typically, less well crystalline films were obtained at lower temperatures while a significant precipitation of metallic Ag was observed at higher temperatures (see Fig.1). This decomposition could be attributed to rather weak O-Ag-O bonds in the structure.

Irradiation of Ti₃SiC₂ with 700keV Si

T14 Thin Films

#TF-9-Or-8

B. King ¹, C. Liu ², Q. Qi ², L. Shi ², J. O'connor ¹.

¹University of Newcastle - Callaghan (Australia), ²Fudan University - Shanghai (China).

The interaction of 700keV Si ions, incident at 45 degrees onto a Ti₃SiC₂ surface, has been studied as a function of sample temperature, from 300K to 820K. The samples were irradiated to a dose of 10¹⁶cm⁻². SRIM shows that the range of the Si is 300nm at this energy with the ions generating substantial energy deposition from the surface to a depth of 400nm. SEM EDAX analysis of unimplanted material shows a small percentage of alumina grains in the surface. Room temperature irradiation produces a few micron large "dark" and "white" zones on the surface with more C and less Ti in the "white" regions. Glancing incidence synchrotron X-ray diffraction was performed for X-ray incidence angles of 0.2, 0.4, 0.6, 0.8 and 1 degree. For these incidence angles, the X-rays dominantly probe the top 100nm of the surface. Peaks corresponding to the (006), (008), (101), (102), (103), (104), (105), (107), (108), (109), (110) reflections from Ti₃SiC₂ were found, as well as very small peaks from Al₂O₃, TiSi₂ and Si₅C₃. In general, all Ti₃SiC₂ peaks broaden under implantation. There is also implantation induced splitting of the Ti₃SiC₂ (104) and (105) peaks for all temperatures other than room temperature, most likely evidence of an expanded Ti₃SiC₂ component. . For RT bombardment, there is growth of a TiC phase with bombardment near the surface, but this is less obvious for higher temperature bombardments. We have found that the crystallinity of the implanted surface is retained better at an intermediate temperature, 573K, during irradiation compared to higher or lower temperatures.

Novel detector based on a-SiC:H for FRET analysis

T14 Thin Films

#SE/PST/TF/BI-3-Or-1

P. Louro Antunes, V. Silva, M.A. Vieira, M. Vieira.

ISEL-ADEETC - Lisboa (Portugal).

Glucose sensing is an issue with great interest in medical and biological applications. One possible approach to glucose detection takes advantage of measuring changes in fluorescence resonance energy transfer (FRET) between a fluorescent donor and an acceptor within a protein which undergoes glucose-induced changes in conformation. This demands the detection of fluorescent signals in the visible spectrum. In this paper we analyzed the emission spectrum obtained from fluorescent labels attached to a protein which changes its conformation in the presence of glucose using a commercial spectrofluorometer. Different glucose nanosensors were used to measure the output spectra with fluorescent signals located at the cyan and yellow bands of the spectrum. A new device is presented based on multilayered a-SiC:H heterostructures to detect identical transient visible signals. The transducer consists of a p-i'(a-SiC:H)-n/p-i(a-Si:H)-n heterostructure optimized for the detection of the fluorescence resonance energy transfer between fluorophores with excitation in the violet (400 nm) and emissions in the cyan (470 nm) and yellow (588 nm) range of the spectrum. Results show that the device photocurrent signal measured under reverse bias and using appropriate steady state optical bias, allows the separate detection of the cyan and yellow fluorescence signals.

Evaluation of selected nanolayered and nanostructured coatings for cutting applications

T14 Thin Films

#SE/TF-P2-16

M. Cekada ¹, G. Geiger ².

¹Jozef Stefan Institute - Ljubljana (Slovenia), ²Vienna University of Technology, Institute of Production Engineering - Vienna (Austria).

PVD hard coatings are nowadays commonly used in protection of cutting tools such as milling tools, cutting inserts, etc. In the development of the coatings, most attention is paid to their structural and mechanical properties. When implemented into selected industrial applications, different objectives become relevant, i.e. the ones related to economical issues. These include increase of tool lifetime, enhanced productivity, workpiece quality, etc.

There are several other issues with a significant influence, yet a relatively small emphasis has been given insofar. In this work we concentrated on two such aspects: (i) evaluation of surface quality of the base material before coating deposition, (ii) testing of the cutting performance on a milling system with in-situ diagnostics of the cutting process.

Cemented carbide mills were used for tests having a diameter of either 6 mm or 10 mm. Two coatings were selected for evaluation: the nanolayer TiAlN/TiN coating and the (Ti,Al,Si)N coating, which consists of a TiAlN base layer, a nanocomposite TiSiN middle layer and a nanolayer/nanocomposite TiAlSiN toplayer. A standard TiAlN coating was used for selected reference tests. They were all deposited by magnetron sputtering in a commercial deposition system CemeCon CC800/9 with a thickness of around 3 µm.

The surface quality was systematically evaluated using a confocal optical microscope. Identical motives were taken on bare tool, after coating deposition, and after cutting tests. We analysed, how do individual failures (both on the bare tool

surface and on the coating alone) influence the cutting performance. Special attention was given to the cutting edge rounding/chipping.

The machining tests were performed on an OPS600 3-axis milling machine equipped with a high-speed spindle. To describe the shifting of the tool behavior during the lifetime several parameters have been measured during every cut of the tests such as cutting forces, tool temperature and tool wear. Afterwards surface quality, chip formation and tool wear analysis have been done. The two coatings have been tested by cutting three different materials: C45E (1.1191), X40CrMoV5-1 (1.2344) and X153CrMoV12 (1.2379) running dry and with minimal quantity lubrication. The tests show that the TiAlN/TiN coating performs best related to the tool wear independent of test material and cooling using the same cutting parameters.

Optoelectronic Properties of Zinc(II)-Phthalocyanine

T14 Thin Films

#TF-7-Or-8

M. Kozlik, S. Paulke, M. Gruenewald, R. Forker, T. Fritz.

Friedrich Schiller University of Jena - Jena (Germany).

New optoelectronic devices use more frequently organic materials nowadays, e.g. in OLEDs and organic solar cells (OSCs). Zinc(II)-phthalocyanine (ZnPc) is a widely used organic molecule, and the bulk material crystallizes mainly one of the following polymorphs: the metastable α -ZnPc (high conductivity) and the stable β -ZnPc (low conductivity) [1]. In our contribution we will discuss the optical and morphological differences between both phases as well as the critical transformation temperature. Description and simulation of the performance of organic devices require the knowledge of material parameters. We will present the determination of the optical constants (complex index of refraction) and the exciton diffusion length by means of UV-Vis spectroscopy and external quantum efficiency measurements. Based on transmittance and reflectance spectra we extract the real and imaginary part of the refractive index [2]. In combination with the parameters derived we will show the performance of a simplified photovoltaic cell and identify the region of exciton dissociation and the exciton diffusion length.

Thin nanofilms obtained by citric acid ethylene glycol mixture were deposited by 13,56 MHz radio-frequency plasma from 5 to 50W power supply and 10Pa pressure. The results showed that the functional groups of the nanofilms molecular structures were preserved. However, it was observed films modifications by X-ray photoelectron spectroscopy that showed compositional modifications in the samples. It was observed an increasing oxygen-carbon and oxygen-hydrogen bond while carbon-hydrogen decreases as the deposition power increases from 5 to 50W. The films deposition rate increased from 2 to 6nm:min while the power supply increased from 5 to 30W and decreased after this value. This result showed good agreement with the activated growth mechanism that presents competition among polymerization and ablation (1-2). The samples wettability was investigated using goniometric technique and for all depositions conditions the nanofilms presented hydrophilic character. Atomic force microscopy showed that films surface profiles and the glass substrate were similar when the films presented low thickness. The samples refractive index was investigated by UV-Visible spectroscopy presenting values from 1,47 to 1,53.

Zinc sulfide belongs to group II-VI compound semiconductor materials. ZnS is a very important semiconductor material with a large optical gap (> 3.5 eV), a large utility in thin-film devices, such as photoluminescent devices and LEDs. In addition, the ZnS is an important material in solar cells based on thin layers in heterojunction as buffer layer. In this work, we became interested in the development of thin layers of a semiconductor type II-VI: Zinc sulfide (ZnS), and the study of optical, electrical, structural and morphological were prepared by the technique SILAR (Successive Ionic layer adsorption and Reaction). Our goal is to provide a comprehensive study on the effect of cycle number on the physical properties of thin films of ZnS. In the first part of this work we have developed deposition techniques, the second part relates to the development of a series of films with different deposition conditions to optimize the process in order to obtain films with good optoelectronic properties for application in photovoltaic eventually. Keywords: ZnS buffer layer, SILAR.

During the past decade transition metal oxides were extensively studied as electrode materials for electrochemical capacitors. The semiconductors MnO₂, V₂O₅, Fe₃O₄, among others, were studied due to their several oxidation states of the metal atoms, accessible within a potential window of 1V allowing the surface redox reactions in aqueous electrolytes to take place. Recently, nitrides such as VN, TiN and MoN have been studied, and impressive specific capacitance values up to 1340 F g⁻¹ at 2 mV s⁻¹ were reported for VN [1]. According to Choi et al., the high specific capacitance of VN results from its high electronic conductivity and from a combination of electrical double layer formation and redox reactions at the surface of the electrode. This presentation aims to compare the properties of various transition metal nitride (TMN) films for application as electrodes in supercapacitors.

TMN films were deposited on glass by reactive sputtering of TM targets. The following TM have been studied: Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu and Ru. The deposition conditions were adjusted as a function of the reactivity of transition metal with nitrogen atoms. Whatever TM, the morphology of the films is columnar. Only Cu- and Ni-based films crystallized in a TM₃N-like structure while most of the deposited films exhibit a metal to nitrogen atomic ratio of 1 and. Although the structure of ScN, TiN, VN, CrN and γ'-FeN is widely described, few information about the structure of MnN and RuN are available in the literature. The synthesis of ruthenium nitride (RuN) was reported for the first time in 2007 [2]. The authors suggest that this compound crystallises in a NaCl-like structure. However, ab initio calculations show that this structure is not the most stable [3]. Relative to manganese nitride (MnN), Suzuki and al. have sputter-deposited MnN films that crystallise in a NaCl-type distorted tetragonal structure (fct) [4]. Nevertheless, Miao and al. suggest that the most stable structure is ZnS [5]. Both MnN and RuN films exhibit a strong preferred orientation in the [111] direction and a grain size in the 10 – 25 nm range. X-ray diffraction

analyses and the Rietveld's method evidence that both RuN and MnN thin films crystallize in a ZnS-like structure with lattice constant of 0.451 and 0.428 nm, respectively.

The electrochemical properties of the deposited films were determined by cyclic voltammetry in KOH electrolyte. ScN, Ni₃N, FeN, CrN have shown a poor capacitance suggesting that only double layer is involved in the charge storage mechanism. The large capacitance of MnN, RuN and VN and the waves in the voltammograms suggest a pseudofaradaic process. These nitrides have shown a capacitive behavior at high scan rates due to their high electronic conductivity and fast reversible redox process. The cyclic voltammograms of VN films in KOH 1M at different scan rates evidence a potential window of 1.2 V (from -1.2 to 0 V vs. Hg/HgO). On the other hand, the potential window of RuN thin films is about 0.9 V (from -0.5 to 0.4 V vs. Hg/HgO).

TF-2-Or-5

Synthesis of conductive semi-transparent silver films deposited by a Pneumatically Assisted Ultrasonic Spray Pyrolysis Technique

T14 Thin Films

#TF-2-Or-5

C. Falcony, E. Zaleta-Alejandre, R. Balderas-Xicoténcatl, M.L. Pérez Arrieta, Z. Rivera-Álvarez, A.N. Meza-Rocha.

CINVESTAV-IPN - Mexico Df (Mexico).

The synthesis and characterization of nanostructured silver films deposited on corning glass by a deposition technique called Pneumatically-Assisted Ultrasonic Spray Pyrolysis are reported. Silver nitrate and triethanolamine were used as silver precursor and reducer agent respectively. The substrate temperatures during deposition were in the range of 300 to 450 °C and the deposition times from 30 to 240 sec. The deposited films are polycrystalline with cubic face-centered structure, and crystalline grain size less than 30 nm. Deposition rates up to 600 Å•min⁻¹ were obtained at substrate temperature as low as 300 °C. The electrical, optical, and morphological properties of these films are also reported. Semitransparent conductive silver films were obtained at 350 °C with a deposition time of 45 sec. The preparation and study of metallic silver films have been of interest due to their better electrical and optical performance with respect to other metallic films and to the wide variety of technological applications such as electrical interconnections in microelectronic circuitry, gas sensors, bactericidal coatings, low-emissivity coatings on tempered glass and on bent glass panes for vehicles and recently for electrical contacts in photovoltaic devices on flexible substrates [1]. In this work, the synthesis of conductive silver thin films on corning glass by a pneumatically-assisted ultrasonic spray pyrolysis (PAUSP) technique are reported. This deposition scheme uses a gas jet to assist the ultrasonic spray pyrolysis deposition process of a film by given an additional impulse to the precursors in aerosol drops towards a hot substrate. The structural, electrical and optical properties as a function of the deposition parameters are reported as well. The SEM micrographs for films deposited at 350 °C for two deposition times, 30 and 120 s are shown in fig.1. The micrograph for the film

deposited in 30 sec. (fig. 1a) shows an initial formation of clusters of silver of random sizes with no interconnection, while the film deposited for 240 sec (fig. 1b), shows a totally covered surface by a superposition of small silver grains. This behavior of silver islands formation and later transition to a continuous film has been observed and reported for other deposition techniques.

The industrial use of hydrogenated microcrystalline silicon ($\mu\text{c-Si:H}$) for photovoltaics requires high-quality thin films deposited at high rates. For radio-frequency plasma enhanced chemical vapour deposition (RF-PECVD) techniques, this implies achieving a high plasma density (and feedgas dissociation) while maintaining a low mean ion-bombardment energy (IBE). The use of Tailored Voltage Waveforms (TVW's) allow one to unequally divide the plasma sheath voltage between the powered and grounded electrode, and thus reduce the mean IBE on the substrate [1], a technique also known as the Electrical Asymmetry Effect [2]. The use of such a TVW to excite a plasma for PECVD has been recently used to deposit the intrinsic microcrystalline layer of $\mu\text{c-Si:H}$ cells using SiH_4 diluted in H_2 [3].

In addition to being of interest for industrial applications, the ability to decouple plasma density from IBE allows one to perform deeper, direct examination of the importance of IBE for the growth of $\mu\text{c-Si:H}$, and we do so in this work. This is achieved through the use of both in-situ (spectroscopic ellipsometry, (SE)) and ex-situ (AFM and Raman scattering) techniques. For this study, intrinsic $\mu\text{c-Si:H}$ layers were deposited by PECVD excited with TVWs using both the "Peaks" and the "Valleys" waveforms. In-situ SE was performed during the deposition, and an example of the curves obtained for a high IBE condition is seen in Fig. 2. One can see that such curves result in a constantly changing surface, and given the very low value of the imaginary part of the dielectric function, one that is very rough or porous. To get a complete picture of the process, similar curves were acquired for a variety of process gas mixtures, include the classic SiH_4/H_2 mixture, but also more exotic $\text{SiH}_4/\text{SiF}_4/\text{H}_2$ and $\text{SiF}_4/\text{H}_2/\text{Ar}$ mixtures. This last mixture is of particular interest as

the devices generated from this mixture are of particularly high quality [4]. These in-situ results can be combined with Raman scattering and AFM images to get a coherent picture of the specific role of elevated IBE during μc material growth.

We have studied the optical properties of GaAs and AlGaAs thin films using low-temperature photoluminescence and infrared spectroscopy. The GaAs and its alloys were grown by MOCVD using solid arsenic instead of arsine as the arsenic precursor. The precursors of gallium and aluminum are organometallic compounds, trimethylgallium and trimethylaluminum. Some difficulties in the AlGaAs growth by solid-arsenic-based MOCVD are the composition homogeneity of the layers and the oxygen and carbon incorporation during the growth process. The composition homogeneity of the films was demonstrated by low-temperature photoluminescence and Raman spectroscopy. Infrared measurements on the samples allowed to identify the responsible residual impurities, which are carbon-substitutional, Ga₂O₃, molecular oxygen, humidity and, two unidentified impurities. Samples grown at temperatures lower than 750°C were highly resistive, independently of the III/V ratio; the samples grown at higher temperatures were n-type, how it was proved by Hall effect measurements.

Plasma potential control for film structure modification in high power pulsed magnetron sputtering

T14 Thin Films

#SE-1-Or-6a

T. Nakano, T. Umahashi, S. Baba.

Seikei Univ. - Tokyo (Japan).

In plasma processes, thin film structure is strongly affected by the substrate temperature (T_s) and energetic particle bombardment onto the growing film surface [1]. With the aid of the latter, fibrous structure with smooth surface can be obtained even at low T_s . To achieve this, it is advantageous to use the ionized physical vapor deposition (IPVD) which is characterized by the high degree of ionization of sputtered atoms. By applying negative substrate bias and attracting the positive ions, the energy flux onto the film surface can be controlled.

High power pulsed magnetron sputtering (HPPMS) is one of the IPVD variant. It applies target power in short pulses with low repetition frequency and very small duty ratio. It can generate high density plasma required for IPVD, while avoiding heavy thermal load to the target. In a previous study [2], we have raised the target voltage during the power-off period of HPPMS and found that the plasma potential V_p of the after-glow plasma was raised. The structure of deposited film was substantially flattened even on the water-cooled and electrically grounded substrate. It was understood that positive ions in the high V_p plasma could bombard the growing film surface.

In this study, we have introduced another electrode to apply positive bias and tried to control V_p for both on and off periods of HPPMS. Figure 1 shows the schematic of this chimney-like electrode above the sputter gun of 2 inch diameter. By applying different electrode potential V_c , Cu films were prepared by HPPMS with 5% of duty ratio and 100 W of average power, in 5 Pa of Ar gas. As shown in Fig. 2, the film surface was greatly flattened at 40 V of V_c . It was also confirmed by the probe measurement that V_p was raised with an increase in V_c . The raise in V_p will be discussed in view of the diode like behavior of the plasma sheath and the current conservation between 3 electrodes.

Impedance Measurements in Delta Bismuth Oxide Thin Films

T14 Thin Films

#TF-P2-29

C. Gomez ¹, P. Silva-Bermudez ¹, S.E. Rodil ¹, H. Estrada ².

¹Instituto de Investigaciones en Materiales, Universidad Nacional Autonoma de Mexico - Mexico D. F. (Mexico), ²Centro Nacional de Metrologia - Queretaro (Mexico).

Bismuth oxide Bi_2O_3 has interesting technological applications, which have not been largely used due to the particular polymorphism of the material. Among the interesting properties, it is worth mentioning a large energy gap (from 2 to 3.96 eV depending on the phase) [1], high refractive index, dielectric permittivity, noticeable photoconductivity and photoluminescence. Bismuth Oxide has five polymorphic forms: α , β , γ , δ and ω - Bi_2O_3 . Among them, the low-temperature α and the high-temperature δ phases are stable and the others are high temperature metastable [2]. The face-centered cubic δ - Bi_2O_3 is stable over a narrow range 729 - 825 °C (melting point) and it is the material that shows one of the highest ionic conductivity. Decreasing the temperature leads to the formation of intermediate metastable phases such as tetragonal β - Bi_2O_3 and/or body-centered cubic γ - Bi_2O_3 before transforming into stable monoclinic α - Bi_2O_3 at room temperature (RT). Remarkably, it has been proved [3-4] that the deposition of nanocrystalline thin films allows the stabilization of the high temperature phase at room temperature. Nevertheless, very few works have tried to measure the ionic conductivity of such thin films. In this work, after studying different deposition conditions: deposition power and substrate temperature, 180 - 430 nm thin films presenting the δ - Bi_2O_3 were consistently obtained. The films were deposited on glass by reactive magnetron sputtering starting from an α - Bi_2O_3 target and using an Ar/O₂ (80:20) atmosphere. The films were characterized by X-ray diffraction, Raman spectroscopy, X-ray photoelectron spectroscopy, as well dc-electrical and optical characterization to ensure the formation of the delta-phase. Finally, ac impedance measurements were done to study the ac conductivity as a function of the temperature. For this, rectangular Pt electrodes were deposited on the surface of the films 0.8 mm apart. The ac impedance was obtained from 0.01 Hz to 100 kHz and the temperature was increased up to 200°C. The results of the ac conductivity were compared to the dc conductivity.

INTRODUCTION

This study reports on hydroxyapatite (HA) coatings and HA-based coatings doped with silicate or silver ions. The targets consisted of powders of Si-containing HA (Si-HA) $\text{Ca}_{10}(\text{PO}_4)_{6-x}(\text{SiO}_4)_x(\text{OH})_{2-x}$ ($x=0.5$ and 1.72) and Ag-containing HA (Ag-HA) $\text{Ca}_{10-x}\text{Ag}_x(\text{PO}_4)_6(\text{OH})_{2-x}$ ($x=0.3$). Thin nanostructured calcium phosphate-based coatings were deposited by RF-magnetron sputtering (RFMS) at a power level 30-290 W, a negative substrate bias up to 100 V, and a pressure of 0.1 Pa. As-deposited (up to 1 μm thick) coatings were characterized by EDX, ESEM, XRD, IR spectroscopy, and a pull off test. The cell viability was assessed by the MTT assay with MG-63 osteoblast-like sarcoma cells. In case of Ag-HA coatings, antibacterial tests in vitro using *E. coli* bacteria were performed.

RESULTS AND DISCUSSION

As-deposited calcium phosphate-based coatings are dense, pore-free and their composition resembled that of the precursor target. The chemical, and phase composition as well as thickness and structure can be varied by a particular set of deposition control parameters. A low rf-power density ($0.1-0.5 \text{ W}\times\text{cm}^{-2}$) resulted in amorphous or low crystalline calcium phosphate-coating structure, an increase in rf-power level ($>0.5 \text{ W}\times\text{cm}^{-2}$) induced the coating crystallization. The coatings consisted

of hydroxyapatite as all of the observed X-ray diffraction peaks matched the ICDD 9-432 card. The four strongest peaks were observed at 25.8° (002), 31.7° (211), 32.2° (112), and 32.9° (300). The XRD pattern of the coating at different negative bias showed a halo located at 32° typical for a nanostructured state. A negative substrate bias allowed us to vary the Ca/P ratio between 1.53 and 4 [1]. The adhesion strength of the coatings was higher than 40 MPa. The MTT test showed that the cell viability for the coatings with the different Ca/P ratio was up to 70 percent higher than that in case of the control substrates. Osteoblast-like cells attached and grew well on the surface of the coatings. The experiments with *E. coli* showed that there is no significant influence of the given Ag-content in the Ag-HA films on the vitality of bacteria. No significant antibacterial effect was found in the case of Ti plates with or without Ag-HA coatings. The concentration of Ag was below 0.1 $\mu\text{g L}^{-1}$ after dissolution of the coating by HNO_3 and subsequent Ag determination by atomic absorption spectroscopy, when a coating thickness did not exceed 500 nm. The presence of Ag in HA coating was estimated by EDX to ~1-3 at%. In the case of the Ag-HA target, a clear antibacterial effect was observed. We assume that a higher concentration of Ag in the target or increase in the coating thickness will allow us to prepare a RFMS Ag-containing calcium phosphate coating with antibacterial effect.

CONCLUSIONS

RFMS is well suited to prepare HA-based coatings with different structure and stoichiometry. Based on the obtained results, we suggest that RFMS-deposited coatings are prospective to be used in clinical practice, i.e. in stomatology or craniofacial medicine, where the initial material surface porosity for a further bone in growth should be preserved.

Growth behavior of cyclic chemical vapor deposited Al₂O₃ layer for passivation of OLEDs lighting devices

T14 Thin Films

#TF-P2-44

H. Jang, B.H. Choi, J.H. Lee.

Korea Institute of Industrial Technology - Kwangju-Si (Korea, republic of).

One of challenging issue in OLEDs is to prepare high quality passivation layer with high water vapor transmission rate and density. Up to now, alternating structure of sputtered Al₂O₃ and organic material was used as passivation layer. However, there is an ever increasing interest to form thin film passivation layer with comparable characteristics and thinner thickness. In this study, we have proposed and developed modified deposition technology of Al₂O₃ layer for the application to passivation layer of OLEDs devices. By modifying ALD into cyclic CVD, very uniform Al₂O₃ layer was prepared with high density with high deposition rate. TMA and oxygen plasma were used as precursor and reactant, respectively. The precursor injection time and oxygen plasma treatment time was optimized to obtain uniform Al₂O₃ film with high density. One cycle consist of precursor feeding, reactant feeding followed by plasma treatment and purge. Instead of injecting the precursor and reactant separate cycle, TMA and oxygen was co-fed into the process chamber, followed by plasma treatment like CVD process. Fig.1 shows thickness of Al₂O₃ as a function of deposition cycles. As deposition cycle increased, the total thickness was increased linearly, which shows typical characteristics of ALD. At low deposition cycles under 50, only Al₂O₃ islands were observed, which means incubation time is needed. The measured deposition rate was 0.4nm/cycle, which is 3 times higher than normal ALD. The measured density was 3.2 g/cm³, which is a comparable value obtained from bulk Al₂O₃, and stoichiometry was well matched. Fig.2 shows FE-SEM images of surface and cross-sectional view of prepared Al₂O₃ layer by cyclic CVD. As shown in Fig. 2, very uniform Al₂O₃ layer was formed by cyclic CVD technology with high deposition rate and density. Our study shows cyclic CVD grown Al₂O₃ layer can be used as a passivation layer of OLEDs devices.

Optical and structural properties of ITO and ITON thin films

T14 Thin Films

#TF-P2-30

M. Sparvoli, R. Onmori.

Universidade de São Paulo - São Paulo (Brazil).

The oxynitrides of many metals have been investigated during the last decade [1]. Indium tin oxide (ITO) is a n-type degenerate semiconductor with a band gap that varies between 3.2 and 4.0 eV. Recently it was obtained a new oxide type that combines ITO and nitrogen: the indium-tin-oxynitride (ITON). The incorporation of nitrogen into the film could improve further the optical and structural properties of the ITON films and thus making ITON film an ideal transparent and conducting material for opto-electronic applications. The deposition of the oxynitride thin films is generally performed in plasma-containing systems like sputtering and pulsed-laser deposition systems. In this work, ITO and ITON films were fabricated by evaporation and annealing techniques. The substrate was silicon (75 mm, p type, 1-10 W.cm) and optical three-inch glass wafers with 0.5 mm thickness. The thin films were analyzed with UV-Vis-Nir spectra transmittance and absorbance, SEM (Scanning Electron Microscopy) and RBS (Rutherford Back Scattering). The optical band gap was estimated for samples annealed with oxygen and nitrogen; the band gap values obtained were 3.23 eV and 3.05 eV, respectively. RBS spectra showed the presence of nitrogen. These materials are naturally nanostructured (Figure 1) and show amount of optical properties as transparence in visible region.

A Study on Poly(3,4-ethylenedioxythiophene) Thin Film Vapour Phase-Polymerized with Iron(III) Oxidants on 3-Aminopropyltriethoxysilane Self-Assembled Monolayer

T14 Thin Films

#TF-P2-14

S. Kim, S. Choi, F. Ma, J.W. Lee, B.B. Choi.

Pai Chai University - Daejeon (Korea, republic of).

In this study, Poly(3,4-ethylenedioxythiophene) (PEDOT) thin films polymerized with Iron(III) chloride (FeCl_3) and grown on atomically smooth and highly dense 3-aminopropyltriethoxysilane self-assembled monolayer (APS-SAM) surfaces by vapour phase polymerization (VPP) method have been investigated. PEDOT thin films were synthesized on various substrates, i.e., APS self-assembled SiO_2 wafer, glass, and quartz surfaces. Our recent study discovered that electrical conductivity of PEDOT thin film (~100 nm thick) vapour phase-polymerized on SiO_2 surface reaches up to nearly 4,000 S/cm.¹ Such highly conductive polymer film was accomplished via a new combination of a base inhibitor and tri-block copolymer during VPP. In order to explain unusually high conductivity, the films were closely examined by using various analyzing tools such as field emission-scanning electron microscope, atomic force microscope, x-ray reflectivity, grazing angle incidence x-ray diffraction. The close examination is still underway. After careful analyses, it is highly anticipated that how the film conductivity is affected by the additives (base inhibitors and polymers) can be at least in part explained.

Advances in Process Technology and Deposition Equipment for HiPIMS Coatings for Cutting Tools

T14 Thin Films

#TF/SE-1-Or-10

C. Schiffers, T. Leyendecker, O. Lemmer, W. Kölker.

CemeCon AG - Würselen (Germany).

Abstract for RSD2013

HiPIMS is characterised by short power pulses with an extremely short signal rise time. The design of the coating equipment need to take this characteristic into account with regard to feeding the electrical energy into the sputtering cathodes and finally into the plasma. This paper will present recent results on the correlation of the hardware design of the machine and the coating process. Fundamental research about the efficiency of the pulse transfer and about methods to transmit an undistorted pulse shape and wave form into the process was done.

The end user of a cutting tool sets its focus to the properties of the coating and, most important, to the machining characteristics of the film. Examples and field data will show how the most up-to-date HiPIMS coatings boost both productivity and quality.

SEM images reveal a dense morphology of HiPIMS coatings. To this feature can be attributed that HiPIMS films combine high hardness and a relatively low Young's modulus indicating a high coating toughness in a way most favourable for metal cutting.

Super smooth coatings, free from any droplets, and low compressive stress are the most beneficial characteristics of sputter coatings for cutting tools. The effective bombardment of the growing film with highly ionized species further improves the surface of HiPIMS coatings.

TF-P3-12

Transparent and conductive amorphous stannic oxide thin films deposited by plasma-enhanced pulsed laser deposition

T14 Thin Films

#TF-P3-12

N. Oda, K. Nose, M. Kamiko, Y. Mitsuda.

Institute of Industrial Science, The Univ. Tokyo - Tokyo (Japan).

Transparent conductive thin films (TCF) have been widely used in optoelectronic devices such as flat panel displays and solar cells. TCF based on SnO₂ are studied extensively because of their high chemical and thermal stability, resource sustainability, and relatively low cost. Fabricating SnO₂ films with high crystallinity is an active area of this material research, since high electron mobility can be obtained in large grains^[1]. On the other hand, amorphous SnO₂ films have potential to show high electron mobility due to less scattering at grain boundaries. In this study, we fabricated transparent and conductive amorphous SnO₂ thin films through plasma-enhanced pulsed laser deposition (PE-PLD).

PE-PLD was performed in N₂O gas atmosphere of 5.0×10^{-2} Pa, using pure SnO₂ sintered pellet as targets. Glass substrate was placed at 47 mm distance from the target and set to be 570 K. The energy, wavelength, and repetition frequency of the Q-switched Nd:YAG laser were 30 mJ/pulse, 266 nm, and 10 Hz. Continuous rf power (13.56 MHz) was capacitively supplied during deposition. Deposition rate and time were controlled so that the film thicknesses were constant (around 100 nm). The films were analyzed by XRD, XPS, Hall-effect measurement system, and UV-vis transparent spectrometer.

Figure 1 shows the XRD patterns of the films deposited in pure N₂O atmosphere. Input rf power was (A) 40 W, or (B) 0 W. The film (A) exhibited amorphous structure, while the film (B) was (001)-oriented crystalline SnO. Sn in the film (A) was found to be tetravalent by XPS spectra (not shown). These results indicate that amorphous SnO₂ film on glass substrate was obtained by PE-PLD. The film (A) was highly transparent in visible light (Fig. 2). Resistivity, mobility, and carrier density of the film (A) were 9.6×10^{-3} Ωcm, 13.2 cm, and 4.9×10^{19} /cm³, respectively.

Universidad Autonoma de Madrid - Madrid (Spain).

Nickel oxide is an interesting material both from the fundamental and technological point of view [1-3]. Although stoichiometric NiO is a strong insulator, with resistivity values of order of 10^{13} Ω cm, structural disorder and lack of stoichiometry considerably lower these values [4]. Indeed, NiO thin films have been proposed as a p-type semiconducting transparent material [5]. We have grown NiO thin films by RF magnetron sputtering with a mixed O₂-Ar plasma. The oxygen content of the plasma was varied between 0% and 100%, in order to change the structure and stoichiometry of the resulting NiO films. The films were characterized by X-ray diffraction (XRD), and X-ray absorption spectroscopy (XAS), both in XANES and EXAFS mode. The oxygen content of the plasma modifies the structure and properties of the coatings. XRD results reveal a grain refinement and an increased disorder of the lattice when the oxygen content of the plasma is increased. These microstructural effects are confirmed by EXAFS, measured at the Ni-K edge, where an increase of the Debye-Waller factor for higher O₂ content is clearly observed.

The electrical resistivity of the NiO films has been determined by the Van der Pauw method. The resistivity of the samples grown with oxygen in the plasma is lower than that of the sample grown with pure Ar, and decreases as the oxygen content of the plasma increases. Figure 1 shows XANES spectra at the O-K edge of samples grown with different oxygen content in the plasma. The observed peaks are related to empty Ni-3d states hybridized with O-2p states above the Fermi level. The spectrum of the sample with 0% oxygen shows the typical features of standard NiO. For the samples grown with oxygen in the plasma, a peak appears 3 eV below the absorption edge. This peak can be assigned to empty states below the Fermi energy, i.e., to hole states. The intensity of this peak increases with the oxygen content of the plasma, as does the conductivity of the films. Consequently, there is a direct

correlation between the intensity of this peak, associated to hole states, and the conductivity of the NiO films.

Production of SiC hollow cylinders starting from CNTs Pillars

T14 Thin Films

#TF-1-Or-2

M. Giorcelli, M. Pavese, M.I. Shahzad, A. Tagliaferro.

Politecnico di Torino - Torino (Italy).

We fabricated Silicon Carbide (SiC) hollow cylinders by reacting silicon monoxide (SiO) powder with Multiwalled Carbon Nanotubes (MWCNTs) pillars. The result was obtained using a multi-step process:

- 1) a silicon substrate was patterned in order to define the regions where CNTs will grow. In particular, we delimited circular region where to grow CNTs
- 2) MWCNTs pillars (Fig.1-1) were grown by Chemical Vapour Deposition (CVD) starting from solid precursors, in particular Camphor and Ferrocene [1].
- 3) CNT pillars were removed from the substrate
- 4) CNT pillars were heated at high temperature in inert atmosphere in presence of SiO powder. This led to coat (Fig. 1-2) the CNT pillars with a SiC shell
- 5) Coated pillars were heated at high temperature in presence of oxygen in order to burn carbon material inside SiC Cylinders. SiC hollow cylinders were produced (Fig.1-3)

The SiC nature of the hollow cylinders shell is confirmed by X-ray diffraction (Fig 2), where the characteristic SiC peaks are evidenced.

TF-7-Or-2

Coating of granulates and powders by magnetron sputtering

T14 Thin Films

#TF-7-Or-2

G. Schmid, C. Eisenmenger-Sittner.

Vienna University of Technology - Vienna (Austria).

This work presents methods of coating granular or powder particles in general, using magnetron sputtering, and more specifically of coating hollow glass microspheres (diameter 5-70 μm , wall thickness approx. 1 μm). Microspheres of this type may serve as efficient system to store hydrogen at high pressures.

Hydrogen is released from previously-filled hollow glass microspheres when they are heated to a temperature of approximately 120 $^{\circ}\text{C}$. To reach this temperature is the main challenge of this storage system. It is possible to use an exothermal chemical reaction, in this case a NaBH_4 -water (Venpure™) reaction, which produces hydrogen as a most welcome by-product. This chemical reaction has to be initialized by a catalyst deposited on the hollow glass microspheres. Therefore, it is necessary that every single sphere is coated with the catalyst, which was done by magnetron sputtering.

To generate uniform coatings on the microspheres, an apparatus was designed with a coating vessel of a special shape rotating beneath the sputtering target. As it is known however, in vacuum the particles tend to adhere to one another and to the surfaces of the containing vessel as coating proceeds, especially when the powder is coated with pure metal. This prohibits most of the particles from being coated since they are not exposed to the sputtering beam. To overcome these problems a new concussion mechanism was developed to break up the particle clusters. This concussion mechanism was found to work much more reliable than the mechanism described in an earlier work of the author [1].

It will be shown that powder substrates of different kinds can be coated successfully. In addition results of the catalytic experiments to generate hydrogen and to increase the reaction temperature will be presented.

This work was supported by the Austrian Science Fund (FWF), project "CatSphere", grant number P-22718.

TF-9-Or-5

Film thickness measurement with high spatial resolution on granular materials via optical methods

T14 Thin Films

#TF-9-Or-5

H. Mahr, M.T. Smolle, C. Eisenmenger-Sittner.

Vienna University of Technology - Vienna (Austria).

Coatings on powders or granulates may play an important role regarding surface activation, manipulation of sintering properties or in catalysis. The determination of film thickness and thickness uniformity on granular materials can be a difficult and expensive task using commonly available methods. One possible way is film thickness measurement via visible light transmission spectroscopy, which is a viable method as long as substrate material and coating are transparent. To apply this method to granular materials, a way of spatial resolution has to be implemented to distinguish between measurable objects and artefacts.

This can be achieved by using commercially available transmission light scanners as transmission measurement instruments. Thus providing spatial resolutions up to 157 pixels per mm, i.e. below 10 μm , and three distinct wavelengths in the visible range (red, green, blue, depending on the CCD chip used in the given scanner) for wavelength dependant transmission measurement. The viability of this method is shown by the comparison of measurement results for thin planar metallic coatings via the scanning device and established measurement methods, e.g. profilometry or Scanning Electron Microscopy.

For film thickness measurement on granular materials the spatially resolved transmission data has to be processed via particle detection and calculation algorithms. For this purpose each detected particle must be resolved in a minimum number of pixels (approximately 30), which means that particles with minimal diameters of around 200 μm can be measured with common transmission light scanners. Smaller particles, down to diameters of 10 μm need higher spatial resolutions. To achieve that goal a digital transmission measurement workplace supported by an optical microscope was developed.

Both, common scanning devices and the digital transmission measurement workplace were used for film thickness determination of metallic coatings on granular diamond particles (177 - 400 μm) and hollow micro glass spheres (5 - 70 μm). The measurement algorithms were adapted for each case to consider the different morphologies of diamond particles and glass spheres. These results were compared to thickness values obtained from measurements on FIB cross sections of coated particles by Scanning Electron Microscopy and Transmission Electron Microscopy.

Mid Sweden University - Sundsvall (Sweden).

Coating [1] of thin films is of importance for making functionalized surfaces with applications in many fields from electronics to consumer packaging. To decrease the cost, large scale roll-to-roll [2] coating techniques are usually done at high speed, for example, ordinary printing paper is coated at a speed of tens of meters per second by depositing micrometer thick layers of clay. However, nanometer thin films are harder to coat at high speed by wet-chemical methods, requiring special roll-to-roll vacuum techniques [3] with the cost of higher complexity.

Here, we report a simple wet chemical method for high-speed coating of films down to molecular thicknesses, called soap-film coating (SFC) [4]. The technique is based on forcing a substrate through a soap film that contains nanomaterials. In the simplest laboratory version, the films can be deposited by a hand-coating procedure set up in a couple of minutes. The method is quite general molecules or nanomaterials or sub-micrometer materials (Figure 1) with thicknesses ranging from less than a monolayer to several layers at speeds up to meters per second. The applications of soap-film coating is quite wide and we will show solar cells, electrochromic devices, optical nanoparticle crystals, and nano-film devices. We believe that the soap-film coating method is potentially important for industrial-scale nanotechnology.

It is well known that several materials, when are in nano- or well-ordered form, exhibit catalytic properties different from those of in bulk phase [1]. Gold nanoparticles [2], thin vanadium oxide layers [3] can be mentioned as examples which later gained industrial importance.

In this contribution we present the preparation of non-continuous MoO₂ films which were created by oxidation of nano-porous pure molybdenum films in a controlled atmosphere. The monoclinic phase MoO₂ particles with mean size lower than 10 nm exhibit 42% selectivity to propylene oxide.

Microstructure of PVD deposited metallic layers is described by Thornton diagram of film growth [4]. Detailed study of Thornton's model for the deposition at low substrate temperature was published in 2003 by Petrov et al [5]. In this work there was shown the possibility to deposit non-continuous films with various aspect ratios of individual (consisting) metallic particles. By other words there is possibility to prepare non - continuous metallic film consisting of separated metallic needle-shape crystallites. The pores (voids) in such films extend through the entire thickness of the layer. This film morphology is very suitable for the subsequent oxidation needed for the creation of single phase MoO₂ films (Fig. 1).

The dc magnetron sputtering was used for Mo deposition. The discontinuity of Mo layers was achieved by the deposition at relatively high Ar pressure (approx. 0,1 Pa) and low substrate temperature (approx. -20 °C). By this procedure we obtain the nano-structured Mo non-continuous films.

The nano-morphology of all prepared films was controlled by in-plane and cross-sectional transmission electron microscopy.

Chemoresistive sensors based on semiconducting metal oxides have attracted enormous attention for diverse applications such as environmental monitoring, food processing, semiconductor processing, agriculture, automotive and aerospace industries and medical diagnosis. Among these applications, the detection of human diseases such as lung cancer, asthma and diabetes by analyzing exhaled breath is an emerging field of medical diagnostic, which can be a noninvasive and cost-effective alternative to conventional blood analysis methods. For instance, detecting a NO concentration more than 30 parts per billion (ppb) in exhaled human breath indicates that the human may possess asthma due to inflammatory response in the airways, which is especially serious for young children. However, human breath is a mixture of nitrogen, carbon dioxide, nitric oxide, water vapor (< 80%) and more than 1000 volatile traces with concentrations ranging from several parts per trillion (ppt) to several parts per million (ppm). Due to this complexity of human breath, the selective detection of ppb-level NO using metal oxide-based chemoresistive sensors is very challenging because individual semiconducting metal oxides have in general large responses to both oxidizing or reducing gases such as NO, NO₂, CO, H₂, NH₃, and volatile organic compounds including ethanol and acetone. Herein, we have synthesized the self-assembled villi-like WO₃ thin film nanostructures with large specific surface area which have been achieved using glancing angle deposition. Ultrahigh response, excellent selectivity and a ppt-level detection limit to nitric oxide (NO) in 80% of relative humidity demonstrate the great potential of the porous WO₃ thin film nanostructures for use in high performance breath analyzers.

Deuterium retention in nanostructured tungsten films exposed to high-flux plasmas

T14 Thin Films

#SE/TF-1-Or-3

M. Passoni ¹, D. Dellasega ¹, A. Pezzoli ¹, M.H.J. 't Hoen ², P.A. Zeijlmans Van Emmichoven ².

¹Dipartimento di Energia, Politecnico di Milano; Istituto di Fisica del Plasma, Consiglio Nazionale delle Ricerche, EURATOM-ENEA-CNR Association - Milano (Italy), ²FOM Institute DIFFER, Dutch Institute for Fundamental Energy Research, Association EURATOM-FOM, Partner in the Trilateral Euregio Cluster - Nieuwegein (Netherlands).

We present an experimental research aimed at depositing compact nanostructured W films by Pulsed Laser Deposition (PLD) and establishing their stability and deuterium (D) retention properties against exposure to high-flux plasmas. W films are extensively studied, thanks to their high thermal stability, hardness and low resistivity. They are used as barrier layer in semiconductor integrated circuits, absorption layers in X-ray lithography and components of X-ray mirrors. W coatings have been recently adopted to cover plasma facing surfaces of first walls in Tokamaks (e.g. JET ITER-like wall) [1]. Neutron, particle, e.m. radiation deeply change first wall material properties during machine operation, inducing modifications at the nanometric level, like vacancies, defect formation, nanocrystalline growth [2]. A lot of efforts are currently devoted to the enhancement of non-permeation and resistance properties in hostile environment through suitable control of film nanostructure, but satisfactory results are far from being achieved, mostly because of lack of knowledge in the influence of materials properties at the nanoscale on their macroscopic behavior.

To investigate this issue we deposited by PLD nanostructured W coatings, characterized by high resolution SEM, XRD and EDS [3]. Thanks to the flexibility of PLD it is possible to study a wide range of coating compositions, structures, growths and morphologies, by changing the process parameters. The coatings are dense, non porous and exhibit different crystalline structures, ranging from highly crystallographic oriented with columnar structure to "amorphous like" structure

with high level of nm defects (Fig. 1). Nanocrystalline domain size has been controlled down to less than 2 nm. We exposed the films to high-flux ($>10^{24} \text{ m}^{-2}\text{s}^{-1}$) D plasmas in the divertor simulator Pilot-PSI, to investigate retention and erosion properties varying the crystalline structure. Surface temperatures below 520K and between 600-950K were adopted, to investigate the effect of vacancy migration during D implantation. Thermal Desorption Spectroscopy measurements show that retention properties are highly influenced by nanostructure and disorder. The measured retention levels are similar or even much higher than the highest measured in pre-damaged W. Surface morphology changes, like bubble formation and nano-crystalline structures, were found. An interpretation of this behavior will be given together with possible indications for the surface engineering of Tokamaks divertor/first-wall.

Ceramic thin films are not compatible with flexible electronics, because the crystallization temperature of the ceramic thin films (>600°C) is much higher than melting temperature of flexible polymers (<400°C), although the ceramic thin films have a remarkable functionality such as high dielectric permittivity, ferroelectricity, piezoelectricity, etc. In this works, we used excimer laser annealing (ELA) technique which is attractive heat process for the low-temperature crystallization of the thin films because of its material selectivity, short penetration depth, and the rapid heating time. Amorphous BaTiO₃ (BTO) thin films were deposited on the polymer substrates by RF-sputtering at R.T. To determine the ELA condition, COMSOL multi-physic program was used for heat transfer simulation of thermal gradients in the BTO thin films. The ELA was carried out with various conditions as function of the applied laser energy density, the number of pulses, and the repetition rate. The X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) were used to analyze the structural characteristics. The leakage currents, and dielectric constants and dielectric losses were measured by I-V meter and impedance analyzer, respectively. As a result, the crystallized BTO thin films on polymer substrates exhibited significant improvement of crystal quality and electrical performance. We obtained the flexible thin film capacitors with the enhanced dielectric performance by a particular experimental condition on the ELA as the low temperature crystallization process.

A novel production technique to synthesize of Mg₂Si thin films

T14 Thin Films

#SE/TF-4-Or-7

N. Sezgin, E. Kacar, K. Kazmanli, M. Urgan.

Istanbul Technical University, Department of Metallurgical and Materials Engineering, 34469, Maslak - Istanbul (Turkey).

In the present study, to develop a new methodology for production of Mg₂Si thin films, surfaces of silicon substrates were modified with magnesium cathode, by using cathodic arc plasma treatment process. In the literature to form the Mg₂Si thin films, after deposition process of Mg on Si substrates, vacuum annealing heat treatment were applied to the samples. At this study, unlike the literature, to obtain Mg₂Si intermetallic phase, deposition of Mg was achieved under low bias voltages and then to form alloy by enhancing diffusion/mixing high bias voltages were applied to the substrates. Different coating parameters such as; deposition time, bias voltage, duty cycle were investigated. Structural, morphological and elemental properties were determined by SEM, EDS, Thin Film XRD and GDOES analyzing methods.

In this work, the optimization of an all solid inorganic IR electrochromic device is studied. This electrochromic device works in reflection on absorbing background. Thin layers of amorphous or crystallized WO_3 were deposited on a new, electronically conducting, electrode material based on sub-stoichiometric tungsten oxide " WO_{3-y} " [1]. This stack consists of an IR reflector, crystallized WO_3 in the reduced state, and of an electronic conductor WO_{3-y} which also absorbs IR radiations. This innovative bilayer is deposited on a solid electrolyte composed of tantalum oxide (Ta_2O_5) and a counter electrode serving as a hydrated proton storage layer ($\text{H}_x\text{WO}_3 \cdot n\text{H}_2\text{O}$).

All these layers are deposited by magnetron sputtering (PVD) in one single run.

The study was focused on optimizing the PVD deposition conditions. The oxygen and water was added to the plasma gas (Argon) to deposit these oxide layers. The stoichiometry of these layers is directly related to the O_2 and H_2O partial pressure, while their morphology depends on the total pressure in the chamber and the substrate temperature.

Then, the in-situ intercalation of structural water in the layer $\text{H}_x\text{WO}_3 \cdot n\text{H}_2\text{O}$ was addressed. Finally, proton permeability of the solid electrolyte Ta_2O_5 was optimized. All these oxides were characterized by IR spectroscopy, SEM, TEM, X-ray photoelectron spectroscopy (XPS) and ion beam analysis for film composition determination (RBS: Rutherford Backscattering Spectroscopy and NRA: Nuclear

Reaction Analysis). Electrochromic (EC) properties were investigated by cycling the WO_3 based thin films in various electrolytes including ionic liquids. The relationship between the EC performances and the films characteristics will be discussed in details.

One-dimensional nanostructures (such as wires, rods, tubes) have shown wide potential applications in fabricating nanoscale electronics, optoelectronics and sensors. In order to realize various tailor-made functions, nanowires with a core/shell structure have been created by a variety of techniques but there are a few reports on the fabrication of ZnO sheaths by using a sputtering technique [1, 2]. Compared sputtering with other deposition methods, it seems to be more efficient, well-controllable and precise for nano-coatings of three-dimensional samples [3]. The forming of homogenous coatings by transparent/conductive Ga doped zinc oxide (ZnO:Ga) thin films via continual or sequential RF diode sputtering is presented. ZnO:Ga films (thickness of 100 nm) were continually deposited at the nominal rate of 12 nm/min. A sequential sputtering (layer-by-layer, 1 nm-by-1 nm) of films with thicknesses in the range of 10 nm–100 nm was performed at the nominal rate of 8 nm/min. All films deposited by both sputtering modes were preferentially textured in [001] c-axis direction (an inset in figure) and they showed the columnar structure. Nanocrystalline structure of sputtered ZnO:Ga films depended on the mode of sputtering. Continually sputtered films showed higher size of nanocrystals (≈ 40 nm) in comparison with sequentially deposited films (≈ 15 nm). The XRD patterns of ZnO:Ga thin films in-situ annealed in vacuum at temperatures from room temperature to 400 °C showed that the transition temperature range of structural changes has began at a relatively low temperature about 200°C (figure). The shift of (002) diffraction lines, improvement of their symmetry and intensity – all demonstrate better texture and more ordered crystalline structure. Presented results confirmed the ability of both sequential and continual modes of RF diode sputtering to prepare ultra-thin

homogenous ZnO:Ga coatings with highly ordered nanocrystalline columnar structure.

ABSTRACT

In the present work, a gas sensing device based on Vanadium oxide thin films (V₂O₅)/ Porous Si (PS) / Si structure has been used to detect CO₂ gas at different concentration. The V₂O₅ thin films were deposited on monocristalline silicon, porous silicon and glass substrates by the sol-gel (Dip-coating) technique. The Vanadium oxide has been produced from vanadium alcoxide precursor. Different structures based on V₂O₅ / Porous Si/Si have been realized and studied. **Figure1** shows a schematic diagram of the V₂O₅/PS/Si sensor, and **Figure 2** shows SEM image of V₂O₅ nanostructures.

Current-voltage characterization shows that the sensor characteristics are modified in the presence of gases. The contribution of each layer (Vanadium oxide and PS) has been established. The mechanism of CO₂ adsorption in semiconductor is more complex; however the same mechanism in oxide semiconductor is mainly attributed to physical interaction. It is interesting to note that a same shape current variation with CO₂ gas pressure, has been observed for sensors based on CH_x-PS/Si structure in presence of CO₂ and H₂ gas and hydrocarbon gas [1], indicating that the Al/V₂O₅/PS/Si/Al structure behaves like CH_x/PS/Si structure. However , for a constant CO₂ gas concentration the current variation ΔI of the sensor based on V₂O₅/PS structure is found lower than tha of the CH_x/PS- based sensor [2] probably because of the presence of the vanadium oxide.

Understanding of Cu-Mn alloy films is of scientific interest because of their possible application as contact or interconnect materials in memory devices or integrated circuits. In this work we aimed to reveal the physical property - structure relations in the system. Cu-Mn alloy films were co-deposited by DC magnetron sputtering from Cu and Mn targets at room temperature with a thickness of around 1 μ m. Cross sectional samples for TEM were prepared and HREM investigation was carried out. Electric measurements were made by four probe method and nanoindentation was carried out in a UMIS 2000 nanoindenter using a Berkovich indenter. Mapping the structure of the Cu-Mn thin film system we found some discrepancies from the equilibrium phase diagram of the bulk system [1]. Beside the pure fcc Cu and pure α Mn phases the following structure zones were found. The low Mn content films (up to ~25 at% Mn) have Cu based fcc solid solution structure. Between 40 and 65 at% Mn content a disordered phase region is found, while from ~80 at% Mn content α Mn type solid solution forms [2]. Between these one phase regions narrow two-phase regions exist. Measuring the physical properties can also show correlation with the above phase regions. Deviations from the linear behaviour of electrical resistivity (Fig. 1.) mark the two phase regions of the system. The shape of the curve also suggests that the mutual solubility of components is about 20 at%. The appearance of the clear minimum on the hardness curve points to a structural peculiarity (Fig. 2.). Its position corresponds to the border of the one phase disordered region.

This work presents sol-gel technological process for obtaining thin films of ZnO and ZnO:Al, where the Zn/Al ratio varies. The effect of annealing treatments has been studied on their properties. Structural evolution with temperature is investigated by using X-Ray diffraction (XRD). Fourier Transform Infrared (FTIR) and UV-VIS spectrophotometry are applied for characterization of the vibrational and optical properties.

XRD analysis of ZnO and ZnO:Al films revealed that the main XRD maxima, the strongest lines observed in the spectra, are assigned to wurtzite hexagonal crystal phase of ZnO (JCPDS 01-07-8070). It can be seen that the addition of Al leads to wider lines with considerable lower intensities, which suggests that the crystallization degree is decayed. The average crystallite sizes are estimated from XRD patterns according to Scherrer's formula (from the three XRD peaks attributed to hexagonal ZnO: 100, 002 and 101) and the comparison of the results shows that the average crystallite size of ZnO is 32.3 nm, and the value for ZnO:Al is 20.0 nm.

FTIR analysis reveals that both the metal additive affects the vibrational properties of the studied films. The main absorption bands due to metal-oxide bonds are expected to appear in the spectral range 350-1200 cm⁻¹. For the preheating ZnO:Al films, weak peaks at 665 and 681 cm⁻¹ are observed, which might be assigned to the O-Al-O bonding, they are seen for the highest temperature annealed films. The main IR lines are located in the spectral range 390-425 cm⁻¹. The Al component influences the shapes of the obtained absorption bands, they are broader comparing to pure zinc oxide spectra and their intensity also decreases with increasing the aluminum content.

The optical properties of the sol-gel ZnO and ZnO:Al films reveal very interesting features. The ZnO films possess lower transparency compared to the ZnO:Al films and its transmittance decreases with the annealing temperatures. If the Al

component is increased in the sol solutions, the obtained films possess significantly higher transparency. The experiments with higher Al content manifests transparency as high as 90 %, very close to that of pure Al₂O₃ films (sol-gel Al₂O₃ films are prepared for comparison).

The optical band gap values are estimated from the spectrophotometric data. The optical band gap values of pure ZnO show no trend with annealing ($E_g=3.28-3.30$ eV), for ZnO:Al films the values are slightly decreased with annealing temperature. The ZnO:Al films reveal an increase of the optical band gap values with increasing the Al additions from 3.28 up to 3.44 eV.

Sol-gel technology has been successfully applied for deposition of transparent ZnO and ZnO:Al films by spin coating method. XRD analysis reveals predominantly wurtzite crystal phase with significantly decreasing of the crystallization and crystallite sizes due to Al additive. Optical transmittance improves for ZnO:Al films with increasing the aluminium quantity.

Technolgy - Suzuka,mie (Japan), ⁴Q-Light co., Ltd. - Hanamaki, Iwate (Japan).

The evaluation method of the ductility of the materials constituting organic semiconductor was studied, and the relations between applied strain and the fracture of thin films were obtained. The final target of this work is the improvement of flexibility of organic light emitting diode (OLED). The tensile test of the thin films deposited on flexible substrate is conducted, and the vulnerable parts of the constituent material of the OLED is quantitatively understood, further the guideline for designing OLED structure will be obtained. In the present paper, tensile test of aluminum oxide thin films deposited on a polyethylene terephthalate (PET) substrate was carried out under a constant condition, in addition indium zinc oxide (IZO), which is one of a transparent conductive oxide (TCO), and a α -NPD (Bis [N-(1-naphthyl)-N-phenyl] benzidine), which is typical organic light emitting material, deposited on polyethylene naphthalate (PEN) substrates prepared by vacuum processes were also examined. Consequently the following results were obtained:(1)Cracking of the aluminum oxide thin films can be observed using an bright field microscopy in more than 40 times the magnification, (2)Cracking initiated at a strain of about 3%, (3)the number of cracking increased proportional to the strain, and saturated at about 9% strain. (4) Organic thin film α -NPD caused cracking as well as oxide thin films.

Organic polymer nano-thin films have been deposited on silicon substrate by using plasma enhanced chemical vapor deposition (PECVD) method (1,2). Ethylcyclohexane (ECH) was utilized as organic precursor, and hydrogen and Ar (argon) were used as a bubbler and carrier gases, respectively. In order to compare the difference of the thermal, electrical, and mechanical properties of the plasma polymerized nano-thin films, the organic polymer nano-thin films with 300 nm thickness were grown up under the conditions of various RF (radio frequency using 13.56 MHz) powers in the range of 20 ~ 60 W and annealed at various temperatures in the range of 200 ~ 500 °C. The nano-films were first analyzed by FT-IR, SEM, C-V, and Nano-indentation. The result of FT-IR measurement showed that the plasma polymerized nano-thin films have highly cross-linked density with increasing RF power. However, organic polymerized nano-thin films are thermally unstable because the intensity of -OH peak increased after annealing. SEM data also showed that the nano-films with smooth surface and sharp interface could be grown under various deposition conditions. Impedance analyzer was utilized for the measurements of C-V curves. From the electrical property measurements, the lowest dielectric constant was obtained to be 1.71. While, the values of dielectric constant were increased with increasing annealing temperature due to thermal instability above 300 °C. The hardness and Young's modulus of the organic thin films increased with increasing RF power, and decreased with increasing annealing temperature, respectively.

Cu(In,Ga)Se₂ solar cell absorber layers prepared by a single-step reactive co-sputtering process in Ar:H₂Se

T14 Thin Films

#TF-7-Or-9

J. Schulte, K. Harbauer, K. Ellmer.

Helmholtz-Zentrum Berlin GmbH (HZB) - Berlin (Germany).

Reactive and non-reactive magnetron sputtering is widely used in industry for the deposition of thin films for optical and electronic applications, hard coatings etc.. For thin film solar cells, several layers - mostly the electronically inactive ones (front and back contacts) - are deposited by this plasma-assisted, large area deposition method. Our group is studying the deposition of electronically active chalcopyrite absorber films for thin film solar cells deposited by reactive magnetron sputtering in Ar/H₂S atmospheres. For CuInS₂ films we were able to demonstrate the suitability of this process for the deposition of absorber layers by preparing a solar cell with an efficiency of 11.4%, which is comparable with other preparation techniques.

In this work we used reactive magnetron co-sputtering from a CuGa and an In target in an Ar/H₂Se gas mixture. With this one-step process it is possible to prepare single-phase Cu(In,Ga)Se₂ thin films with good crystallinity that can be used as absorber layers for thin film solar cells.

One important process parameter is the H₂Se content of the gas that influences not only the incorporation of Se into the film, but also the deposition rates from the metal targets and therefore the thickness, stoichiometry and the crystallinity of the films.

The XRD patterns of the H₂Se variation in Fig.1 demonstrate the formation of single phase Cu(In,Ga)Se₂ with a preferred (1 1 2) orientation, especially for higher H₂Se contents. For a content of 10% H₂Se in the process gas two additional peaks occur which can be attributed to a metallic Cu phase which indicates, that this reactive gas content is not sufficient for a complete selenization of the metal atoms.

In order to achieve absorber layers with good solar cell quality additional parameters as the specific sequence of process steps (Cu-poor or Cu-rich conditions) and the final film stoichiometry play an important role and are investigated. The influence of Na doping is investigated by comparing standard Mo back contacts to samples which have a Na-doped Mo layer.

The results for the first solar cells processed with absorber layers from these

depositions in Ar:H₂Se are promising and demonstrate the opportunities of reactive co-sputtering of electronically active films for thin film solar cells.

Duplex FCAD/ALD oxide nanocoatings for corrosion protection of steel

T14 Thin Films

#TF-3-Or-10

V. Maurice ¹, B. Díaz ¹, E. Härkönen ², S. Tervakangas ³, J. Światowska ¹, L. Tóth ⁴, G. Radnóczy ⁴, J. Kohlemainen ³, M. Ritala ², P. Marcus ¹.

¹CNRS/Chimie ParisTech - Paris (France), ²University of Helsinki - Helsinki (Finland), ³DIARC-Technology Inc. - Espoo (Finland), ⁴MFA - Budapest (Hungary).

Surface/interface analytical and electrochemical studies have been carried out in order to understand and develop the corrosion protection properties of duplex oxide nanocoatings grown by Atomic layer deposition (ALD) and Filtered Cathodic Arc Deposition (FCAD) on steel (AISI 52100, DIN 100Cr6) substrates. Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS), cross-section Transmission Electron Microscopy (TEM), potentiodynamic polarization and Electrochemical Impedance Spectroscopy (EIS) were used. Immersion tests were performed in corrosive chloride-containing neutral and acidic solutions (0.2 M NaCl, pH 7-7.2 or pH 2) at Open Circuit Potential with in situ monitoring by EIS analysis and post mortem surface and interface analysis mostly by ToF-SIMS. The coating efficiency was derived from the i-V and EIS data.

The results show effective sealing by a thin (typically 50 nm) oxide film deposited by ALD at 150-160°C [1,2]. ALD alumina provides the best sealing properties with a coating efficiency reaching 99.99 % of the substrate surface fraction but dissolves in corrosive environments [3,4]. It is stabilized by introducing tantalum oxide, either forming mixtures or nanolaminates with various architectures. Defects (cracks, pinholes) subsist after deposition due to the use of organic precursors and to organic interfacial residues, requiring to go beyond 10 nm in thickness for sealing of the more defective layers formed in the initial stages of deposition. Fe/Cr oxides poison the interface due to spurious growth prior to actual ALD deposition. In corrosive solutions, the iron-rich interfacial oxide dissolves following the penetration of the corrosive solution to the substrate surface via the coating defects. It creates voids promoting local breakdown and the propagation of localized corrosion.

The key improvement achieved with duplex coated systems is the replacement of the poorly corrosion resistant interfacial iron-rich oxide by a highly resistant interfacial sub-layer. The sub-layer is grown by FCAD that, thanks to sputtering prior to deposition, is able to produce substrate surfaces free of Fe/Cr oxides and organic residues [5]. Ta or Ta/Cr oxide mixtures are then deposited. A 10 nm thickness is enough to produce a continuous interlayer well-adherent to the clean substrate. A conformal 50 nm ALD top layer is then deposited to seal the defects in the FCAD sub-layer. The resulting sealing performance of the duplex system is similar to that of a single ALD layer. As for single systems, defects (cracks, pinholes) subsist after deposition and connect the alloy surface to the environment. In corrosive solutions, the iron-rich interfacial oxide traces also dissolves but only at the substrate surface exposed by the coating defects. There is no propagation of the reaction along the interface due to blocking by the FCAD sub-layer. As a consequence localized corrosion is limited to the bottom of the pre-existing defects and its propagation by coating breakdown is inhibited. The resistance to localized corrosion is thus markedly improved on non passivable substrates.

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° CP-FP 213996-1.

SE/TF-P2-17

A novel deposition method for a protective coating for bipolar plates in PEMFC

T14 Thin Films

#SE/TF-P2-17

Y. You, J.S. Choi, J.H. Joo.

Kunsan National University - Kunsan (Korea, republic of).

Protective coatings for bipolar plates in PEMFC (polymer electrolyte membrane fuel cell) should have high anti-corrosion characteristics and electrical conductivity under very aggressive conditions (sulfuric acid). US DOE set threshold corrosion current density as $1 \mu\text{A}/\text{cm}^2$ as well as contact resistance to $0.02 \text{ Ohm}\cdot\text{cm}^2$. Stainless steel sheets are a strong candidate for this purpose which has very stable chromium oxide surface layer. However, the electrical conductivity does not meet DOE specifications. Higher conductive material should be coated on top of SUS sheets. TiN, TaN, CrN and their alloy compounds are considered to meet the standards. Automotive systems must be cost-effective and high rate reactive PVD methods are necessary. Inductively Coupled Plasma (ICP) was proven to be effective in enhancing the film quality (density, microstructure, adhesion) in many material systems. Magnetron sputtering could be a good candidate, but the high cost would be a first barrier for automotive parts business. Evaporation based technique would be more appropriate for this purpose. Thermal evaporation has high deposition rate for most of materials, but reactive process needs secondary plasma to enhancing the surface reactivity and film to substrate adhesion strength. Cr has very high sublimation rate at high temperature before it starts to melt. We adopted inductively coupled plasma as a heating source for Cr rod for film deposition as well as film property enhancing secondary plasma source. 2 MHz driven ICP was used and dc biased Cr rod with Ar + N₂ mixed gas environment was acting as a high rate sputter-sublimation source to give meet DOE specifications: corrosion current density (at 0.6 V) was $2.097\text{E}-6 \text{ A}/\text{cm}^2$ and contact resistance was $28.8 \text{ mOhm}\cdot\text{cm}^2$.

Reactive sputter deposited nanocoral ZnO for biosensors

T14 Thin Films

#TF-P2-32

M.A. Borysiewicz¹, A. Baranowska-Korczyc², M. Wzorek¹, E. Dynowska², T. Wojciechowski², E. Kaminska¹, K. Fronc², D. Elbaum², T. Wojtowicz², A. Piotrowska¹.

¹Institute of Electron Technology - Warsaw (Poland), ²Institute of Physics, Polish Academy of Sciences - Warsaw (Poland).

Nanocoral ZnO films (see Fig. 1.) are fabricated using a two-step approach including first a deposition of porous Zn through reactive Zn sputtering followed by thermal oxidation. The resulting material exhibits the unique electro-optical ZnO properties (3,4 eV band gap and exciton binding energy of 60 meV) as well as a developed surface enabling absorption-based applications in devices such as gas sensors, biosensors or dye-sensitised solar cells. The growth mechanism of the films is discussed based on Langmuir probe and optical emission spectroscopy measurements of the plasma during sputtering and their correlation with X-ray diffraction and scanning electron microscopy cross-section image data of the films grown. The films for biosensing experiments were prepared on highly doped n-silicon (111) substrates through Zn-reactive sputtering in an O₂-Ar mixture with subsequent ex-situ annealing at 400°C in an oxygen flow. A Ni back contact to Si was subsequently deposited and annealed at 300°C in a forming gas. Finally, the films were stabilized for applications in the adverse biological environment using gas-phase sulphurisation. The prepared samples were used as gate electrodes in an extended-gate FET configuration with a silicon-based FET transistor. The films are characterized using X-ray diffraction and scanning electron microscopy (SEM), which evidence their polycrystalline structure with nanocoral morphology. High-resolution transmission electron microscopy is used for the characterization of individual crystallites and energy-dispersive X-ray spectroscopy cross-section scans evidence full sulphur passivation. Strong near-band-edge (NBE) and green deep level (DLE) emission was recorded in the He-Cd excited photoluminescence (PL) spectra of the films. Temperature dependent PL evidenced a splitting of the NBE peak into donor-bound and free exciton peaks with phonon replicas present at 5K. It was also

recorded, that the sulphurisation of the films caused a reduction of the DLE signal and increase in the NBE line. Using buffer solutions a pH-meter was constructed in the extended-gate configuration, and subsequently bovine serum albumin absorption was detected. Finally, DNA absorption experiments were carried out using complementary DNA strands, one attached to the sample and the other in the detected solution.

This study was partially supported by the European Union within European Regional Development Fund, through grant Innovative Economy (POIG.01.01.02-00-008/08 "Nanobiom") and by the Institute of Electron Technology from Statutory Funds.

An X-ray photoelectron spectroscopy study of Sn_{1-x-y}Co_xMo_yO₂ semiconductor thin films

T14 Thin Films

#TF-8-Or-6

O. Conde ¹, S. Dalui ¹, A.M. Ferraria ², S. Rout ¹, A.M. Botelho Do Rego ², A. Silvestre ³.

¹Universidade de Lisboa, Faculdade de Ciências, Departamento de Física and ICEMS - 1749-016 Lisboa (Portugal), ²CQFM- Centro de Química-Física Molecular and IN-Institute of Nanoscience and Nanotechnology, Instituto Superior Técnico, Universidade Técnica de Lisboa - 1049-001 Lisboa (Portugal), ³Instituto Superior de Engenharia de Lisboa, Área Departamental de Física and ICEMS - 1959-007 Lisboa (Portugal).

Here we present an X-ray photoelectron spectroscopy (XPS) study of undoped, Co and (Co,Mo) codoped SnO₂ films grown by pulsed laser deposition. The thin films were deposited on *r*-cut sapphire substrates, heated at 500 °C under an ambient argon pressure of 7×10^{-2} Pa, from targets with the following nominal compositions: SnO₂, Sn_{0.995}Co_{0.005}O₂, Sn_{0.97}Co_{0.03}O₂ and Sn_{0.96}Co_{0.01}Mo_{0.03}O₂. In all the films the XPS photoelectrons Sn 3d, Co 2p, Mo 3d and O 1s regions were studied in detail. Both XPS surface analysis and depth profile analysis were carried out in order to identify the oxidation states of Co and Mo ions, their concentration ratio and distribution along film depth. Samples were also studied regarding their structure and microstructure, electrical, optical and magnetic properties.

It is shown that the Co 2p region presents several strong satellites centred around 786.5 eV and 803.0 eV (besides the main peak at ~781.0 eV) which are typical of Co²⁺ species and allow to rule out the presence of Co³⁺ based compounds. The Mo 3d_{5/2} region comprises a main peak centred at ~231.1 eV, assigned to Mo⁵⁺, and two other less intense peaks at 228.8 and 232.7 eV assigned to Mo⁴⁺ and Mo⁶⁺, respectively. The O 1s peaks clearly show a main component centred at ~530.5 eV, assigned to the oxygen in the lattice, and a shoulder of variable intensity at higher binding energy that can be considered as due to adsorbed oxygen species on the surface of the samples. The intensity ratio for the two oxygen contributions has been

related to the oxygen vacancies in the samples. In all the doped samples the relative amount of cobalt is larger than the expected nominal one.

The overall XPS results are correlated with the electrical conductivity and magnetic properties of the films allowing to understand their non-expected behaviour.

Hydrogenated amorphous carbon (a-C:H) films show some excellent mechanical and tribological properties due to their high hardness and very low friction coefficient. These properties mostly depend on the ratio of sp^2 to sp^3 hybridized carbon bonds and the hydrogen content of the coating, which can be affected by temperature. When optimized for DLC, Raman spectroscopy is a non-destructive method which allows to obtain details about both sp^2/sp^3 ratio and hydrogen content. The aim of this work was to study the thermal stability of commercial a-C:H films using maximized acquisition parameters.

In this study, in situ heating during Raman analyses were compared with the results obtained for similar samples thermally heated in a vacuum furnace. Raman spectra were performed using a 514.5nm Ar/Kr laser on a Jobin Yvon spectrometer. The choice of parameters such as laser power and acquisition time had to be adapted to the particular temperature conditions of this study, especially for the in situ analyses. Indeed, damaging the samples is more likely due to the combination of laser thermal effect and thermal treatment.

The second part of the work was to analyze spectra acquired in the optimal conditions and to link data to sp^2/sp^3 ratio and hydrogen content. Figure 1 shows spectra obtained for several temperatures during the in situ study. All the spectra

were fitted using two Gaussian peaks corresponding to the features G and D. The G peak (Graphite peak) is associated with all the sp^2 carbon in chains or rings whereas D peak (Disorder peak) is only due to sp^2 carbon in rings. The ratio between the slope of the linear background and the intensity of the G peak is related to the photoluminescence which can be used as a measure of H content. ID/IG ratio, G peak position and full width at half maximum of G peak FWHM(G) have been used to compare the sp^2/sp^3 ratio of our different coatings.

Over a third phase, nanoindentation measurements have been performed before and after heating on each sample in order to compare the influence of the in situ and vacuum furnace heating on the mechanical properties of different coatings.

Finally, a scale up of this method on large real engine parts related to valve train components is presented to illustrate the interest of Raman spectroscopy for wear mechanisms investigation.

Tin oxide (SnO₂) thin films are promising as transparent conducting oxides due to their remarkable physical properties such as high electrical conductivity and high transmittance in the visible part of the spectrum [1-3]. Recently, antimony doped tin dioxide (ATO) thin films have been used in various applications such as transparent electrodes, gas sensors, transparent electric charge shielders, plastic liquidcrystal display devices, touch sensitive overlays, front electrodes of solar cells, and energy efficient windows [4-6].

In this work, the electrical, optical, and structural properties of ATO films prepared on polyethersulphone (PES) by RF sputtering method in the RF power range of 100 W~160 W have been investigated. We investigated the electrical performances of organic thin-film transistor using ATO gate electrodes prepared at various conditions. Antimony-doped tin oxide (ATO) films were deposited on polyethersulphone (PES) substrate by radio frequency (RF) magnetron sputtering method using SnO₂ target mixed with Sb of 6 wt% at room temperature with various RF powers for a transparent electrode in the thin film transistor (TFT). We investigated the structural, optical, and electrical properties by using various analysis measurements, such as X-ray diffraction (XRD), UV-visible, and Hall effect measurement. The crystallinity was increased and the conductivity of ATO film was improved with increasing RF power. Based on the data before, we fabricated the organic thin film transistor (OTFT) with ATO electrodes of various conditions. OTFT device is composed of ATO gate electrode, PVP (poly-4-vinyl phenol) gate insulator layer, pentacene active layer, and Au source/drain electrodes. Consequently, the OTFT using ATO electrode fabricated at RF power of 160 Watt as a gate transparent electrode exhibited a good device performance due to the high conductivity and the crystallinity.

Growth of an ultrathin FeO₂(111) trilayer oxide film followed with ambient pressure X-ray photoelectron spectroscopy

T14 Thin Films

#TF-3-Or-11

N. Johansson¹, E. Grånäs¹, M.A. Arman¹, J.N. Andersen², J. Schnadt¹, J. Knudsen¹.

¹Division of Synchrotron Radiation Research, Lund University - Lund (Sweden), ²MAX IV Laboratory, Lund University - Lund (Sweden).

Many studies of ultrathin oxides for both basic science and future applications have been conducted since Vurens et al. reported a reliable method for ultrathin oxide growth in 1988 [1]. In particular, great interest has been received by trilayer oxide structures due to their catalytic activity; e.g. a trilayer iron oxide grown on Pt(111) has been found active in the low temperature CO oxidation [2].

Here we present results from an x-ray photoelectron spectroscopy (XPS) study of a trilayer iron oxide growth on Pt(111). As a precursor structure ultrathin FeO films are grown on the Pt(111) surface, which are found to form a bilayer with the Fe atoms located between the Pt support and an oxygen layer towards the vacuum. For the creation of the trilayer mbar pressures of O₂ are required, out of reach for standard *in situ* XPS measurements. Therefore, we have employed the ambient pressure XPS (APXPS) setup at the MAX IV Laboratory [3] to perform an *in situ* study of the trilayer growth.

The formation of the trilayer on Pt(111) could be followed *in situ* from the occurrence of a new peak at higher binding energy in the O 1s spectrum [4]. Further, the main peak that originates from oxygen atoms in FeO(111) before oxidation shifts to lower binding energies upon oxidation to FeO₂(111). The intensity ratio between the new peak at high binding energy and the main peak is found to be 1:3. We also observe a

0.3 eV shift of the Fe 3p core level upon formation of the trilayer film. Additionally, the low energy electron diffraction (LEED) patterns for the bilayer and trilayer are very similar suggesting a similar long range ordering of the two films. Based on our results we will discuss different growth models of the FeO₂(111) film in the talk.

Once the trilayer film is formed in mbar pressures of O₂ we found that it is stable in UHV, which suggest that it is possible to form the trilayer in UHV using strongly oxidizing reagents. To confirm this hypothesis we used NO₂ to oxidize a FeO(111) film at UHV conditions. This study revealed the expected XPS signature of the FeO₂(111) trilayer.

The catalytic activity of trilayer FeO₂(111) was also investigated by gas phase APXPS and simultaneous mass spectrometry measurements. However, no catalytic conversion of CO into CO₂ was observed at the experimental conditions at which the FeO₂(111) film exists. To test that our experimental setup is able to measure catalytic activity, we tested CO oxidation on a clean Pt(111) surface and CO₂ production was clearly observed both with XPS and mass spectrometry.

Plasma polymerisation of aminopropyltriethoxysilane in ECWR plasma: influence of plasma parameters

T14 Thin Films

#PST/SE/TF-3-Or-3

S. Bulou ¹, G. Frache ¹, P. Choquet ¹, T. Belmonte ².

¹Centre de Recherche Public Gabriel Lippmann - Belvaux (Luxembourg),

²Institut Jean Lamour - Nancy (France).

Amino-functionalised plasma polymers (pp) have gained a high interest in the field of immobilization of bioactive molecules, improvements of implants biocompatibility and adhesion enhancement. For this purpose, alkylamine precursors (allylamine, heptylamine) are widely used. Nevertheless, such plasma polymers commonly exhibit low adhesion on metallic substrates or on specific polymer substrates. A way to overcome this issue is to deposit amino-functionalised siloxane layers that exhibit good adhesion with metallic substrates. Plasma polymerisation of amino-alkylsiloxane is a promising way to deposit such coatings. Nevertheless, it requires a selected activation of the monomer in order to promote the polymerisation of the siloxane network while efficiently incorporating amine functions. Hence, a study of the influence of the plasma parameters on the as-grown thin films and on the plasma phase has to be performed in order to progress in the understanding of the growth mechanisms.

We report here the deposition of pp-aminopropyltriethoxysilane (APTES) in Ar remote ECWR plasma. ECWR plasmas are high density-low pressure plasma sources which have been shown to be well suited for the synthesis of inorganic and hard material. The successful use of ECWR plasma source for plasma polymerisation is reported here for the first time. The influence of experimental deposition parameters (RF incident power, additional gases, pressure) on the morphology, atomic composition and molecular structure of the synthesised plasma polymers as well as on the plasma phase is studied. The aim is to obtain plasma polymer thin films with a high primary amine function density and to progress in the understanding of the plasma chemical pathways and of the polymerisation mechanisms.

pp-APTES thin films are characterised by means of ToF-SIMS, FTIR, XPS and SEM. The reactor is equipped with a high-vacuum transfer suitcase that is used to transfer the as-grown plasma polymers into ToF-SIMS and XPS instrument, allowing “quasi in-situ” surface analysis, i.e. without exposure to air after deposition. The plasma is analysed by means of Optical Emission Spectroscopy, in order to follow the plasma species (reactive species, radicals, by-products) and progress in the comprehension of the deposition process. Addition of low flow of N_2 and/or O_2 leads to important molecular structure modifications of the deposited films, especially on the primary amine density. In the light of thin film characterization and plasma diagnostics, plasma polymerisation and thin film growth mechanisms are proposed.

DIELECTRIC PERFORMANCE IN MWCNTS/EPOXY COMPOSED

T14 Thin Films

#TF-5-Or-1

P. Savi ¹, M. Giorcelli ¹, A. Naderi ², A. Tagliaferro ¹.

¹Politecnico di Torino - Torino (Italy), ²Semnan University - Semnan (Iran, islamic republic of).

Multi Walled Carbon Nanotubes (MWCNTs) have been used as polymer fillers for a number of years . In fact, they can improve, even at low filler contents, the mechanical and electrical performances of the host polymer. Moreover, the higher surface area and large aspect ratios that can be achieved with respect to single wall CNTs lead to superior dielectric properties among nanotubes composites [1;2]. In this work, we tested composites obtained using an Epoxy resin and several types of commercial MWCNTs. Due to the different aspect ratio (length vs diameters ratio) and concentrations used, we have been able to widely tune the dielectric properties of the composites. In particular, we investigated in a wide frequency band (3-16 GHz) the behavior of real and imaginary part of permittivity. Composites samples, moulded in appropriate cylindrical shape, were analyzed using a capacitive sensor (Agilent 85070D) with a Network Analyzer (E8361A) (see Fig.1). A direct correlation between type and density of MWCNTs and the dielectrical properties was observed. The possibility of tuning capacitive and dissipative effect of polymer was also investigated. Finally, all the samples were characterized by SEM in order to investigate the role of dispersion in the polymer matrix in determining the properties (Fig.2).

How does redeposition influence reactive sputtering?

T14 Thin Films

#TF/SE-1-Or-2

K. Strijckmans, D. Depla.

Ghent University, Research group DRAFT - Ghent (Belgium).

During sputter deposition sputtered atoms can return to the target due to gas scattering, a process entitled redeposition. The key parameter defining the level of redeposition is the working gas pressure. Monte Carlo simulations (SIMTRA [1]) of the sputtering of aluminium in argon, show that at a pressure of 0.4 Pa approximately 4% of the sputtered atoms return to the target. This value increases up to 45% at 5 Pa. Hence, the importance of redeposition can not be neglected during reactive sputtering.

This was previously demonstrated when aiming to model the sputter process of a rotating cylindrical magnetron[2]. In that case, the redeposited material at a given position on the target will rotate into the race track, and will in this way influence directly the poisoning behaviour.

For a planar target, a continuous growth of a layer due to redeposition is expected outside the race track. The inhomogeneous target erosion results in a different level of redeposition over the race track. This complex interplay between sputtering and layer growth will affect the hysteresis behaviour in a non-straightforward manner, which can only be accessed by modelling.

The need for this kind of work is motivated by the industrial relevance of arcing. Indeed, a study by Segers et al. [3] showed that arcing is related to the formation of a porous, non-stoichiometric oxide layer at racetrack rim. Further, this study showed that i) arcing seems to happen only in the narrow transition zone between racetrack and the stable oxide outside the racetrack, ii) for a given set of process parameters the onset of arcing occurs after a fixed time. In our study it will be shown that the time to reach a given number of arcs depends inversely on the argon pressure. According to Segers et al. arcing starts when the layer reaches a given thickness. This seems to confirm the experimental trends. However, the model is lacking from a detailed description of the target condition during reactive sputtering.

In this work, we investigate the effect of redeposition for a planar circular magnetron with a new implementation of the original RSD model in the RSD2012 tool. RSD2012 enables the user to simulate the hysteresis behaviour of a reactive sputtering system.

A graphical user interface (GUI) easily enables to switch on or off the inclusion of redeposition in the model. It also allows us to simulate the time dependency of the compound formation on substrate and target, in a spatial resolved way. This latter option will be used in this work. In particular we are interested in the in-depth oxide formation of an aluminium target sputtering in an Ar/O₂ atmosphere. This can give us an idea about the higher observed arcing levels when the process pressure is increased. Combining this model with the work of Segers et al. results in a more complete description of arcing.

Hybrid PVD-PECVD process of titanium sputtering in a mixture of argon and acetylene combines aspects of both conventional techniques: sputtering of a rotating cylindrical titanium sputtering target (target size: Ø110 x 510 mm) by DC power and deposition from plasma activated acetylene which acts as a source of carbon for polymerization (PECVD). Titanium carbide/carbon nanocomposite hard coatings, which consist of TiC nanocrystallites embedded in amorphous carbon matrix (nc-TiC/a-C:H coating), were deposited on high speed steel and tungsten carbide cermet substrates which were placed on a DC biasable holder performing complex rotation around the Ti cathode. nc-TiC/a-C:H coatings with varying chemical composition prepared at 10 kW DC power (320 °C), 20 kW (450 °C) and 30 kW (450 °C) and bias of -100 V reached maximal hardness of 24 GPa, 37 GPa and 28 GPa respectively. Because it could be expected that the optimal composition of the coating leading to maximal hardness should be reached independently on the applied power a process study was performed. Ti/Ar line intensity and discharge voltage showed sudden drop at the conditions where the maximal hardness was reached. EDX analyses show also sudden drop in Ti atomic concentration at this moment. The maximal hardness of a coating was reached always at conditions preceding the sudden drop which could be used for setting optimal deposition parameters to produce hard, well adherent and thick enough TiC/C coatings with low internal stress using industrially attractive concept of rotating cylindrical magnetron. We acknowledge GACR project 205/12/0407 and CZ.1.05/2.1.00/03.0086 project.

Lanthanide dititanate family, Ln₂Ti₂O₇, adopts two types of structure and the stability depends of the ratio between the cations radii Ln³⁺ and Ti⁴⁺. For $r(\text{Ln}^{3+})/r(\text{Ti}^{4+})$ included in the range {1.46-1.78}, the formed compound will privilege a pyrochlore-like structure (cubic) for Ln = Sm to Lu [1]. For ratio higher than 1.78, the layered perovskite type is preferred (monoclinic) for Ln = La to Nd [1]. In recent years, pyrochlore structure compounds have attracted considerable interest due to many potential applications. Indeed, they are used as photocatalyst for the water splitting, they possess a great ability for the realization of immobilization matrices of highly active radionuclides from nuclear wastes and they show photo-luminescent properties when doped with rare earth ions. The layered perovskite structure compounds are known for their ferroelectric [2] and piezoelectric [3] properties mainly used for the elaboration of high temperature devices. In this work, we show it is possible to extend the range of the layered perovskite structure for smaller Ln³⁺ ionic radii (i.e. Sm, Eu, Gd, ...) through epitaxial strains induced by the substrate in the film. We especially focus on the Sm₂Ti₂O₇ (SmTO) compound. The growth of thin films is achieved by Pulsed Laser Deposition (PLD) on SrTiO₃ (STO) and LaAlO₃ (LAO) substrates. We present the microstructural characteristics of the films performed by High Resolution X-ray Diffraction on both (100)- and (110)- oriented substrates. Studies performed on (110)-oriented STO or LAO substrates, reveal the

films are (001)-oriented, while considering the (100)-oriented STO or LAO substrates, the films are (012)-oriented, such (012) planes being slightly disoriented with respect to the plane of the substrate. Such crystalline orientations have already been observed and described for $\text{La}_2\text{Ti}_2\text{O}_7$ thin films in a previous work [4]. Finally, the ferroelectric property, in this metastable $\text{Sm}_2\text{Ti}_2\text{O}_7$ thin film, is evidenced through measurements performed at the nanoscale level by Piezoresponse Force Microscopy (PFM) [5].

The physics of transition metal oxide heterostructures is a subject of great interest due to the observations of new interface electronic and magnetic states [1]. The two-dimensional electron gas (2DEG) discovered at the interface between insulating LaAlO₃ (LAO) thin films and bulk SrTiO₃ (STO) crystals stands as a model and has boosted the great expectations placed in oxide electronics [2,3]. Recently, it has been found that also (001) clean SrTiO₃ surfaces [4-6] exhibit two-dimensional electronic states, independent of the bulk doping. From these studies it emerges that, despite possible different doping mechanism, a similar band splitting characterizes the electronic properties of vacuum/STO and LAO/STO [7] interfaces.

As matter of fact, while electron doping is believed to occur by creation of oxygen vacancies in STO surfaces, in LAO/STO interfaces the primary origin of the charge carriers is attributed to an electrostatic instability of the system. In particular, a scenario of electronic reconstruction has been proposed [8] where a Zener breakdown takes place above a LAO thickness of 3 unit cells (uc), as experimentally observed [9]. According to this picture, once the electron transfer occurs, carriers spontaneously occupy bands composed by Ti-3d orbitals, starting with dxy-symmetry bands located within the first adjacent SrTiO₃ layers [10]. DFT calculation on LAO/STO bilayers [11] agrees with a distribution of electrons accumulated within the first STO layers that gives rise to an electric field, which in turn induces a rumpling of the SrO and TiO₂ interface atomic planes within the same region hosting the 2DEG. Thus, a polar instability scenario predicts for LAO/STO heterostructures structural and electronic modifications of the first SrTiO₃ unit cells occurring simultaneously

with the appearance of a 2D-metal. However, not all the experimental results are fully consistent with this picture [12,13]. To clarify these issues, structural synchrotron measurements were performed to study the evolution of the ionic positions at LAO/STO interfaces as a function of the LAO thickness.

Single molecule chemistry on an ultrathin MgO film

T14 Thin Films

#TF-6-Or-8

Y. Kim ¹, J. Jung ¹, H.J. Shin ², M. Kawai ³.

¹RIKEN - Wako (Japan), ²UNIST - Ulsan (Korea, republic of), ³Tokyo University - Kashiwawa (Japan).

Ultrathin oxide films grown on metal substrate are of great interest not only as supporting materials for chemically active nanoparticles but also as catalysts in the field of heterogeneous catalysis, because they provide an additional dimension, i.e., film thickness, to control the catalytic properties [1]. Using scanning tunneling microscopy (STM) and density functional theory (DFT) calculations, we have demonstrated that the chemical reactivity for water dissociation on an ultrathin MgO film grown on Ag(100) substrate depends greatly on film thickness and is enhanced as compared to that achieved with their bulk counterpart [2]. The artificial manipulation of the local structure at the oxide-metal interface is expected to play a pivotal role in controlling the catalytic activity of oxide film [3]. In this presentation, we show that the chemical reactivity of MgO/Ag(100) for the dissociation of individual water molecules can be systematically controlled by interface dopants over the film thickness [4]. We introduced the 3d transition metal dopants (Sc ~ Zn) into the oxide-metal interface due to the high tunability with a number of d electrons. DFT calculations revealed that the adhesion at the oxide-metal interface can be addressed by the interaction between a dopant and the oxide layer with aid of ligand field theory and is linearly correlated with the chemical reactivity of the oxide film. Controlling the chemical reactivity via the manipulation of oxide-metal interface can be therefore considered the remote tuning of surface property like 'Marionette'. In addition, our results indicate that the concentration of dopant at the interface can be controlled by tuning the "drawing effect" of oxide film (see figure). Our study provides not only profound insight into the chemical reactivity control of ultrathin oxide film supported by metal substrate but also an impetus for investigating ultrathin oxide films for a wider range of applications.

In addition, a recent result of coupling between molecular vibration and surface phonon in the CO hopping process on MgO/Ag(100) with tunneling electrons will also be introduced [5].

The influence of the bias voltage on the corrosion behavior in artificial saliva of the TiSiON coatings

T14 Thin Films

#SE/PST/TF/BI-P1-08

C. Vitelaru ¹, M. Balaceanu ¹, A. Vladescu ¹, T. Petreus ², V. Braic ¹.

¹National Institute for Optoelectronics - Bucharest (Romania), ²University of Medicine and Pharmacy “Gr. T. Popa” - Iasi (Romania).

The low cost fabrication process, combined with good corrosion resistance, make the NiCr alloy one of the most used alloy type for dental applications. In order to reduce the release of Ni and Cr ions in human body, which produce discoloration of soft tissues and allergic reactions, we investigated the role of TiSiON coating on the improvement of corrosion behaviour of this alloy. TiSiON coating was chosen because the oxynitrides are known to possess good biocompatibility and superior corrosion resistance [1, 2].

In this paper, the influence of the bias voltage (ranging from -50 to -200 V) on the corrosion resistance of the TiSiON coatings deposited on NiCr alloy in artificial saliva solution, intended for use in dental applications, was analyzed. The coatings, deposited by cathodic arc method, were characterized in terms of elemental composition (AES), chemical bonds (XPS), crystalline structure and texture (XRD), surface morphology (SEM), and mechanical characteristics. Special attention was devoted to the corrosion tests in artificial saliva (electrochemical tests), quantification of Ni and Cr ion release (atomic absorption spectroscopy), as well as to the investigation of the cell viability.

Coatings with about 4 at.% Si and O/(O+N) ratio of about 0.2 were obtained. The X-ray diffraction patterns indicated the formation of crystalline structure for all the coatings, with a (111) preferred orientation. For coatings of about 3 μm thick, hardness values of about 28 GPa and critical loads of 56-58 N at adhesion scratch test were measured. As compared to the uncoated NiCr substrate, all the coated samples exhibited superior corrosion behaviour in saliva solution, and a significant diminution (3-5 times) of Ni and Cr release. The best polarization resistance (243 k Ω), lowest porosity (0.19) and highest protective efficiency (99.1%) were found for the TiSiON films deposited at a bias voltage of -100 V, indicating a good corrosion resistance. All coatings were found to possess good biocompatibility, as compared to

NiCr alloy. The TiSiON films deposited at bias voltage of -100 V exhibited the highest cell viability (98.3%), close to the positive control sample (100%), and the most favourable surface for osteosarcoma cell colonization.

Electron cloud (e-cloud) represents one of the major problems in achieving high quality of the beam in modern particle accelerators [1]. Among several approaches to solve this problem, deposition of low secondary electron yield (SEY) amorphous carbon coatings (a-carbon) onto the inner walls of the accelerator seems to be the most promising solution for suppressing the electron cloud [2]. However, it is known that these coatings change their electron emission properties due to the long-term exposure to air. Carbon coated samples, provided by CERN with initial (as received) SEY of about 0.9, were exposed to different environments and temperatures in order to study the nature and mechanisms of the ageing process.

The a-carbon coatings were deposited on technical stainless steel via magnetron sputtering using Ne as the discharge gas. The samples arrived from CERN Technology Department– Vacuum Surfaces and Coatings group in a UHV container filled with 500 mbar of pure nitrogen.

X-ray Photoelectron Spectroscopy (XPS) has been performed in a multipurpose surface analysis system with a base pressure in the low 10^{-10} mbar range. A homemade apparatus for SEY measurements was mounted to the introduction chamber of the same system providing base pressure in the low 10^{-8} mbar region. Depth profiling of the surface composition has been performed using Time of Flight Secondary Ion Mass Spectroscopy (TOF-SIMS) with a gallium ion gun for the analysis and oxygen ion gun for the sputtering.

Measurements of XPS and sputter depth profiling were systematically carried out in order to follow the changes in the surface composition. SEY measurements are done in parallel with XPS and TOF-SIMS measurements. In our previous work we showed that these samples do not age only in air but also under high vacuum (HV) conditions

[3,4]. The SEY increase can be correlated with the surface concentration of oxygen. In this work, we present and discuss novel and surprising temperature effects on SEY when the samples are annealed in HV and heated in air in a standard furnace. The study of the temperature effects on SEY is done systematically, heating the samples at different temperatures and during different periods. The results show that heating the samples in air at 100-200 °C reduces the ageing rate and even recovers previously degraded samples. The depth profile results suggest that heating the sample leads to a reduction of the hydrogen content in the coatings. The role played by hydrogen in SEY will be discussed.

Well defined platinum nanoclusters are produced on microporous carbon substrates by conventional Magnetron Sputtering (MS) and High Power Impulse Magnetron Sputtering (HiPIMS) for PEMFC (Proton exchange membrane fuel cell). Magnetron sputtering has already applied to the synthesis of catalyst for fuel cell and gave very good results. Most of Pt atoms are localized in the first 100 nm depth of the porous material (electrode-membrane interface). In the best conditions, MS allows a Pt utilization of $20 \text{ kW g}_{\text{Pt}}^{-1}$ and a power density of 0.7 W cm^{-2} .

The transport of Pt atoms inside the microporous carbon has been investigated using Rutherford Backscattering Spectroscopy as function of the deposition parameters and as a function of the deposition technique: MS/HiPIMS. The influence of the electrical characteristics of the HiPIMS power source on the deposition parameters is investigated. Different coated microporous carbon substrates are tested for the oxygen reduction in a proton exchange membrane fuel cell station and compared with each other.

A comparison of Dielectric properties of TISbS₂, TISbSe₂ and TISbTe₂ Thin Films

T14 Thin Films

#TF-P2-10

K. Ulutas, D. Deger, S. Yakut, M. Parto, H. Kara.

Istanbul University, Science Faculty, Physics Department - Istanbul (Turkey).

A comparison of structures and dielectric properties of TISbS₂, TISbSe₂ and TISbTe₂ thin films deposited in different thicknesses (400-4000 Å) by thermal evaporation of their crystals grown by Stockbarger-Bridgman technique are presented.

The dielectric constant ϵ_1 and dielectric loss ϵ_2 of them have been calculated by measuring capacitance and dielectric loss factor in the frequency range 20 Hz - 10 KHz and in the temperature range 273-433K.

Both of ϵ_1 and ϵ_2 of the samples decrease with frequency, but increase with temperature. These behaviors were interpreted depending on polarization mechanisms in the structure. It was observed that the frequency and temperature dependent behaviors of dielectric constant in TISbTe₂ samples were similar with TISbSe₂ and TISbS₂ samples. But, it was shown that the dielectric constant of TISbTe₂ samples increased because of addition of Te, which has upper atomic number.

The temperature variation of ac conductivity of the three sample can be reasonably interpreted in terms of the correlated barrier hopping model since it obeys the ω^s law with a temperature dependent s ($s < 1$) and going down as the temperature is increased.

X-ray analysis showed that the structure of thin films are amorphous.

Dielectric Properties of TISbTe₂ thin films

T14 Thin Films

#TF-P2-11

D. Ulutas, K. Ulutas, S. Yakut, H. Kara.

Istanbul University, Science Faculty, Physics Department , Vezneciler - Istanbul (Turkey).

Thin films of the TISbTe₂ on the glass substrates were prepared by thermal evaporation of TISbTe₂ crystals grown by Stockbarger - Bridgman technique. Film thickness is 180- 3300 Å. The dielectric properties of the prepared films have been studied in the temperature range 173- 373 K and in the frequency range 20 Hz – 400 KHz. The structure of the bulk TISbTe₂ were examined using X-ray diffraction. It was determined that at 1kHz frequency and 293K temperature dielectric constant of TISbTe₂ thin film samples ϵ_1 changes between 39-740 and dielectric loss ϵ_2 changes between 51-12000 depending on film thickness. The dielectric constant ϵ_1 and dielectric loss ϵ_2 were found to decrease with increasing frequency and to increase with increasing temperature

TF-7-Or-7

Sputter deposition of AlN and AlScN piezoelectric films for energy harvesting and ultrasonic applications

T14 Thin Films

#TF-7-Or-7

The paper will report on the deposition and characterization of piezoelectric AlN and AlScN films. Deposition was performed by reactive pulse magnetron sputtering of a metal target in a gas mixture of Argon and Nitrogen. In the case of AlN deposition pure Al targets were used. AlScN was deposited by reactive co-sputtering of Al and Sc targets. Using suitable powering and reactive gas control a deposition rate of up to 200nm/min was achieved by stationary coating on 8" substrates. This very high deposition rate allowed the deposition even of very thick films with up to 50µm thickness.

Films were characterized regarding piezoelectric coefficient, mechanical stress, structure and morphology. Piezoelectric coefficient d_{33} of AlN films was up to 9pC/N on silicon substrates. By scandium doping of the film, d_{33} could be raised up to 29pC/N. Mechanical stress of AlN ranges from -2GPa to +0,5GPa and strongly depends on film thickness, deposition pressure and pulse mode. Precise adaptation of film stress was required to achieve very thick films without film delamination. Potential applications of the films are in ultrasonic microscopy, energy harvesting and SAW/ BAW filters. A pulse echo method was used for characterization in ultrasonic applications. For characterization in energy harvesting, AlN films with electrodes on Si stripes were investigated in bending vibration. In resonance an energy density of 20mW/g·cm⁻³ and a generated power of 270µW were measured. Characterization of AlScN films with respect to energy harvesting will be performed in the near future.

Figure 1: Piezoelectric coefficient d_{33} of AlScN films in dependency on Sc content

Hydrogenated amorphous-nano-crystalline Si, a-nc-Si:H, is a promising material for high efficiency solar cells. Due to industrial relevance, it is particularly interesting to produce it using standard plasma enhanced chemical vapor deposition (PECVD). In order to test the stability of this kind of material and examine the possibilities of post-deposition treatment, the as deposited samples were exposed to isochronal thermal annealing with a duration of 1 hour at 200, 300 and 400 °C. The a-nc-Si:H films were deposited by the PECVD method, using a radio frequency discharge in a gas mixture of silane and hydrogen. The hydrogen to silane partial pressure ratio was 20. The structure of as deposited and treated films was studied by high-resolution electron microscopy (HRTEM), Grazing Incidence Small Angle X-ray Scattering (GISAXS), Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) and Raman spectroscopy. HRTEM micrographs showed that the initial films contained isolated nano-sized ordered domains, nano-crystals, with log-normal size distribution and average size between 5 and 8 nm. The Raman crystal fraction was between 20 and 40%, depending on the preparation parameters. The Raman spectra of as deposited a-nc-Si:H samples showed a crystalline TO peak at frequencies lower than the mono-crystalline Si peak. After thermal treatment, this peak shifts further towards lower frequencies. GISAXS pattern showed that the films contained particles with similar sizes as seen by HRTEM. The analysis of the width of the GIWAXS diffraction lines confirmed that crystals are as small as expected from HRTEM and indicated that strain was present in the samples.

After thermal treatment, the critical angle for total external reflection increased gradually indicating an increase of the mass density, and also the width of the diffraction lines increased indicating an increase of strain. The optical properties of the films were calculated from transmittance measurements in the uv-visible part of the spectrum, and from photo-conductivity. The initial optical gaps of the a-nc-Si:H samples were larger than those from amorphous and crystalline Si, possibly due to two effects: one is quantum size effects, and the other is a consequence of more silicon-hydrogen bonds than in a pure amorphous layer. As a consequence of thermal annealing the optical gap decreases and the absorption coefficient changes. The absorption at energies higher than the optical gap decreases while the absorption at lower energies increases. The observed changes in the optical and structural properties will be discussed as a consequence of hydrogen effusion and redistribution in the film since the hydrogen concentration gradually decreases during annealing from some 12-15 at% for as deposited samples towards 4-5% in samples annealed at 400 °C.

Surface and interface properties of TiO₂ thin films grown on oxidized Fe(100) substrates

T14 Thin Films

#SE/TF-4-Or-3

A. Brambilla, A. Calloni, G. Berti, L. Duò, F. Ciccacci.

Dipartimento di Fisica, Politecnico di Milano - Milano (Italy).

Titanium dioxide (TiO₂) has been the subject of intense studies in recent years, due to its photoelectric and photochemical properties and its high refractive index and dielectric constant. Thanks to such properties, many applications have highlighted the crucial role played by the TiO₂ surface (see Ref. [1] for a comprehensive review). Many of the fundamental properties that are at the basis of the applications are related to surface and interface properties of TiO₂ coupled to other materials, in particular metals. Such studies would substantially benefit from the use of thin oxide films. For instance, the possibility of synthesizing new titanium oxide phases at low coverages has been demonstrated [2,3]. Additionally, the oxide surface can be electrically and magnetically coupled with the substrate, possibly inducing and stabilizing interesting new phenomena. We report on the growth of thin TiO₂ layers on pre-oxidized Fe(100) substrates by Ti deposition in a reactive O₂ atmosphere. The experimental approach followed for the growth on Fe(001) is based on our results recently obtained for the growth of thin rutile TiO₂ films on Au(100) [4]. In particular, we have shown in such a case that a crystalline and stoichiometric TiO₂(100) oxide could be produced by Ti reactive deposition with the substrate held at 300 °C, while the growth at room temperature (RT) produced a defective oxide. At variance with the TiO₂/Au case, the growth on Fe(100) was rather difficult to control, due to substrate oxidation and Ti-Fe interdiffusion, activated at high temperature. In this contribution, we discuss experimental results based on X-ray photoemission spectroscopy (XPS), ultraviolet photoemission spectroscopy (UPS) and low energy electron diffraction (LEED). We observed that growing TiO₂ on Fe(100) at 300 °C produced stoichiometric films but was characterized by a significant chemical mixing at the interface, with part of the oxidized Fe layer segregated to the sample surface. On the other hand, the room temperature growth allowed us to greatly reduce the effects of the interface reactions and to avoid the surface segregation, while the TiO₂

layer was featuring the presence of oxygen vacancies. Finally, we have also investigated the possibility of using a gold buffer layer to obtain better quality TiO₂ films on Fe(001), resulting in crystalline rutile films with a reduced number of oxygen vacancies when compared to room temperature grown samples.

Crystallization control of hydrogenated amorphous silicon layers grown on Si(100) and Ge(100) through a glow-discharge of SiH₄

T14 Thin Films

#TF/SE-P3-03

L. Hong, G.X. Lee, T.H. Le.

Department of Chemical Engineering, National Taiwan University of Science and Technology - Taipei (Taiwan, republic of china).

We have explored the growth behavior of intrinsic amorphous silicon layers (i a-Si:H) on both Si(100) and Ge(100) wafers in a conventional PECVD reactor through a glow-discharge of silane. The onset of crystallization for the i a-Si:H layers grown on both Si(100) and Ge(100) as functions of deposition temperature and deposition rate was explored and compared. The result showed a critical temperature of 150 °C for a-Si:H grown on Si(100) to phase-transform from amorphous to epitaxial. The critical deposition temperature was extended to over 170 °C when a trace of oxygen was added during a-Si:H growth. Then we achieved a very low surface recombination velocity of 5.9 cm/s for a double-sided intrinsic a-SiO_x:H coating on an n-type crystalline Si(100) wafer. The growth behavior of a-Si:H layers on Ge(100) was compared.

TF-3-Or-7

Roll-to-roll deposition of optical coatings using magnetized mid-frequency powered plasma processes

T14 Thin Films

#TF-3-Or-7

M. Fahland, T. Vogt, R. Bluethner, T. Preussner.

Fraunhofer FEP - Dresden (Germany).

The topic of the contribution is the roll-to-roll deposition technology for a full-dielectric solar control film. Such layers can be incorporated into automotive windshields or architectural glazing, thus reducing the energy consumption for air conditioning. Embedded silver layers can be regarded as the state of the art in this application. However, their performance is limited by the absorption of the metal. Additionally, the low sheet resistance can cause problems with mobile devices inside the car. The layer system presented in this contribution consists of nine transparent non-conductive single layers, creating an adapted transmission spectrum by interference effects. The total thickness of the stack is approximately 1.3 μm . Titania and silica were used for the high index material and for the low index material, respectively. Special emphasis will be put on the plasma processes which were used for the deposition of the single layers.

Titania was produced by reactive sputtering. Two independent closed loop control channels for the oxygen inlet ensured a stable and uniform coating over 600 mm deposition width. The intensity of two spectral lines extracted from the emission spectrum of the plasma served as the indicator for the process working point. A maximum deposition rate of 30 $\text{nm}^*\text{m}/\text{min}$ with a refractive index of 2.38 (at 500 nm) could be obtained by this method.

Silica was deposited in a hexamethyldisiloxane (HMDSO) atmosphere using a double-magnetron as the plasma source for the precursor activation. One of the main advantages of this method compared to other PECVD technologies is the low process pressure (approximately 1 Pa), making the process compatible with the reactive sputtering of the high index material.

Maintaining the long term stability is the major challenge for the magnetron-based PECVD process. It generally suffers from instabilities due to target poisoning in reactive gas atmospheres. The paper presents an approach to this problem using a dual rotatable magnetron for the plasma activation of the precursor. There will be a

comparison of the process behavior of rotatable magnetrons to their planar counterparts. It is demonstrated that the oxygen affinity of the target material has a major influence on the process parameters. A maximum dynamic deposition rate of more than 200 nm³/min was achieved. The mechanical properties of the PECVD layers are superior to those obtained by sputtering. The crack onset strain could be shifted from 1% for sputtering to 5% for PECVD, both measured for 500 nm thick SiO_x-single layers. The stack obtained by the combined PVD-PECVD approach is compared to a reference sample with identical layer structure, which was made entirely by sputtering. The optical properties achieved by the combined PVD-PECVD are matching almost exactly those of the fully sputtered reference sample. However, the curling caused by the intrinsic stress of the deposited layers is considerably reduced in case of the combined PVD-PECVD approach.

Transparent conductive oxides (TCO) have become increasingly important in a large variety of applications due to demands as transparent and conductive materials. Applications of these devices include thin-film solar cells, display devices, optoelectronic devices, polymer-inorganic composite solar cells, gas sensors, and frost-resistant surfaces [1-4]. ITO is an n-type semiconductor where indium oxide (In_2O_3) has been doped with tin oxide in order to improve many of the material's properties, including its electrical conductivity [5]. However, ITO experiences a reduction of electrical conductivity when exposed to oxygen at elevated temperatures ($> 300\text{ }^\circ\text{C}$). Therefore, FTO, which is much more thermally stable, is often used as an alternative. FTO is an ideal candidate for applications requiring TCO due to its ability to adhere strongly to glass, resistance to physical abrasion, chemical stability, high optical visible transparency, and electrical conductivity. FTO is more thermally stable because it does not depend on oxygen vacancies to provide charge carriers, when exposed to elevated temperatures, FTO does not experience the characteristic decrease in conductivity seen in the ITO system. In this work, Spray pyrolysis automatized technique was used to deposit FTO films on glass corning. This technique allows us to obtain a better control on thin FTO films, with different properties just by varying the concentration of the fluorine. Figure 1 show the XRD diffractograms of the FTO films. Also, photoluminescence spectra and transmittance spectra were obtained. Structural, optical, and electrical properties of FTO films

prepared by spray pyrolysis and an analysis of the composition, transmittance, nanocrystal size, PL emission, carrier's concentration and conductivity are presented.

Adapted tools for accurate deposition of complex optical coatings in an inline sputter-system: computational manufacturing and optical broadband monitoring system

T14 Thin Films

#TF-P3-13

C. Franke, M. Schürmann, S. Wilbrandt, O. Stenzel, N. Kaiser.

Fraunhofer-Institute for Applied Optics and Precision Engineering IOF - Jena (Germany).

The manufacture of complex dielectric optical coatings on curved (e.g. aspheric) substrates requires a high degree of reproducibility and precision of both layer thicknesses and optical constants. Moreover, predicting the suitability of a deposition system with respect to manufacture of different designs that fulfill a given specification on curved substrates requires a reliable knowledge of distribution and variations of physical thickness and optical constants.

It has been proven earlier, that computational manufacturing is a powerful tool to predict the reproducibility of the coating performance as well as the corresponding production yield [1]. To determine the reproducibility in layer thickness and optical constants relevant for the applied coating system, a series of subsequent single layer depositions runs may be used [2]. During the simulation of the production process of complex optical layer systems the impact of different monitoring strategies (termination by optical broadband monitoring or by time) to the yield can be investigated, as well as the dependence of the yield on coating design and specification.

In the present work the approach for computational manufacturing simulations is extended to application in a large inline sputtering system. Numerous series of single layer reproducibility runs have been accumulated to generate relevant input data on optical constants and film thickness for subsequent use in the simulations. As a result

of the simulations it has been shown, that the application of an optical-broadband monitoring can significantly increase the production yield of the system. In this contribution first results of the outlined computational manufacturing simulations will be presented. Further, a short overview of the current state of adapting and implementing the optical broadband monitoring system OptiMon [3] into the inline sputtering system will be given. Thereby, advantages and disadvantages of different measurement set-ups based on in situ reflectivity- or transmission measurements have been evaluated, and different concepts to integrate optical components of the existing approach (e.g. detector, light source) are compared. Additionally, computational manufacturing simulations have been used to compare different optical monitoring strategies with respect to spectra acquisition and evaluation.

Thin films based on oxides, nitrides or carbides (a-SiC:H), for optics, dielectric properties (SiO₂, a-SiCO:H) and passivation (a-SiN:H), are used in microelectronics, opto-electronic sensors, thermomechanical applications, photovoltaics (PV), and are evaluated as candidates for selective coatings in high temperature solar receivers. From SiN:H to SiC:H, SiCN:H materials can satisfy a large part of those applications. Such deposits are classically grown using low (LF) or radio-frequency (RF) plasma PACVD, and SiH₄/Hydrocarbons/Nitrogen based gases (N₂/NH₃) common mixtures. Our work aims at studying the interest of growing such SiCN:H materials by use of VHF plasmas coupled with liquid organosilicon precursors (tetramethylsilane TMS) to replace dangerous industrial gases such as SiH₄/NH₃ mixtures. The advantage is to possibly manage Si-C, C-C, and Si-N bonding as well as hydrogen content, and attain high growth rates ($R_g > 1$ nm/s) interesting for industry. A PACVD reactor, where the plasma is sustained by microwave applicators (2,45 GHz: Boreal Plasma), is used to grow thin films, that can be DC biased, at a total pressure of 0.15 Torr ($250^\circ\text{C} < T_{\text{substrate}} < 480^\circ\text{C}$). Studies are focused on the influence of TMS/NH₃ partial pressures ratio ($R_{\text{TMS/NH}_3}$) and applied DC surface bias, on plasma characteristics, SiCN:H films composition and optical properties. Complex refractive index (n, k) of SiCN:H layers were measured by spectroscopic ellipsometry in the 430-850 nm range. SiCN:H thin films were evaluated as i)

antireflective silicon-PV layers (low n and k) using low TMS/NH₃ ratios (nitride-like films family) and ii) as matrix materials for absorber layers in selective coatings (high n and k) for solar receivers using high precursor ratios (carbide-like layers). FTIR analysis brings out that in SiCN:H materials, 800-900 cm⁻¹ FTIR band is complex. It appears that high NH_x and SiN contributions occur at low R_{TMS/NH₃} (< 0.22), as on the contrary Si-C-C and Si-C bonds are of major prominence (in addition NH_x groups are limited) when R_{TMS/NH₃} is increased (> 0.45). DC bias application leads to hydrogenation for nitride-like materials as crosslinking (C-C and Si-C bonding) is observed for carbide-like films. In Ar/NH₃ Langmuir probe analysis reveals electron densities n_e close to 10¹⁰ cm⁻³ (lower than n_e=10¹¹ cm⁻³ found in pure argon), consequence of electron consumption to dissociate NH₃ molecular and produce NH_x⁺, NH_x species. Two electron populations occur, according to DC bias and NH₃ content that enhance hot electron density. Deposits bonds evolutions are finally related to plasma OES measurements performed on CH, C₂, SiH, NH, Si, H, H₂ excited carriers close to the growing surface.

Nowadays, titanium dioxide (TiO₂) thin films in the anatase phase are functional because its photocatalytic characteristics, photoinduced hydrophilicity, self-cleaning and antibacterial properties [1-3]. Meanwhile, those of rutile phase are used as biomaterials for implants and prosthesis [4]. In this work is described an effort to deposit titania film in anatase and rutile phases without any additional annealing over two different substrates glass and silicon. The proposed process has been conducted within a Pyrex-like glass cylindrical vessel used as plasma reactor. A copper solenoidal antenna is placed around this vessel occupying a length equivalent to one quarter of the RF wavelength. The plasma is supplied by a calibrated 70% argon-30% oxygen gas mixture and generated by transferring 500W to the antenna through a coupling network from a 13.56MHz RF generator. The vessel was evacuated at pressures lower than 1×10^{-4} mbar by a mechanical pump. Once the base pressure is attained, the working gas mixture was admitted through a precision leak valve up to $4-5 \times 10^{-2}$ mbar pressure at which the highest plasma density is reached. A commercially pure titanium cylindrical target was introduced to the vessel and biased up to -2.0kV and 10mA DC. The collisions of argon and oxygen ions from plasma during 5 hours on the target promoted sputtering on material and its consequent oxidation process due to the presence of several oxygen species. The ion bombardment raised the target temperature around 600°C measured with a K-type thermocouple. Whereas substrate temperature was obtained with a K-type thermocouple in the range of 292 and 387°C in function on the supplied power to the plasma. Electrically floated silicon or glass substrate was placed on the holder 2cm in front of the target. TiO₂ films developed on the substrates were characterized by

several devices. Raman spectroscopy outcomes denote the presence of anatase obtained from deposited film on glass exposed at $\sim 292^\circ\text{C}$. And rutile phase growth on glass exposed at 387°C . Chemical composition of deposited coatings were analyzed using SEM/EDS for both substrates. Resulting outcomes give atomic compositions around 75% oxygen/23% titanium. XPS spectrum of Ti_{2p} shows the Ti_{2p} splitting into $\text{Ti}_{2p_{3/2}}$ and $\text{Ti}_{2p_{1/2}}$ doublet peaks two peaks situated 458eV and 464eV with a splitting ($\Delta=5.6\text{eV}$) which corresponds to Ti(IV) in TiO_2 . Deposited thickness film was determined by means of a profilometer. The film presents a maximum value about $1\ \mu\text{m}$ over a semicircular pattern area located just in front of the target. This semicircular deposition behavior decreases until 200 nm as the measured point approaches the border of the substrate. X-ray diffraction spectrum reveals several peaks corresponding with crystalline anatase phase deposited on silicon substrate.

TF-P2-19

Tailoring of diamond film morphology and electrical properties by CH₄/H₂/CO₂/N₂ gas chemistry in large area MWCVD

T14 Thin Films

#TF-P2-19

M. Vojs¹, M. Mikolášek¹, T. Ižák², M. Varga², O. Babchenko², A. Kromka².

¹Institute of Electronics and Photonics, Faculty of Electrical Engineering and Information Technology, Slovak University of Technology, Ilkovičova 3, 812 19 - Bratislava (Slovakia), ²Institute of Physics, Academy of Sciences of the Czech Republic, v.v.i., Cukrovarnicka 10, 162 53 - Prague (Czech republic).

Diamond film is promising material for a variety of applications. However, its production by standard deposition techniques makes it not attractive for industrial applications (limited deposition area, high temperature of deposition). Recent trends in the deposition techniques, e.g. surface wave plasma [1], linear antenna plasma [2], make diamond growth possible in large areas (up to 1x1m²) and at lower temperatures [3]. Moreover, addition of oxygen-containing gases leads to enhanced growth rates and film quality.

Yet it is stated, that diamond growth appears only in defined area of C-H-O ternary diagram [4]. However, in our previous study we have shown that diamond growth is possible also out of that area for diamond films deposited in linear antenna plasma [5].

The actual work is a complementary study of our previous results completed by addition of N₂ into CH₄/H₂/CO₂ gas chemistry. This unique four-compartment gas system allows controlling of diamond morphology from micro- to nanocrystalline, ballast-like or porous-like character over large areas suitable for destined application. Detailed study was carried out by variation of gas mixture components CH₄, CO₂ and N₂ in hydrogen. The surface morphology of samples was studied by Scanning Electron Microscopy, the character of the films was investigated by Raman Spectroscopy, and growth rates were evaluated by optical methods.

It was found that at the higher oxygen content and no nitrogen in the mixture a

“blockstone-like” structures were formed, while increased N_2 content leads to a “porous-like” and/or nanowires diamond structures (Fig. 1). At lower oxygen content, increased N_2 led to decreasing of growth rate of (ultra)nanocrystalline diamond. In the article the relation between the diamond film morphology and electrical properties will be pointed out, as well as the early stage of the growth process including plasma chemistry and growth kinetics together with extended region of diamond formation in modified Bachmann ternary diagram will be discussed too.

We present a generic method for elaboration of nanocomposite films by combining the supersonic jet technology and magnetron sputtering. This technique offers the possibility to achieve the nanoparticles synthesis, doped or undoped, and the film growth in a single step process and without any limitation in the respective chemical compositions of the particles [1] and the matrix. The general scheme of the process is presented in Fig. 1. A supersonic expansion is generated by a double stage differential pumping system through an expansion nozzle and a skimmer, so that a supersonic gas beam carrying the nanoparticles is created in an intermediate chamber at low pressure (10^{-5} mbar). As the speed acquired by the nanoparticles is high [2], their kinetic energy is sufficient to pass through a relatively high pressure ($5 \cdot 10^{-3}$ mbar) deposition chamber and get deposited on a substrate. The pressure in this chamber is adequate for running a magnetron sputtering device able to deposit the matrix of the composite film simultaneously to the nanoparticles. A rotary motion of the substrate on its axis ensures the film homogeneity. As an example, in this work, doped silicon nanoparticles (n or p) are synthesized for the first time by laser pyrolysis, and then embedded in a silica matrix produced by magnetron sputtering.

Selfcleaning and Antireflective Coatings by Sol-Gel Process on Glass Substrate

T14 Thin Films

#TF-2-Or-4

K. Camargo ¹, A.F. Michels ², F.S. Rodembusch ³, F. Horowitz ³.

¹LPMCN - Lyon (France), ²UCS - Caxias Do Sul (Brazil), ³UFRGS - Porto Alegre (Brazil).

The hydrophobicity of a surface is improved from a chemical modification that lowers the surface energy and also by increasing the surface roughness, and this is due a combination of micro and nano-structures at surface. Superhydrophobic surfaces with low of angular hysteresis allow selfcleaning property^{1,2}.

In this work, our proposal was obtain the superhydrophobic coating with anti-reflective properties on glass substrate by sol-gel technique. We used to prepare the first layer a thin film with silica nano-particles coated with dymethylsilane, superhydrophobic nano-particles, and after we prepare the second layer a thin film with silica aerogel to improve optical transmittance and finally recovered with a third thin film of polytetrafluoroethylene (PTFE) by PVD (Physical Vapor Deposition).

Interference coating are the way to many optical devices with anti-reflective properties. The anti-reflective coating consists of a single quarter-wave layer of transparent material whose refractive index is the square root of the substrate's refractive index³. In theory this gives zero reflectance at the center wavelength and decreased reflectance for wavelengths in a broad band around the center.

A good technique to obtain the anti-reflective coatings is a combination between refractive indexes, where it is interesting obtain the thin film with highly-index coated under a thin film with low-index, this method makes the contrast between refractive index to coatings two-layer.

Super-hydrophobic thin film was made with super-hydrophobic nano-particles that are hydrophobic fumed silica after treated with dimethyldichlorosilane (Aerosil R972 - Degussa).

Results obtained to this sample were 171° to the contact angle and less than 2° to angle hysteresis^{4,5}, what meaning in a selfcleaning surface. The optical transmittance was around 97% to visible region and 99%^{4,5} to near infrared region, in this case we

get an anti-reflective coating by just three layers on a soda-lime glass substrate by sol-gel technique.

TF-9-Or-3

Selective formation of silicon film by chemical transport technique using a high-pressure narrow-gap hydrogen plasma

T14 Thin Films

#TF-9-Or-3

H. Ohmi, H. Kakiuchi, K. Yasutake.

Osaka University - Suita, Osaka (Japan).

Selective growth technique of Si film has become important technology for various device fabrications. Generally selective Si film growth has been demonstrated by CVD method which requires toxic, flammable and halogenated gases, such as SiH_4 , SiH_2Cl_2 , and etc.

Recently, we have developed a Si film formation method by using a chemical transport in high-pressure, including atmospheric-pressure, hydrogen plasma[1]. This method requires no source gases, because the etching reaction of solid Si by atomic hydrogen (H) behaves as an on-site SiH_4 generator. In this method, H acts as an effective etchant for Si in the same manner as halogen species in selective CVD process. Hence, it is expected that selective deposition of Si film can be achieved by this method. In this study, we have investigated the substrate selectivity of Si film formation and demonstrated selective Si growth.

The apparatus was described in other report[2]. The chamber was filled with H_2/He gas mixture to the total pressure of 400 Torr. The hydrogen compositions of gas mixture and substrate temperature were varied as parameter. The plasma was generated by 150 MHz VHF power. The substrates used for studying substrate selectivity were Si and quartz glass. Furthermore, Si with patterned SiO_2 window was used for selective growth.

Fig.1 shows the temporal evolution of R_d on Si and glass substrates. In case of Si substrates, R_d has no dependence on deposition period (t_d). On the other hand, in the case of glass, R_d gradually increases with t_d and saturates after a certain period of t_d . Fig.1 suggests that Si film is preferentially formed on Si rather than on glass in the initial deposition stage. The selective deposition was demonstrated on patterned SiO_2/Si substrates. Fig.2 shows the surface SEM image. From this image, Si film can

be prepared only on SiO₂ window. Moreover, selectively deposited Si film showed epitaxial growth at T_{sub} of 300°C.

In the latest years an increasing environmental sensibility leads the research of more sustainable energy resources. Direct sunlight harvesting obtained by dye sensitized solar cell is a promising technology based on organic materials, extremely cheaper with respect to inorganic based technology. The quantum efficiency for these systems is relatively high, but charge ignition from the chromophore to the electrodes is a key issue that still limits the entire process. Using resonant photoelectron spectroscopy we compare the lifetime of the excited states and the ignition dynamic of a single layer of Zn-tetra phenyl porphyrin (Zn-TPP), a commonly used dye, deposited on a nanostructured ZnO substrate and on a TiO₂ (110)-(1x1) reconstructed surface.

Results show a different dynamic for the excited states localized on phenyl groups and on the macrocycle. While the global quenching of the resonances is more effective for Zn-TPP/TiO₂, the unoccupied states localized on the macrocycle show a faster charge transfer time in Zn-TPP/ZnO with respect to Zn-TPP/TiO₂.

Institute of Physics ASCR - Prague (Czech republic).

WO₃ and Fe₂O₃ semiconductor structures were recently found very promising as a photoanode material for water splitting applications [1-4]. These materials can absorb a relatively significant portion of the available solar light, due to their lower band-gap energies. The photoelectrochemical characteristics of Fe₂O₃ photoanodes are typically found to have a marked dependence upon the anode preparation conditions and the type of dopant incorporated into the host lattice. Nanocrystalline WO₃ thin films on a conducting glass electrode also provides excellent induced photocurrent efficiency (IPCE) for photoelectrochemical water decomposition under visible light. Semiconductor oxide thin films of Fe₂O₃ and doped Fe₂O₃ by Sn were deposited by reactive sputtering in a pulse magnetron and in a pulsed hollow cathode plasma jet sputtering systems without external heating of the substrate. It was possible to prepare by both methods nanocrystalline or polycrystalline semiconductor thin films with structure of hematite Fe₂O₃. Application of different magnitudes of duty cycle was tested in the range 1% - 50%. Quite different preferred orientation of crystallites relative to the substrate surface was observed in dependence on the duty cycle. This texture was apparent at as deposited films and also at thin films annealed after deposition on 600 °C. Nanocrystalline WO₃ thin films were deposited by reactive pulsed magnetron sputtering system. Tungsten target was reactively sputtered in Ar+O₂ gas mixture. Deposition experiments were done for different concentration of oxygen in the plasma discharge and different magnitudes of duty cycle. Crystalline structure, optical properties and surface roughness of deposited WO₃ thin films was studied for as deposited films and on annealed films as well. Photoconductivity and photoelectrochemical properties were measured on deposited Fe₂O₃ and WO₃ thin films under 1 AM illumination. IPCE was obtained for these samples.

Performance evaluation of a TiO₂ thin films for textile wastewater treatment. Catalytic activity, toxicity assay, deactivation, and regeneration

T14 Thin Films

#SE/PST/TF/BI-3-Or-3

A. Pedroza Rodríguez ¹, A. Blanco Vargas ², C. Campos Pinilla ³, A. Florido Cuellar ⁴, J. Cardona Bedoya ⁴.

¹Grupo de Biotecnología Ambiental e Industrial. Pontificia Universidad Javeriana - Bogotá (Colombia), ²Universidad Javeriana - Bogotá (Colombia), ³Grupo de Biotecnología Ambiental e Industrial. Pontificia UNiversidad Javeriana - Bogotá (Colombia), ⁴Universidad del Tolima - Ibagué (Colombia).

In the present work thin films of titanium dioxide were obtained by sedimentation over borosilicate glass at 50 °C and calcination at 450o C for 1 h. The films were characterized by XRD, UV-Vis scanning and SEM. The XRD of the films showed anatase as the only crystallographic phase with planes (101), (004), (200), (105) and (211). The gap value for control film was 3.25 eV. SEM images showed aggregates and different particle size

The photocatalytic activity of the thin films was evaluated using a cubic reactor and textile wastewater. According to results, the photocatalysis with TiO₂/UV was significantly better ($p < 0.0001$) than photolysis, obtaining removals of 83%, 35%, 58% and 53% for discoloration, COD, BOD₅ and inactivation of microorganisms at 15 hours of treatment. When performing spectral curves it was seen a decrease in the wavelength of maximum absorption (600 nm) with the appearance of peaks in the ultraviolet spectrum that may be associated qualitatively with chemical transformation process mediated by the action of oxidizing species

Regarding to the toxicity tests to evaluate the wastewater treated by the TiO₂ thin films, it was noticed an increase in the percentage of mortality for *H. attenuata* but in the same concentration than the initial 6.25% v/v. In *L. sativa* the percentage of inhibition was of 12% to 75% v/v therefore the final toxicity was not increased.

Neither in the curves of photolysis (UV) was evidenced an increase in toxicity for *H. attenuate*. And in the opposite, in *L. sativa* it was noticed a slight change obtaining inhibitions of 6 and 10% at the concentration of 50% v/v, lower value than the initial one 75% therefore, it decreased the toxicity.

In order to demonstrate that both TiO₂ films as the treated effluent could be reused we performed two experiments. The first one was to reuse the TiO₂ films for 4 consecutive cycles of 12 hours each, valuing the effect of the thermal reactivation of the semiconductor oxide and without heat reactivation on the discoloration and inactivation of microorganisms. According to the results obtained in the TiO₂ films, they can be reused for 24 hours continuous with discoloration of 53% and 50%, without having significant differences between the thermal reactivation or without reactivation. With regard to the inactivation of microorganisms the inactivation in the 4 cycles ranged between 49 and 33%, respect. No significant differences were observed between cycles and reactivation strategies.

With the second experiment it was demonstrated that the effluent treated by photocatalysis could be used for dyeing of cotton fabrics without having significant differences when comparing with potable water and distilled water. The percentage of adsorption to the fabrics was superior to the 80%, proving that in water on dyeing there was only left the 20% of residual coloring, amount which is lower than reported by the literature for dyeing processes on an industrial scale, which is of the 30%.

This work presents an alternative for microcrystalline (MCD) and nanocrystalline (NCD) diamond CVD film deposition on steel using a thermochemical modification in substrate surface. The thermochemical treatment consists in the formation of a thermodiffused layer of vanadium carbide (VC) [1] on steel substrates at 1220 K with. For the thermodiffusion process it was used a salt bath of vanadium pentoxide (V_2O_5), boron carbide (B_4C) e sodium borate decahydrate ($Na_2B_4O_7 \cdot 10H_2O$). CVD of MCD and NCD diamonds films was realized using HFCVD reactor [2] type in different conditions of steel substrate composition, substrate surface roughness, melting salt composition and thermodiffusion temperature. For the best combination of process parameters the deposited diamond films presented a good adherence to the VC interface, despite the high compressive stress measured. The diamond CVD films and the VC interface were characterized by Scanning Electron Microscopy (SEM) associated with Energy Dispersive X-ray (EDX), X-Ray Diffraction (XRD). The adhesion tests were made with Rockwell C (120°) conical indenter and characterized by Optical Profilometry. The quality of the diamond CVD films on thermodiffused VC coating was evaluated by Raman spectroscopy.

Corrosion behaviour of organosilicon coatings prepared by cold remote plasma assisted chemical vapour deposition process

T14 Thin Films

#SE/TF-1-Or-5

C. Jama.

ENSCL, UMET CNRS 8207, Equipe ISP, - 59650 Villeneuve D'ascq (France).

Plasma enhanced chemical vapour deposition (PECVD) is known nowadays as a key technology applied in a whole range of industries. It enables deposition of thin films of controlled physico-chemical properties using a variety of different organosilicon precursors. Its advantage over chemical processes is besides being a dry process is the wide range of settings and changeable parameters such as the gas flow rates, the gas ratio, the type of plasma used, which enable to accurately control the growing film characteristic. The organosilicon films formed using PECVD are mostly amorphous in nature and usually associated with a high electrical resistivity (10^9 - 10^{15} Ω cm). In this work, the barrier properties of organosilicon coatings against corrosion were investigated. The films were deposited on carbon steel using remote microwave nitrogen plasma assisted chemical vapour deposition (MW-PECVD). The monomer precursor used was 1,1,3,3, tetramethyldisiloxane (TMDS, purity 97 %), which was premixed with oxygen (purity ≥ 99.5 %). Corrosion tests were performed by immersing the uncoated and coated carbon steel samples in aerated 3% NaCl at 30 °C. The evolution of the open circuit potential (E_{OCP}) with time provides information about the corrosion activities of a metal interface. The evolution of E_{OCP} curves when uncoated and coated carbon steel substrates were immersed into saline aqueous solution (NaCl 3 %) were recorded. In the case of unprotected steel, a decrease in E_{OCP} is observed after about 40 h of immersion into NaCl 3 %. This is attributed to the dissolution of iron. The behavior was different for the steel coated with organosilicon films. The E_{OCP} was shifted to more positive potential values and no obvious fluctuation of E_{OCP} was observed in the measurement time frame, indicating that these interfaces seem to have an increased corrosion resistance. Potentiodynamic polarization curves of the different interfaces show clearly that the pre-treatment has a strong influence on the corrosion potential. An increase in the

corrosion resistance behaviour of the organosilicon coated carbon steel specimen was found when the carbon steel interface was pre-treated with an argon plasma. The argon plasma pre-treated samples show the noblest corrosion potential together with decreased corrosion current densities, which are sustained after 30 days immersion into 3 % NaCl.

Modulation of oxygen flow during deposition of titanium and cobalt oxide films by reactive sputtering

T14 Thin Films

#TF-6-Or-7

J. Dias Da Silva ¹, A.L.J. Pereira ², N.F. Azevedo Neto ¹, J. Acuna ³, I.S. Brandt ³, A. Pasa ³, A. Beltran ⁴, P.N. Lisboa Filho ¹.

¹Unesp University - Bauru Sp (Brazil), ²Univ Politecnica de Valencia - Valencia (Spain), ³Federal University of Santa Catarina - Florianopolis Sc (Brazil), ⁴University Jaume I - Castelon (Spain).

Most thin film deposition methods rely on substrate thermal energy to provide the atomic arrangement, chemical bonding, film structure and morphology. By contrast, in the glow discharge sputtering processes the primary source of energy is generally the kinetic energy of the species provided by the plasma. In this analysis, the consequences of the energy enhancement and modulations of the oxygen gas flow to the properties of titanium and cobalt oxide films (~500 nm) are investigated. Structural, morphological and electronic aspects are focused in association with the deposition parameters and the corresponding ion/atom collision energetics provided by computer simulations. The films have been deposited using RF and DC plasmas of Ar and O₂ and pure metallic (Ti/Co) targets in a planar diode magnetron configuration. The relatively low total pressure used is compatible with mean free paths bigger than the target to substrate distance, favoring the energetic collisions with the growing film surface. Periodic short term interruptions of the O₂ flow during depositions are made in order to produce oxygen depleted thin layers inside the films. Electron and atomic force microscopies, X-ray diffraction, and Raman scattering results, show that the produced films present compact columnar morphology and orientation texture characteristic of the energy enhanced depositions. Concerning the TiO₂ films, modulations of the O₂ flow during reactive sputtering produces a systematic increase of the optical absorption, without significant changes in structure, composition and morphology. In special no evidence for the existence of pure Ti layers are found in the characterizations, particularly on high resolution transmission electron microscopy. Density functional theory calculations and optical absorption results evidence the corresponding changes in

the electronic structure which are associated with oxygen vacancy complexes [1,2]. In cobalt oxide nanostructures the effects of the interruptions to the optical and structural properties are much stronger indicating a better definition of the metallic layers (~2-20 nm). The increase in the optical absorption and electrical conductivity resulting from the oxygen depletion in thin layers of the material are potentially useful for the improvement of the magnetic and photocatalytic properties of the titanium and cobalt oxide films.

TF-5-Or-2

Ultra-low density carbon foams produced by pulsed laser deposition

T14 Thin Films

#TF-5-Or-2

V. Russo, D. Dellasega, I. Prencipe, A. Zani, M. Passoni.

Dipartimento di Energia and NEMAS - Politecnico di Milano - Milano (Italy).

We report on the manufacturing by Pulsed Laser Deposition (PLD) of ultra-low density carbon foams, characterized by very low density regimes down to 1 mg/cm^3 . Ultra-low density materials (foams) show unique properties, assuming great interest both for fundamental material science and for several applications ([1] and Refs. therein). The density of this kind of material, considered as a mean value over a scale larger than the typical microscopic inhomogeneity scale-length, spans in the range $1\text{-}100 \text{ mg/cm}^3$. The possibility to produce foams with controlled and reproducible mean density, area and thickness, with a satisfactory adhesion on a solid substrate is of great importance to achieve desired material properties. Carbon represents a suitable choice to obtain mono-elemental foam, being a light element with volatile oxides. The extension of carbon-based materials to the ultra-low density regime represents a challenging and nearly unexplored topic.

Here we produced carbon foams by PLD with unusual combinations of deposition parameters for the growth of porous carbon, i.e. fluence below 1 J/cm^2 , Ar and He ambient gases, pressures in the range $0\text{-}1000 \text{ Pa}$, 10 Hz repetition-rate [1]. The film properties have been investigated by means of quartz crystal microbalance (QCM), scanning electron microscopy and Raman spectroscopy as a function of pressure for the two different ambient gases. Areal density has been evaluated with two different methods, the first based on QCM measurements, the second with proper interpretation of Energy Dispersion X Ray Spectroscopy data [3]. Combining such areal density values with an estimate of mean thickness by cross-section SEM analysis, we obtained values of mean density in the range $1\text{-}1000 \text{ mg/cm}^3$.

SEM images (fig.1) showed that film morphology was due to the aggregation of nanoparticles in larger particles, which then assembled with each other giving rise to a mesoscale getting opener with increasing pressure. Raman analysis indicated that the deposited material corresponded to a nearly pure sp^2 network of topologically disordered graphitic domains with very low sp^3 content and suggested that a similar nanoparticle structure was achieved for almost all the deposition conditions.

Finally films grown using 100 Pa of fluxing Ar represented an optimal condition to

obtain a very low density foam with satisfactorily homogenous morphology on the mesoscale.

Based on these results, this work showed how pulsed laser deposition can be exploited as a versatile tool for the deposition of carbon foams with tunable and tailored density, thickness and uniformity.

Binary copper oxides (Cu_2O , Cu_4O_3 and CuO) are the spontaneous p-type semiconductors and have attracted much attention due to the great potential applications in thin film solar cells, transparent thin film transistors, photodiodes, and photocatalyst for solar-driven water splitting. In our work, these three kinds of oxides have been deposited on glass substrates at room temperature by reactive direct-current magnetron sputtering. A process map, which describes the composition as a function of the deposition total pressure and oxygen flow rate, has been depicted. Thin films with different preferred orientations can be attained by varying the total pressure and oxygen flow rate, which can be used to tune the electrical and optical properties of thin films. Taking Cu_2O as an example, thin films deposited at low total pressure (0.5 Pa) has a highly [100] textured orientation, but the highly [111] preferred orientation will appear when the total pressure changing to 1 Pa, as shown in Fig. 1. The [111]-orientated Cu_2O thin film has the room temperature resistivity of 41 Ω cm, which is 10 times lower than that of [100]-orientated film. This low resistivity will be useful to improve the conversion efficiency of Cu_2O -based solar cells. Besides, the optical band gap of Cu_2O can be widened from 2.38 eV to 2.56 eV when the textured orientation changing from [100] to [111], shown in Fig. 2. The Burstein-Moss shift due to the larger carrier concentration is thought to be responsible for this enlargement. Similar behaviors have also been observed in Cu_4O_3 and CuO thin films.

Fig. 1 XRD patterns of Cu_2O thin films deposited at 0.5 Pa and 1 Pa total pressure.

Fig. 2 Plots of $(\alpha E)^2$ vs E of Cu₂O thin films with different textured orientations.

Alloys of titanium, niobium, and zirconium are potential candidates for implant due to the combination of good biocompatibility, high mechanical strength, excellent thermal stability, and optimal corrosion behavior [1-3]. Finding a surface chemical signature of biocompatibility, which is governed, in its first adsorption steps, by the adsorption of proteins, is very important to improve implants [4]. In this work, model titanium, niobium, and zirconium coatings, deposited by DC magnetron sputtering on Si(111) substrates at an elevated oxygen flow, have interacted with bovine serum albumin (BSA) solutions of different concentrations, in physiological-like conditions. The chemical composition and morphological characteristics of the films were analyzed by X-ray photoelectron spectroscopy (XPS) and atomic force microscopy (AFM). The thicknesses of the films were 500 nm. The BSA solutions (pH 7.4, phosphate buffer-saline (PBS)) were deposited at 37 °C for 1h.

The solution concentrations of BSA were 20 and 100 µg/ml. After rinsing with PBS and drying in air, the XPS analyses were performed. The spectra showed that the surfaces were composed by TiO₂, Nb₂O₅, and ZrO₂. AFM images showed that the oxidized films had nanostructured grains and low roughness. After interaction with the BSA solution at 100 µg/ml, the AFM images showed aggregates of adsorbed albumin. The surface morphology of the adsorbed BSA thin films appears different on the three surfaces: the AFM images indicated a monolayer adsorption of BSA onto Nb₂O₅ films, onto TiO₂ surfaces, the adsorption seems to result in two layers of adsorbed protein, and the ZrO₂ surface presented an uncomplete layer of adsorbed

protein. These results are discussed in terms of conformation of the adsorbed protein and tentatively compared to XPS equivalent thickness data and Time of Flight Secondary Ion Mass Spectra (ToF-SIMS) molecular spectra information.

Lead oxide (PbO) films are frequently used in various applications due to their excellent semiconducting and photoelectrochemical properties. Indeed the numerous researches show the great potential of photoactivity of lead oxide PbO_x[1][2]. In this study, PbO_x coatings are deposited by reactive magnetron sputtering with a metallic target (Pb) on glass slides and alumina (Al₂O₃) substrates. The operating conditions: O₂/Ar flow ratio, current intensity and voltage of target were controlled to study effects of these parameters on thin film deposition. The obtained coatings were crystallized by using a rapid thermal annealer (RTA) and were characterized by X-ray diffraction to analyze the crystallization behavior. The Scanning Electron Microscopy (SEM) was used to examine morphology of PbO_x films. The results obtained will be allowed thereafter to consider evaluate response of coatings films by optical spectrophotometer.

$\text{In}_x\text{Ga}_{1-x}\text{As}$ ($0 < x < 1$) is a semiconductor where the optical and structural properties can be varied by changing the Indium and Gallium ratio [1]. This implies a control of emission and absorption frequencies indispensable to fabricate photonic devices, or efficient solar cells. In this work we have prepared indium gallium arsenide (InGaAs) films on silicon (100) substrate by using R.F. magnetron sputtering, and by varying the power source of In target. Elemental chemical mapping using EDAX in a scale of $20 \mu\text{m}^2$, allow us to identify the elements in the alloy, and their spatial distribution. We observed homogeneity in each of the elements, as well as a marked contrast with the In increase. Morphology of InGaAs samples were analyzed using SEM in plain view in a $10 \mu\text{m}$ scale. These images show several features that depend on the In content. The presence of micro-drops scattered over the surface are likely due to the In segregation. XRD spectra of the as-deposited InGaAs films at different In power source ($0 < P_{\text{In}} < 30 \text{ W}$) are shown in Fig.1. In order to avoid the (004) main reflection plane of the Si (001) substrate that is located at $2\theta = 65^\circ$, all spectra were cut at $2\theta = 60^\circ$. The InGaAs samples are polycrystalline, but the preferential orientation depends on the In content. In order to identify the vibrational phonon modes relating to GaAs and InAs, a deconvolution of the Raman spectra using Gaussian functions were performed. These results show a strong correlation between the In content and vibrational phonon modes [2].

Surface patterning is of tremendous importance in many technological fields with features ranging from nanometers to millimeters. There are different patterning techniques that generally can be assigned to the top-down and bottom-up approaches. One bottom-up method for the generation of self-organized nanostructures is low-energy ion beam erosion. It is an easy one step process for the generation of large scale nanostructures of different materials, usually with a mean size below 100 nm [1, 2]. However due to the stochasticity of the process there is a lack of large scale ordering of nanostructures and of positional control.

In this contribution results on self-organized nanostructuring by ion beam erosion with simultaneous Fe co-deposition of pre-patterned Si surfaces will be presented. This method known as guided self organization has its inspiration in nature and is already successfully applied in heteroepitaxy and in diblock-copolymers. The idea is to combine the top-down technique for pre-patterning of surfaces followed by the ion beam induced self-organization process (bottom-up). Due to the periodicity, shape and lateral ordering of pre-patterns an improved ordering, and an exact positional control of nanostructures is achieved. The method allows also for the formation of new structures not possible on planar surfaces.

The pre-patterned substrates are fabricated by various lithographic techniques in combination with etching techniques for structure transfer. Depending on the shape of the pre-patterned structure (binary gratings with different periods, square arrays of cylinders, gratings with V-grooves) different results are obtained. Some experimental observations are: i) formation of curved ripples on the surface, where the curvature is caused by a continuous change in the local topography within pre-patterned regions; ii) perfectly square ordered dots on exact positions on the surface; iii) enhanced ordering of ripples and the formation of ripples with different orientation due to the local surface orientation; (iv) formation of patterns on curved surfaces.

In recent years, the pollution of the wastewaters with dyes is becoming a major environmental problem due to the growing use of a variety of dyes. Consequently there has been an increasing interest in developing new methods, more effective than the conventional processes, commonly used, to eliminate these environmental contaminants. Advanced oxidation processes (AOP), characterized by the production of hydroxyl radicals (OH[•]) and superoxide anion (O²⁻), which are generated when a semiconductor catalyst absorbs radiation when it is in contact with H₂O and O₂ are a promising technology. Among various photocatalysts TiO₂ has been intensively studied. Nevertheless two limitations are recognized for a wide practical application, such as the small percentage of the solar radiation, which has the required energy to photogenerate electrons and holes and their high recombination rate. A lot of researches have been done to improve the TiO₂ photocatalyst activity and show that the efficiency of the photocatalytic reaction can be enhanced in heterogeneous semiconductor systems, such as Fe₂O₃-TiO₂, TiO₂-SnO₂, WO₃-TiO₂ etc [1]. Photocatalysts can either be used as powders in a slurry form or as supported films, being this latter configuration advantageous. Among many techniques used to prepare catalytic materials immobilized in film form the sputtering method presents several advantages mainly because the structure, morphology and optical properties of sputtered films can be modified by changing the deposition parameters [2]. This work reports some results of the preparation and characterization of TiO₂/WO₃ nanocomposites films for photocatalytic applications. TiO₂/WO₃ bilayered films were deposited on glass substrates by DC-magnetron sputtering. The crystallographic, optical and morphological properties (figure 1) of WO₃ and the TiO₂ layers were studied.

The films photocatalytic activity was tested, under visible irradiation, on the decolorization of Rhodamine 6G aqueous solutions and studied considering the

influence of the crystalline structure and morphology of the prepared films.

Indium Nitride (InN) is a semiconductor material with possible applications in solar cells [1]. In this work we report the formation of micro and nanoparticles of InN on Si (100) substrate obtained by magnetron sputtering in an Ar+N mixture atmosphere. The InN samples were analyzed by scanning electron microscopy (SEM), X-ray diffraction (XRD), UV/Vis absorption and photo-acoustic measurements. The InN layers are polycrystalline and exhibit the formation of crystals with a hexagonal structure. SEM images show the formation of micro and nanoparticles (~50 nm diameter and spherical shape) which depend on the substrate temperature (Fig. 1). Bandgap energy (E_g) of InN layers obtained from UV/Vis spectra showed a blue shift [2] as a function of substrate temperature. The thermal diffusivity of each layer was determined by photo acoustic measurements assumed optically and thermally homogeneous slab sample geometry (Fig 2).

Reflection High Energy Electron Diffraction (RHEED) is perhaps the most commonly used in-situ monitoring method for molecular beam epitaxy, providing quantitative information about surface reconstructions, lattice parameters, growth rates and growth modes, together with semi-quantitative information about surface morphology. The main disadvantages with RHEED are linked to its high energy electron beam, which penetrates several atomic layers of the crystal surface, leading to damage in sensitive materials [1], and making the extraction of information about the reconstruction and morphology of only the topmost atomic layer difficult.

We present here an alternative, recently developed, diffraction technique, which is fully compatible with conventional MBE growth and has the advantage over RHEED in that it is truly surface sensitive. This technique, known as Grazing Incidence Fast Atom Diffraction (GIFAD) [2] uses a beam of neutral atoms such as Helium, with energy of less than 1keV, incident on the surface at a shallow angle. Due to this shallow incidence angle, the energy of the atoms perpendicular to the surface is very small, giving rise to diffraction of the atom beam from the corrugated

surface potential perpendicular to the beam direction. We have mounted a GIFAD system on a commercial MBE machine, and demonstrate the capacity to monitor changes in the surface in real-time during growth (see e.g. Fig. 2). We will discuss the information about surface ordering provided by this technique compared to RHEED.

Plastic deformation and structural change in the surface layer of metals under the impact with high-speed nanoparticles

T14 Thin Films

#TF-9-Or-12

A. Mayer.

Chelyabinsk State University - Chelyabinsk (Russian federation).

High-power pulsed ion or electron beams are widely used now for surface treatment: they can produce strengthening of the surface layer material [1], smoothing of the surface relief [2], deposition and reinforcement of different protective or functional coatings. In this case, microscopic fast particles, accelerated by the electric field, bring their energy to the material and heat it; therefore, the main action of the beam is the material heating. The classical bead-blasting treatment is another limit, in which macroscopic particles strike on the surface and produce its plastic deformation due to the momentum transfer.

The metal surface bombardment by high-speed nanoparticles is an intermediate case, which can be a useful tool for the surface treatment. Previously prepared and charged nanoparticles with diameter of the order of 100 nm can be accelerated by the electric field in vacuum up to velocities of the order of 100 - 1000 m/s. Impact of a high-speed nanoparticle with the metal surface produces a shock wave with amplitude of about several GPa, which is enough for intensive plastic deformation and structural change (change of the dislocation density, et cetera). Each shock wave is spherically diverging, its amplitude decays on the length scale of the nanoparticle diameter; therefore, modification affects only the thin surface layer with the corresponding thickness. Pit impressed on the surface by a nanoparticle is small; therefore, this treatment can be used for processing of the fine-polished surfaces.

In this report, the metal surface layer deformation under the impact with high-speed nanoparticles is numerically investigated on the base of mechanics of continua, supplemented by the dislocation plasticity model [3-5]. Investigation is made from the

viewpoint of potential application of this technology for the surface treatment. Optimal size and velocity of nanoparticles are determined, as well as the features of the obtained structural change in the metal surface layer. Pit impression and the conditions of sticking are analyzed.

The study was supported by The Ministry of education and science of Russian Federation, projects 14.B37.21.0384 and 2.2320.2011.

Abstract:

Chromium doped TiO₂ thin films grown by co-sputtering of titanium and chromium in a Cathodic Arc Plasma evaporation system on various substrates. X-ray diffraction (XRD), Rutherford backscattering spectroscopy (RBS), SEM with EDS used to characterize the films. Deposited pure titanium dioxide thin films possess a mostly anatase structure while Cr-doped TiO₂ films are amorphous. Amorphous Cr-doped TiO₂ films transformed to a mixed anatase and rutile phase by annealing at various temperatures. Changes in the morphology and composition of the films examined by SEM-EDS. Crystalline Cr-doped TiO₂ films became super-hydrophilic which indicate that the absorption edge shifted from an ultraviolet region for TiO₂ to a visible region for annealed Cr-doped TiO₂ films, which is further confirmed by UV–visible spectroscopy.

Key words: XRD, EDS, RBS, Cathodic Arc Plasma evaporation system, UV–visible spectroscopy.

Deposition of dense and adherent polymer coatings containing phosphate groups on thermally sensitive substrates is very interesting for protective or biological applications. Non-equilibrium atmospheric-pressure plasmas have been studied in many processes but phosphorus-containing precursors were never injected into a dielectric barrier discharge (DBD) to deposit organophosphorus coatings on polymer substrates.

In this work, TriEthyl Phosphate (TEP) is injected in a DBD in order to deposit organophosphate coatings at atmospheric pressure. The coating structure (SEM, Ellipsometry) and the coating chemistry are studied (FTIR, XPS, ToF-SIMS, ³¹P NMR) in order to understand the deposition mechanisms of TriEthyl Phosphate (TEP). FTIR (Figure 1) and XPS indicate a coating containing phosphate, organophosphate and different C-containing groups. N-containing groups are also detected in the coating due to reaction of precursor with reactive nitrogen species coming from process gas N₂. Polyphosphate chains are revealed by ³¹P NMR (Figure 2) and the polymer structure of the coating is highlighted by SIMS. Electrical and optical (OES) characterizations of the discharge are presented to go further in the understanding of the deposition mechanism.

Figure 1 : ATR-FTIR spectra of the TriEthyl Phosphate monomer (a) and of the plasma-polymerised coating (b)

Diamond-like Carbon (DLC) is a disordered carbonaceous material composed of hydrogen and carbon, which is bonded in sp^2 and sp^3 electronic configurations with a significant C-C sp^3 bonds. There are several carbon-based photocathodes, like polycrystalline diamond, hydrogenated amorphous carbon and nanostructured fullerene films.

The influence of diamond like carbon films technology and properties on quantum efficiency of prepared photocathode has been investigated. Diamond-like carbon films were deposited on silicon substrate and stainless steel mesh by reactive magnetron sputtering using carbon target and gas mixture of Ar and reactive gases H_2 and D_2 . The concentration of elements in films was determined by RBS and ERD

analytical method simultaneously. Chemical compositions were analyzed by Fourier transform infrared spectroscopy (FT-IR). Raman spectroscopy was used for I(D)/I(G) ratio determination. The quantum efficiency was calculated from the measured laser energy and the measured cathode charge. RBS and ERD analysis indicated that the films contain carbon, hydrogen, deuterium and small amount of oxygen. IR results showed the presence of main C-D, C-H, H-O, D-O bonds. Raman spectra of DLC films show the D and G band conversion which were Gaussian-fitted and identified. The emission process from diamond like carbon films, excited with near-UV radiation, seems to be governed by the intensity ratio I(D)/I(G). Results show, that photocathodes prepared with deuterium as reactive gas have higher quantum efficiency than photocathodes prepared with hydrogen as reactive gas and photocathode quantum efficiency rise up with deuterium and hydrogen flow rate.

This research has been supported by the Slovak Research and Development Agency under the contracts APVV-0713-07, APVV-0321-11 and has been executed in the framework of the Topical Plan for JINR Research and International Cooperation (Project 02-0-1067-2007/2012).

TF-6-Or-10

Surface structures of ultrathin TiO_x and BaO films on Au (111)

T14 Thin Films

#TF-6-Or-10

C. Wu, M. Marshall, M.R. Castell.

Department of Oxford, University of Oxford - Oxford (United kingdom).

Following the discovery of enhanced catalytic properties of oxide supported nanoparticles of noble metals, especially Au, interactions between the two have become a focus in research [1-3]. The growth of oxides on Au(111) surfaces serves as an inverse model and provides insights into their interactions. Well-ordered TiO_x and BaO layers were grown on $(22 \times \sqrt{3})$ -reconstructed Au(111) surfaces by Ti and Ba deposition and oxidation. Surface structures of these ultrathin oxide films were studied by scanning tunneling microscopy (STM) and Auger electron spectroscopy (AES).

In the growth of TiO_x thin films on Au(111), three different structures were observed with increased amounts of Ti deposited [4]. The first structure occurs for Ti surface coverages of <0.5 monolayer (ML), and exhibits a (2×2) -reconstructed structure resembling a honeycomb pattern. The second structure arises after depositing 0.5 ML - 1.8 MLs of Ti and exhibits a pinwheel shape. The pinwheel structure forms a $(\sqrt{67} \times \sqrt{67})R12.2^\circ$ Moiré pattern. The third structure occurs for >0.5 ML Ti depositions and forms triangular shaped islands. Film growth continues via the coalescence of triangular islands with further increased Ti coverage. Auger electron spectroscopy (AES) indicates that the structures have different chemical compositions.

For BaO ultrathin film growth on Au(111), coexistence of a honeycomb (4×4) and a hexagonal $(4\sqrt{3} \times 4\sqrt{3})$ periodicity were observed. Both structures lift the Au herringbone reconstruction [5]. Using the sub-monolayer TiO_x structures on Au(111) as templates, new reconstructions were created following Ba deposition which were not observed when BaO was grown on Au directly. Atomic models are proposed for the observed structures and we demonstrate the possibility of creating novel epitaxial oxide structures on both metal substrates and other oxide templates.

TF-1-Or-7

Multi-Dye-Molecule-Stacked Structures Grown by Molecular Layer Deposition (LP-MLD) on ZnO

T14 Thin Films

#TF-1-Or-7

T. Yoshimura.

Tokyo University of Technology - Hachioji, Tokyo (Japan).

Molecular Layer Deposition (MLD)¹⁻³ grows tailored organic thin films with designated molecular arrangements by introducing source molecules sequentially onto substrates. The monomolecular-step growth is achieved by selective chemical reactions or the electrostatic force. Multi-dye-molecule-stacked structures, which will be applied to the dye-sensitized solar cells,^{2,3} were grown by the liquid-phase MLD (LP-MLD) on n-type ZnO.

As Fig. 1 shows, a sequence of p-type dye (p1) - n-type dye (n1) - p-type dye (p2) constructs a [ZnO/p1/n1/p2] structure. Here, "p-type dye" and "n-type dye" were defined by Meier.⁴ The former tends to have negative charge and the latter tends to have positive charge. Rose bengal (RB) and eosine (EO) were used as p-type source molecules, and crystal violet (CV) as n-type source molecules.

As Fig. 2 shows, in [ZnO/RB] the surface potential becomes negative, which is attributed to electric dipole moments generated by the negative charge in the p-type dye molecules. In [ZnO/RB/CV], the surface potential shifts to the positive side due to the positive charge in CV on the top. When p-type EO molecules are adsorbed on [ZnO/RB/CV] to fabricate [ZnO/RB/CV/EO], the surface potential shifts to negative side.

It was found that photoluminescence spectrum of [ZnO/RB/CV/EO] measured by excitation light of 532 nm in wavelength is a superposition of spectra of [ZnO/RB/CV] and [ZnO/EO], which implies widening of the absorption wavelength range in the multi-dye-molecule-stacked structure.

These results suggest that multi-dye-molecule-stacked structures are definitely constructed on ZnO surfaces with monomolecular steps by LP-MLD.

Reduction of particle defects on Mo/Si multilayer films for extreme UV mask blank by controlling the surface roughness of chamber shields in ion beam sputtering

T14 Thin Films

#TF-9-Or-11

J. Kageyama¹, M. Yoshimoto², A. Matsuda², V. Jindal³, P. Kearney³, F. Goodwin³.

¹Asahi Glass Co., Ltd. and Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology - Yokohama (Japan),

²Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology - Yokohama (Japan), ³SEMATECH, Inc. - Albany (United states).

Extreme UV lithography using a 13.5 nm light is an emerging technology for the next generation lithography¹. EUV mask blanks comprise the multilayered Mo/Si film deposited on a glass substrate². The multilayer film is capped with a Ru layer. In fabricating the mask blanks, defects on the film cause the malfunctioning of semiconductor chip. Reducing the defects in the EUV mask blank presents a major challenge to the commercialization of EUV lithography.

In this work, the underlying cause of deposition-derived particle defects in the ion beam sputtering process was investigated with focused on the surface roughness of the chamber shield in order to reduce the defect density on the mask blank film. As a result, it was demonstrated that the shields of roughness exceeding 8 μm greatly reduced the Si-rich particle defects on the mask blank film.

Fig. 1 is a schematic top view of the Ar⁺ ion beam sputtering system using rotating targets of Si, Mo, and Ru. The interior walls of the chamber were wholly protected by detachable stainless-steel shields placed in the zones 1 and 2 (zone 1: near the sputtering targets and the substrate, and zone 2: along the chamber interior wall). We prepared shields of different arithmetic average surface roughness R_a in the range of 3.1 μm to 19.9 μm . The defect count of each EUV mask blank was inspected across 142 \times 142 mm² area prior to and following deposition. Particle

composition was analyzed under focused ion beam/SEM, and by EDX spectroscopy. The total defect count of Si and Si/Mo particles (Si-rich particles) having size of several tens of nanometer or more per mask blank was averaged for each experiment. Si-rich particle defect was found to inversely decrease with the square of the surface roughness of the shield, suggesting that Si-rich particles arise from the shield surface.

The obtained results reveal a linear relationship between Si-rich particle defect counts per mask blank and the inverse square of shield surface roughness. To investigate the influence of shield location, we repeated the plot for zone 2 data with Ra_1 (zone 1) maintained approximately constant. These results suggest that Si-rich particle defects coming from the shield surface in zone 2 (the chamber wall shield) similarly affect the defect on the mask blank.

TF-P2-35

Grain Crystallization Control and Large Magnetoresistance Emergence in Fe₃O₄/a-SiO₂ Thin Films Produced by Rapid Thermal Deoxidation Method

T14 Thin Films

#TF-P2-35

H. Kobori ¹, T. Murakami ¹, A. Yamasaki ¹, T. Taniguchi ², T. Shimizu ³.

¹Konan University - Kobe (Japan), ²Osaka University - Osaka (Japan), ³National Institute of Advanced Industrial Science and Technology - Tsukuba (Japan).

We have observed large magnetoresistance (MR) in Fe₃O₄/a-SiO₂ thin films produced by rapid thermal deoxidation (RTD) method. By use of the RF magnetron sputtering technique, 500nm-thick α -Fe₂O₃ thin films were grown on a-SiO₂ (SiO₂ glass) substrates, through the oxygen reactive process from an Fe (99.99%) target. After that, those films were deoxidized and varied to Fe₃O₄ films by rapid thermal deoxidation (RTD) method. The RTD for α -Fe₂O₃/a-SiO₂ thin films were carried out in the atmosphere of Ar(90%)/H₂(10%) mixture gases by using an infrared image furnace. The heat treatment conditions for the RTD are 430 °C/20min, 460 °C/10min, 500 °C/5min, 550 °C/2min, and 600 °C/1min. For comparison, a 500nm-thick Fe₃O₄/a-SiO₂ thin film was also produced by the oxygen reactive process without the RTD. From the X-ray diffraction measurement, it is found that the crystallinity of the α -Fe₂O₃/a-SiO₂ and Fe₃O₄/a-SiO₂ thin films without the RTD are low, whereas that of Fe₃O₄/a-SiO₂ ones with the RTD are highly increased by the heat treatment. In addition, from the atomic force microscope measurement, we find that the Fe₃O₄ nano-particle size in Fe₃O₄/a-SiO₂ thin films with the RTD increases with increasing the heat treatment temperature. Magnetite (Fe₃O₄) is a ferrimagnetic material which has a high Curie temperature (858K) and is also known as a halfmetal. A halfmetal is regarded as one of most promising materials of spintronics devices. The electrical resistivity (ER) and the magnetoresistance (MR) ratios of the Fe₃O₄/a-SiO₂ thin films with and without the RTD were measured between 6 K and 300 K. The ER of the Fe₃O₄/a-SiO₂ thin film without the RTD showed the temperature dependence of the Mott's variable range hopping conduction. This behavior implies that the sample is amorphous-like. On the other hand, the ER of Fe₃O₄/a-SiO₂ thin films with the RTD showed a kink at around the Verwey transition temperature (~120 K), which indicates

that the crystallinity of those is high. Figure 1 shows the temperature dependence of the MR ratios for the $\text{Fe}_3\text{O}_4/\text{a-SiO}_2$ thin films without and with the RTD. Here $\rho(H)$ is the MR at the magnetic field H and the MR ratio is expressed as $\Delta\rho(H)/\rho(0)=\{\rho(H)-\rho(0)\}/\rho(0)$. The MR ratio of the sample without the RTD is small and monotonically decreases with increasing the temperature. That ratio at 0.7T is 1.8% at 50 K and 1.2% at 300 K. For the samples with the RTD, it is clearly found that the MR ratios are drastically increased as compared with the sample without the RTD. The MR ratio at 0.7T for the sample with the RTD (550 °C/2min) is 7.6% at 128 K.

Low-temperature scanning tunnelling microscopy and spectroscopy have been employed to study the adsorption of individual Au atoms on well-defined CeO₂(111) films grown on Ru(0001). For slightly reduced films, two types of Au species are found on the surface. The first one appears as isolated protrusion, while the second type always forms pairs of 8-10 Å distance and develops distinct Sombrero-shapes. The relative abundance of the two species sensitively depends on the reduction state of the surface, i.e. on the density of oxygen vacancies. According to DFT calculations, we assign the two species to Au atoms in two different charge states. While the simple protrusions correspond to a neutral Au that bind to the ideal, defect-free lattice, the paired species are negatively charged and decorate nearby subsurface oxygen-vacancies. The latter type pairs up, as each O-defect generates two Ce³⁺ cations that are able to transfer one electron each to two surface Au atoms. The presence of Au pairs therefore provides direct evidence for charge-transfer processes between reduced Ce³⁺ ions and electronegative Au species, but also indicates the typical separation of the two Ce³⁺ associated to an O vacancy.

Delamination and buckling of thin films from an interface step

T14 Thin Films

#TF-1-Or-8

A. Ruffini, J. Durinck, J. Colin, C. Coupeau, J. Grilhé.

P' Institute - Futuroscope (France).

The coatings technology of materials with sub-micron thin films find applications in many industrial fields such as microelectronics or optics. During the deposition process, high stresses reaching sometimes several GPa may develop in the film leading to the interface delamination. The delaminated zone of the film will subsequently buckle if the stress is in compression and its magnitude is beyond a critical value. Understanding the mechanisms responsible for this damaging phenomenon is a major technological challenge in different fields such as materials science, metallurgy and continuum mechanics. Since the early-2000s, the buckling of thin films has been studied in the framework of the continuum theory of elastic thin plates developed by Föppl and von Kármán (FvK). This model has been widely used to describe successfully the elastic behavior of structures such as straight-sided blisters or telephone cord buckles.

More recently, post-mortem AFM observations have evidenced that buckled structures have preferentially grown from nano-steps which have been formed at the interface by the emergence of dislocations coming from the substrate [1]. It is in this context that a twofold study has been set up in order to investigate this phenomenon.

On one hand, atomistic simulations have been performed to understand the elementary mechanisms at the origin of the delamination at the interface between metallic film and substrate. It has been first shown that a delaminated zone extends on both sides of the step as dislocations glide from the substrate to the interface and the step height increases. The buckling of the film has been found to occur for critical step height and applied strain. On the other hand, the expression of the critical strain beyond which the film buckles has been derived, in the framework of the continuum FvK theory, as a function of the step height. The model explains why the buckling of the film is favored above step-like nanostructures.

SE/PST/TF/BI-3-Or-4 Polydopamine Nanoscale Thin Films as Multifunctional Coatings

T14 Thin Films

#SE/PST/TF/BI-3-Or-4

W. Zhang, F. Yang, B. Zhao.

University of Waterloo - Waterloo (Canada).

Dopamine is a “sticky” biomolecule containing the typical functional groups of mussel adhesive proteins. It has a chemical structure of catecholamine (Figure 1a); under alkaline conditions the catechol group can be oxidized to quinone, allowing dopamine to self-polymerize and form a nanoscale thin film on its support surface (Figure 1b). [1] Although the application of polydopamine (PDA) film has been demonstrated as a promising way to functionalize material surfaces, the mechanical and adhesion properties of the PDA film are still largely unexplored. [2] To this end, we recently conducted a systematic study of PDA nanoscale thin films coated on both soft (PDMS) and rigid (glass and epoxy) substrates, and investigated the mechanical and interfacial stability of the thin films both in air and under water. [3] It has been found that PDA films were highly hydrated in wet conditions because of their porous membrane-like structures and hydrophilic groups. Upon dehydration, the films form cracks when they were coated on the soft substrate due to internal stresses and the large mismatch in elastic modulus of the film and the substrate (Figure 1c). We also found a significant decrease of friction forces in water on all three PDA-coated surfaces. Thus, we proposed that the PDA film might be able to serve as a water-based lubrication coating. We attributed the different behaviors of PDA film in air and under water to its hydration effects (Figure 2). These research findings provide insights into the stability, mechanical and adhesive properties of the PDA films, which are critical for their effective transfer to practical engineering.

Zinc oxide (ZnO) is a transparent conductive material and a promising candidate for optoelectronic applications. Its optical properties depend on its crystalline quality, microstructure and defect chemistry. The knowledge of these optical properties is necessary to improve the performance of devices¹. Nevertheless, there is a large scatter in the data reported in the literature, which can only partially be related to the variation of the intrinsic properties.

ZnO_x thin films were synthesized by DC magnetron sputtering. Different compositions were obtained by varying the oxygen flow rate (OFR). Spectroscopic ellipsometry has been used to determine the optical properties of transparent ZnO_x thin films. The optical constants are extracted using the Forouhi-Bloomer (FB) model ^{2,3}. The dispersion of the dielectric function, the absorption coefficient and the optical band gap E_g are presented and analysed as a function of the OFR and chemical composition. For the sake of comparison, E_g was also extracted using the Tauc plot of data obtained by spectroscopic ellipsometry, spectrophotometry in transmission mode and by photoluminescence (Figure 1). We find a significant variation of optical responses with the OFR. More particularly, E_g is found to be sensitive to the OFR and to the presence and density of optical defects as detected using photoluminescence measurements. Moreover, this study evidences significant differences in the evolution of E_g as evaluated by the different methods, explaining in a large extent the dispersion of data in the literature.

TF-P2-36

Porous Anodic Alumina as Antireflection Coatings of Thin Film Solar Cells

T14 Thin Films

#TF-P2-36

S. Cheng.

Fuzhou University - Fuzou (China).

Porous anodic alumina (PAA) formed by an electrochemical oxidation method has been investigated for decades. But the potential use of PAA films as antireflection coatings for photovoltaic applications rarely attracted people's attention. In fact PAA films with both antireflection and light scattered properties could help to enhance the light absorption according to the statistical ray optics [1]. Junwu Chen studied PAA films for traditional graded-index antireflection coatings [2], but the light scattered properties of the PAA films were ignored.

Here PAA thin films were also formed by an electrochemical oxidation method. The transmission spectra of the films were measured by a spectrophotometer. The refraction index was characterized by the transmission spectra, using the dielectric model and K-K transformation. The refraction index could be controlled by the time of wet etching, which was the advantage of PAA films as antireflection coatings. We have obtained optimal PAA film sample with the thickness of about 110nm and the refraction index of 1.15, and the transmission of the optimal sample is much better than that of glass substrate in the visible waveband (seen in Fig.1). But the maximum value of transmission at 550nm is about 95% rather than about 100% as theoretical prediction of a thin film with smooth surface. It is perhaps due to the scattered properties of porous structure, which could be used in thin film solar cells to enhance the light absorption. We also formed double layer PAA films on the glass substrates with transmission of 94.56% (91.17% for the glass substrate) in the visible region, which presented better antireflection properties (shown in Fig.2). Therefore, PAA films are suitable for antireflection coatings of thin film solar cells.

Although gate stack structures with high-k materials have been extensively investigated, there are some issues to be solved for the formation of high quality gate stack structures. In the present study, we employed hard x-ray photoelectron spectroscopy in operating devices(1). This method allows us to investigate bias dependent electronic states while keeping device structures intact. Using this method we have investigated electronic states and potential distribution in gate metal/high-k gate stack structures under device operation. We have found that potential gradient was formed at the metal/HfO₂ interface by analyzing the shifts of the core levels as a function of the applied bias voltage. Angle resolved photoelectron spectroscopy revealed that SiO₂ layer was formed at the metal/HfO₂ interface. The formation of the SiO₂ layer at the interface might concern the Fermi level pinning, which is observed in metal/high-k gate stack structures(2).

Novel method of reactive magnetron sputtering process control

T14 Thin Films

#TF-9-Or-1

M. Jilek ¹, P. Vasina ², R. Zemlicka ².

¹PIVOT a.s. - Sumperk (Czech republic), ²Masaryk University - Brno (Czech republic).

Novel method of control of reactive magnetron sputtering process is presented. To control reactive magnetron sputtering process the process pressure is regulated by the flow of the reactive gas (nitrogen). Oscillations of the flow of the reactive gas are determined and used as feedback to find the right overall pressure, where stoichiometric coating is deposited. To see typical process behavior, see fig. 1. Proposed method of control was used for deposition of several coatings (TiN, AlTiN, AlCrN, CrTiN, ...) on industrial scale central rotating unbalanced magnetron. To achieve superior adhesion of these layers, novel cleaning method called LGD was used. These coatings were used in industrial applications. Applications results in comparison with market standard coatings will be presented along with other measurements of deposited layers (EDX, SIMS, SEM, ...).

On-line thin film deposition on cylindrical metallic substrates is of great interest for the development of composite materials, sensors, or for the realization of protective or adhesive layers. Thus, we have built a prototype consisting of a tubular dielectric barrier discharge working at atmospheric pressure. Deposition of organic coatings can be achieved with high deposition rates (up to 50 nm/s when the deposition is performed in static mode) and with a large variety of precursors.

Two examples will be described: organosilicon thin films from octamethylcyclotetrasiloxane (OMCTS or $C_8H_{24}O_4Si_4$) and organochlorinated thin films from methylene chloride (CH_2Cl_2), with or without addition of myrcene ($C_{10}H_{16}$). Precursors are first nebulized in an argon flow before being injected into the reactor.

Influence of experimental parameters (gas flow, dissipated power in the discharge and high voltage frequency) on the morphology and thickness of thin films has been studied by scanning electron microscopy. On the other hand, the discharge has been characterized by electrical measurements and optical emission spectroscopy. By setting ad hoc experimental parameters, dense, smooth, adhesive, stable and homogeneous coatings can be obtained.

In the case of coatings obtained from pure methylene chloride, X-Ray Photoelectron Spectroscopy depth profiling has revealed that the stoichiometry of the film is remarkably constant throughout the layer, indicating a steady thin film growth. Size Exclusion Chromatography has also been performed to determine the chemical structure of the deposited film.

It is worth indicating that with this type of precursors, a 100 nm thick film can be deposited on a wire at a linear speed closed to 1 m/min in a 15 cm long reactor featuring a 2.5 cm long electrode. Therefore, versatility and scalability of the process make it promising and suitable for industrial applications, by simply increasing the electrode length or multiplying the number of reactors, as illustrated in figure 1.

The superconductivity of lead films with a thickness of a few monolayers and even of a single Pb layer on silicon has stimulated an active scientific interest in thin Pb films [1-3]. The experimental findings inspired a great amount of theoretical work focused on the thin film properties as well as on the impact of quantum size effect.

We present a theoretical study of the influence of spin-orbit interaction on the electron-phonon (e-ph) coupling strength at the Fermi level as well as on the phonon-induced linewidth of unoccupied and occupied quantum-well states (QWS) in ultrathin Pb(111) films of the thickness ranging from 4 to 10 monolayers. The strength of e-ph interaction as well as the contribution to the QWS linewidth coming from the e-ph scattering were obtained directly using layer-dependent ab initio density functional calculations for free-standing Pb(111) films. The calculations take full account of quantum-size effects on film electron and phonon band structures as well as on the e-ph coupling. It is shown that the spin-orbit interaction produces a large enhancement of the electron-phonon coupling strength regardless of the film thickness. This partly reflects a strong SOC-induced softening of the film phonon spectra, and partly a SOC-mediated increase in electron-phonon coupling matrix elements. For thin films quantum size effects result in pronounced oscillations of the average coupling constant with the number of layers, which become damped for thicker films.

CIRIMAT / University of Toulouse / CNRS - Toulouse (France).

The preparation of nanocomposite thin films can lead to devices with attractive optical, magnetic, and semiconducting properties. The majority of authors active in the field of oxide thin films, reports the elaboration of oxide thin films by reactive magnetron sputtering from a metallic target using an Ar–O₂ gas mixture. The proportion of oxygen present in the plasma then determines the stoichiometry of the oxide. However the control of this chemical reaction is quite difficult. Another method to obtain oxide thin films is by radio frequency (RF) sputtering of an oxide target. During sputtering, the target and the layer growing on the substrate are subjected to continuous bombardment by energetic species. In the case of oxide deposition, oxygen atoms can even be ejected from the target and/or the film when the bombardment becomes stronger. Under-stoichiometric oxides, reduced phases or metallic particles result from such conditions. The amount of reduced phase can then be adjusted by the modification the sputtering conditions. The additional bias polarization of the substrate is a complementary way to increase the bombardment on the growing layer. These extreme conditions of preparation lead to interesting reducing preparation conditions from which metal/oxide or oxide/oxide nanocomposites can result [1, 2].

We present some examples of nanocomposites that have been obtained by direct sputtering from oxide targets in a pure argon gas flow with, or without, additional applied bias power. Especially we report here the preparation of nanocomposite thin films from various targets:

-	Cu/Fe ₃ O ₄ ,	from	CuFeO ₂	target,
-	CuO/CuFe ₂ O ₄ ,	from	CuFeO ₂	target,
-	Fe/FeO,	from	Fe ₃ O ₄	target,

- FeO/Fe₃O₄, from Fe₃O₄ target,
- (Zn,Fe)O/ZnFe₂O₄, from ZnFe₂O₄ target,
- Ni/(Ni,Fe)O/NiFe₂O₄, from NiFe₂O₄ target,
- and (Co,Fe)O/Co_{1.7}Fe_{1.3}O₄, from Co_{1.7}Fe_{1.3}O₄ target.

These compounds were easily obtained by rf-sputtering of ceramic targets under different in-situ reducing conditions.

Regarding some examples of the properties of such materials, we have shown that these nanoscale composites comprising phases with different magnetic properties (e.g. ferri-, ferro-and antiferro-magnetic) can generate magnetic coupling with strong exchange interactions. In addition, the composite CuO-CuFe₂O₄ showed particularly a very strong increase of the sensitivity for the semiconducting detection of CO₂ gaz [3].

TF-3-Or-12

STRUCTURAL CHARACTERIZATION AND THERMAL NOISE PERFORMANCE OF TANTALA AND SILICA DEPOSITED WITH IBS

T14 Thin Films

#TF-3-Or-12

G. Cagnoli.

LMA - Villeurbanne (France).

Tantala and Silica deposited by IBS are the constituent materials for the reflecting coatings of the Advanced Gravitational Wave (GW) Detectors core optics, as well as of the ultimate frequency reference standards having line widths of tenths of Hertz. The Laboratoire des Matériaux Avancés (LMA) in collaboration with the Institute Lumière et Matière of the Université Claude Bernard Lyon1 has started an investigation on the structural properties of these two materials to detect the centres of relaxations responsible of the thermal noise. This investigation should lead to an amelioration of optical and mechanical characteristics of tantala and silica and, in particular, to a reduction of coating thermal noise that at this moment is the major limit to the performance of GW detectors and frequency standards.

In this presentation, after a brief introduction to the problem of thermal noise in optical coatings, results from the correlation between Raman and Brillouin scattering on one side and mechanical loss measurements on the other will be discussed.

TF-8-Or-2

Growth of FeCo soft magnetic thin films by chemical vapor deposition

T14 Thin Films

#TF-8-Or-2

J. Abelson ¹, P. Zhang ¹, S. Babar ¹, S. Sahoo ², M. Kautzky ², L. Davis ¹, G. Girolami ¹.

¹Univ. of Illinois - Urbana (United states), ²Seagate Technology - Bloomington (United states).

FeCo alloys have been widely used in magnetic recording and other industrial applications, due to their excellent soft ferromagnetic properties: high M_s , low H_c and good thermal stability. $Fe_{50-70}Co_{50-30}$ alloys have the highest M_s of 2.4T, which is higher than other soft magnetic alloys such as NiFe and FeSi.

The current methods for FeCo thin film growth are mainly by PVD such as sputtering, MBE or by electrodeposition. It is difficult to coat complex structures conformally using PVD, while chemical vapor deposition (CVD) is known to have better conformality. However, there has been no report of CVD for FeCo alloy thin films yet. Here we demonstrate a process to grow FeCo thin films by low-temperature ($< 250^\circ C$) CVD from a gaseous mixture of commercially available Fe and Co carbonyls. The films have high purity and great magnetic properties ($M_s = 2.52 T$, $H_c \sim 12 Oe$). Film growth is carried out in a UHV chamber. The substrate is planar SiO_2 with 5 nm Ru seed layer. $Fe(CO)_5$ and $Co_2(CO)_8$ precursors are introduced into the chamber by separate gas lines pointing toward the substrate. Precursor fluxes are controlled independently with needle valves. No carrier gas is needed.

Optimized results are obtained at $Fe(CO)_5$ partial pressure of 0.110 mTorr, $Co_2(CO)_8$ partial pressure of 0.060 mTorr and a substrate temperature of $230^\circ C$. No additional magnetic field is applied during growth. Films are capped with CVD grown HfB_2 layer to avoid surface oxidation.

Figure 1 shows a cross-sectional TEM image of FeCo film grown for 6 min. It is 336 nm thick with a dense and smooth structure. Auger depth profile shows a constant Fe/Co ratio of 55/45 throughout the film, and the oxygen content is very small. The hysteresis (Fig. 2) shows a perfect soft magnetic film with H_c as low as 12 Oe, which is consistent with its low impurity level. Its M_s is 2.52 T, which is the highest value that an FeCo alloy can reach theoretically.

Metastable nanotubular TiO₂ and their transformation into anatase nanoparticulate layers on surface of anodized titanium subject to alumina grit blasting

T14 Thin Films

#TF-1-Or-1

M. Mendoza López ¹, C.Y. Torres López ², J. Pérez Bueno ².

¹Instituto Tecnológico de Querétaro - Querétaro (Mexico), ²Centro de Investigación y Desarrollo Tecnológico en Electroquímica - Querétaro (Mexico).

TiO₂ nanotubular/Ti electrodes were prepared into organic and aqueous media for photocatalytical decomposition of an azo dye (methyl orange). For this, nanotubes were produced under anodizing process, using two dissolution media: organic medium (98% ethylene glycol, NH₄F 0.3 %wt, 60 V) and aqueous medium (1 M Na₂SO₄, NH₄F 0.3 %wt, 20 V) [1]. Considering the attained control with an organic medium, this and its conditions were chosen (Figure 1). Titanium surfaces were pretreated by grit blasting with alumina particles. This was proposed in order to increase adherence by physical anchorage at different topological levels of the modified layer.

The alumina grit blasting technique was applied to titanium plates, prior to anodizing, provided changes beyond increasing adherence. The nanotubes layers were metastable and reactive, if not thermally treated, under exposure to OH media, such as water or alcohol. The dye solutions were decolorized by a new prepared sample only once, without applying UV. Anatase nanocrystallites grow and structure changed completely, as shown at Figure 2. The alumina was crucial for such process. EDS analysis show substantial alumina content increase on surface, from 0.5 % up to 12%, attributed to exposure of remnant grits chunks. Titania underwent restructuring losing tubular shapes and acquiring a nanoparticles coverage. These nanoparticles crystallized as anatase with particle sizes about 4 nm.

Near-surface 2D-nanostructures in $\text{TiO}_{2-\delta}$ and $\text{ZnO}_{1-\delta}$ meso-structures

T14 Thin Films

#TF-P2-38

A. Lisachenko, L. Basov.

V.A. Fock Institute of Physics, St. Petersburg State University - St. Petersburg (Russian federation).

Previously [1] we proposed a technique for wide-bandgap oxides TiO_2 and ZnO “self-sensitization” in VIS region using the photo-reduction of surface to $\text{TiO}_{2-\delta}$ and $\text{ZnO}_{1-\delta}$. This creates the coloured electron (F- type) and hole (O^-) V-type centers on the surface and near-surface 2D-nanostructures $\text{TiO}_2/\text{TiO}_{2-\delta}$ and $\text{ZnO}/\text{ZnO}_{1-\delta}$. The aim of the present work was to study the nature of VIS-excitations in $\text{TiO}_2/\text{TiO}_{2-\delta}$ and $\text{ZnO}/\text{ZnO}_{1-\delta}$.

In situ investigations were performed in gas, adsorbate and solid state [2] using mass-spectrometry, optical UV-VIS-NIR, ESR, UPES spectroscopies. For ZnO we used also the photoluminescence (PL), Kelvin probe (KP) and surface photo-voltage (SPV) measurements. Meso- and nano-structured powders of high-purity TiO_2 and ZnO were used. Two types of non interacting excited electron subsystems are established: the “fast” one is excited in bulk under UV irradiation and the “slow” one is excited on the surface in VIS region. The energetic levels in the near-surface energy well are discrete, that explains the long lifetimes of excited states, the high efficiency of the VIS-activated reactions and the “memory” effect [3]. The VIS illumination decreases δ , but does not change the values of SPV nor the intensity of UV-excited PL. The UV irradiation decreases the dipole barrier δ and also the barrier V_1 due to the diffusion to the surface of holes generated in the bulk. Oxygen adsorption occurs on electrons, emerging into the surface via V_1 giving O_2^- species and the green PL quenching. Hole centers give the adsorption species O_3^- which is a precursor in POIE and oxidation reactions. We can expect that “self-sensitization” of $\text{TiO}_2/\text{TiO}_{2-\delta}$ and $\text{ZnO}/\text{ZnO}_{1-\delta}$ -based photocatalysts and solar photoelectric or photo-electrochemical cells using intrinsic

point defects and near-surface 2D-nanostructures is a real way to optimize the design of efficient VIS photoactive elements for the conversion of sunlight energy.

The properties of TiO₂ thin films deposited on silicon by Atomic Layer Deposition

T14 Thin Films

#TF-P2-39

R. Mikhaylov, V. Lavrentiev, V. Titov, V. Drozd, L. Basov, A. Lisachenko.

St. Petersburg State University - St. Petersburg (Russian federation).

The sensitization of TiO₂ to VIS region is a key problem for using TiO₂-based converters of sunlight energy to chemical or electrical one. For this purpose the composites of TiO₂ with narrow-gap semiconductors are designed. Among other an atomic layer deposition (ALD) technique is used. ALD method is promising to create transparent, protective, photoactive layers on the surfaces.

The aim of this work was to investigate a response of thin TiO₂ layers deposited on *p*-Si (100) to VIS light irradiation. TiO₂ layers with various thicknesses (from 2 to 300 nm) were obtained by ALD using TiCl₄ and H₂O as precursors. The UV (8.43 eV) PES, mass-spectrometry, SEM, AFM, UV-VIS DRS, hydrophilicity state measurements were used for characterization. SEM and AFM have shown that the films obtained by ALD have a continuous, homogeneous and plane surface.

The comparative photoelectron spectra of TiO₂ films with various thicknesses (from 2 to 300 nm) were obtained. In case of 2 nm TiO₂ films the photoemission current is the sum of the emissions from the film and the substrate. Thicker films partially capture photoelectrons from the substrate, and for the thickness over 25 nm the UV (8.43 eV) photoelectrons generated in the silicon substrate practically do not penetrate through the film.

The changes in the electron structure of TiO₂ films are induced by irradiation in the inter-band as well as in the sub-bandgap region of TiO₂. Not only UV but also VIS irradiation in vacuum reduces the surface because of oxygen losses, that results in a decrease of both thermoelectric workfunction ϕ_t and contact potential. On the contrary, the irradiation in O₂ leads to oxidizing of TiO₂ surface and to the increase of ϕ_t . For the thin TiO₂ film (2 nm) the noticeable changes in the electron structure occur even under irradiation with $\lambda > 550$ nm due to light absorption by a silicon substrate with subsequent redistribution of charge between Si and TiO₂.

The photoinduced hydrophilicity of films surface was of special interest. On TiO₂ films the effect of super-hydrophilicity was attained under UV irradiation, as well as under VIS one.

The effects associated with the gas phase are eliminated by the deposition of thin (2 nm) dielectric Al₂O₃ film on TiO₂. A thin layer of Al₂O₃ films was deposited on the TiO₂ film by ALD using trimethylaluminium and water as precursors. Such film protects the structure of TiO₂ film in course of heating and irradiation in vacuum or gas atmosphere. The photoelectrons tunnel through this Al₂O₃ film into the vacuum. Oxygen strongly changes the PES spectra of TiO₂ samples not covered with an Al₂O₃ layer but does not change the PES spectra of protected TiO₂ surface.

The obtained results indicate that the composite TiO₂/p-Si can be considered as a perspective photocatalyst for sunlight efficient photocatalytic systems, for a gas sensors and self-cleaning photocatalytic surfaces, in cases when TiO₂ surface contacts with the gas phase. In its turn the active TiO₂ film isolated from gas phase with a thin dielectric Al₂O₃ film may become an effective solar photoelectric or photo-electrochemical cell.

TF-P3-07

Effect of ZnSe quantum dots concentration on optical properties of poly (3-hexylthiophene) thin film by PDS technique

T14 Thin Films

#TF-P3-07

D. Loubiri.

Photothermal laboratory - Nabeul (Tunisia).

Synthesis and incorporation of nanocrystals (NC) offers several opportunities to exploit CNs for the development of next-generation hybrid organic / inorganic solar cells. Among the organic/inorganic hybrids system, the poly(3-hexylthiophene) (P3HT) is one of the most used conjugated polymers (CPs), for inorganic nanocrystals ZnSe quantum dots (QDs) are the most commonly investigated NCs because of their quantum-confined nature and well-matched energy level with P3HT. In this work the Photothermal Deflection Spectroscopy technique (PDS) is used to study the effect of the ZnSe quantum dots concentration in poly(3-hexylthiophene) matrix on optical properties. The optical absorption spectra and the band gap energy are obtained by comparing the experimental curves giving the normalized amplitude variations versus wavelength to the corresponding theoretical ones representing the normalized amplitude variations versus optical absorption coefficient.

Elaboration of iron cobaltite thin films by RF magnetron sputtering. Study of their spinodal decomposition

T14 Thin Films

#TF-3-Or-9

T. Bui, H. Le Trong, C. Bonningue, L. Presmanes, A. Barnabé, P. Tailhades.

Institut Carnot CIRIMAT CNRS - UPS - INP, Université Paul Sabatier 118 route de Narbonne, 31062 - Toulouse (France).

Iron cobaltite thin films with spinel structure were elaborated by radio frequency (RF) magnetron sputtering from a $\text{Co}_{1.73}\text{Fe}_{1.27}\text{O}_4$ target. The sputtering conditions (argon pressure and RF power) directly govern the reduction of deposited spinel phase. At a moderate fixed power, when argon pressure increases from 0.5 Pa to 1.5 Pa, the dominant deposited phase was changed from spinel phase (Sp) at 0.5 Pa to monoxide phase (MO) at 1.5 Pa (figure 1). At low pressure (0.5 Pa), the minor quantity of monoxide phase is also studied versus the RF power. After optimizing the sputtering conditions to obtain the nearly pure spinel phase, the films of about 300 nm thickness were deposited on Si (100) substrates (figure 2), then post annealed at 600°C to investigate the spinodal decomposition. On XRD spectrum of post annealed films, when processing time grows, the characteristic peaks of the initial spinel phase are progressively split into two peaks, corresponding to two phase (rich in Co phase and rich in Fe phase). This division demonstrates pertinently the spinodal decomposition, which was studied on iron cobaltite powder [1] and iron cobaltite thin films prepared by sol-gel deposition [2]. Changes in structure and microstructure, resulting from this transformation, are confirmed by Raman analysis and TEM images.

In recent years, research in carbon films has been focused to diamond thin film synthesis. Low background current and large potential window between oxygen and hydrogen evolution favor to use diamond films for the detection of a variety of analytes, including toxic heavy metals in the environment. Boron-doped diamond (BDD) is a promising material for various applications in electrochemistry. In search for alternative electrode materials, bismuth-film electrodes have been shown to offer comparable performance to mercury-film electrodes for anodic stripping voltammetric measurements of heavy metals. In this contribution, technological steps as a growth of intrinsic nanodiamond (i-NCD)/BDD double layer, electrode fabrication and electrochemical measurements on Zn, Pb and Cd are discussed. Electrochemical measurements were done by square-wave voltammetry (SWASV). During SWASV experiments in Pb(II), Cd(II) and Zn(II) solutions well-shaped stripping peaks were obtained whose heights varied linearly with analyte concentration in the range from 1×10^{-8} M to 3×10^{-7} M and detection limit ($3 \times \text{standard deviation/slope}$) and sensitivity for Zn, Cd, Pb with in-situ Bi electrochemical plating were detected. The results show that the nano-structured electrodes exhibit more than two times higher detection limit and sensitivity than non-structured BDD. Under optimal conditions detection limits for nano-structured BDD of 4.8×10^{-9} M, 3.7×10^{-9} M and 5.8×10^{-9} M were achieved for Pb(II), Cd(II) and Zn(II), respectively. Optimal concentration of Bi was 1×10^{-7} M.

Fig.1. SWASV curves for the stripping of $1-100 \times 10^{-9}$ M Zn, Cd, Pb with 1×10^{-7} M of Bi in solution of 0.1 M acetate buffer for a) None-structured, b) Nano-structured BDD.

Studies on Transparent Conducting Tin Oxide (SnO₂) Films Deposited by Thermal Evaporation

T14 Thin Films

#TF-4-Or-9

B. Beer Pal Singh, R. Rakesh Kumar, J. Jyotshana Gaur, R. Ramesh Chand Tyagi.

CCS University, Meerut - Meerut (India).

Thin films of metallic oxides like tin oxide, indium tin oxide (ITO), and zinc oxide exhibit electrical conductivity while being transparent in the visible region of the spectrum. Such transparent conductive oxides (TCO) coatings find wide spread use in electro-optical devices such as gas sensors, electroluminescent displays and solar cells etc where the transparency of electrical contacts is a vital requirement for device operation. The surface morphology, structural characteristics and optical properties of the Transparent conducting SnO₂ films deposited by vapor deposition of SnCl₂.2H₂O on heated glass substrate have been evaluated by XRD, SEM, EDAX analysis and spectro-photometric studies. The 'as deposited' films of tin oxide were found to be polycrystalline, adhesive and pin hole free. After annealing at a higher temperature these films exhibited an improved crystalline surface morphology and also displayed random perforations having a dendrite structure. It is found that heat treatment of the 'as deposited' tin oxide films results in conversion of the SnO component into SnO₂ phase which resulted in a better transparency, larger crystallite size, and reduced film thickness due to diffusion of tin into the matrix of the glass substrate thereby making the film more suitable for device application. The increased porosity of 'annealed' films provides more surface area for use as sensors and also makes them less likely to fracture when used as high temperature electrodes.

Batteries are crucial for electronic autonomous and portable devices. The size of these devices is a huge challenge, because the miniaturization is increasingly important [1]. The thin-film batteries allow a lighter and small package because no liquids or polymers are used. This technology also increase the safety because no leaking or explosion could occur and the energy density [2]. The thin-film batteries can be fabricated using only physical vapour deposition techniques [3]. A battery is composed by two current collectors, two electrodes and one electrolyte. The electrolyte is an electrical isolator and an ionic conductor to allow the lithium ions pass through it, but not the electrons. The electrolyte selected in this work was lithium phosphorous oxinitride, deposited by RF sputtering, previous reported by our group [4]. The positive electrode selected was lithium cobalt oxide (LiCoO₂). The positive electrode (cathode) is where reduction reactions occurs. The LiCoO₂ was deposited by RF sputtering with power source of 150 W, deposition pressure of 3×10⁻³ mbar, Ar flow of 40 sccm, a deposition rate of 3,2 Å/s and a thickness of 700 nm. An annealing of 2h at 650 °C in vacuum was performed for enhance the crystallization and consequently, the capacity of LiCoO₂ receive and deliver lithium ions. The oxidation reaction occurs in the negative electrode (anode). The metallic lithium was selected and fabricated by thermal evaporation, with 3 µm thickness. The cathode and anode current collectors were selected to ensure an excellent electrical conduction without reacting with the respective cathode and anode materials selected before. Platinum was selected for LiCoO₂ current collector and titanium for metallic Li current collector. Thin-film lithium battery materials were deposited and characterized in this work. The materials are deposited one after another till the battery is completed. The design for the battery is presented in figure 1 and materials indicated. This design is archived by using shadow masks during depositions.

Effect of Sputtering Pressure on mechanical properties in sputtered TiNi thin films

T14 Thin Films

#TF-9-Or-13

F. Meng ¹, Y. Li ², F. Lin ¹, W. Zheng ¹.

¹Jilin University - Changchun (China), ²Harbin Engineering University - Harbin (China).

Recently, shape memory alloys have attracted great attention [1]. It is a perfect micro-actuator candidate for the micro-electrical mechanical system, which require actuation and sensing mechanisms with high efficiency, thus the mechanical properties of films are concerned [2]. The TiNi films are deposited onto glass substrates by magnetron sputtering. The sputtering conditions are as follows: base pressure 4.0×10^{-4} Pa; argon pressure 6.0×10^{-2} Pa, 8.0×10^{-2} Pa and 10.0×10^{-2} Pa, respectively; sputtering power, 280 W; sputtering time: 4h; substrate to target distance, 60 mm. The NiTi films thickness is about $6 \mu\text{m}$. The films composition determined by energy dispersive X-ray spectroscopy is about Ti-51.17at.%Ni. The as-deposited film is treated at 798K for 1h. The microstructures of thin films are studied by the X-ray diffractometer with Cu K α radiation. The mechanical properties are studied by MTS IIXP Nano-Hardness Tester. From the X-ray diffraction (XRD) profiles of heat-treated films, it is seen that the peaks of austenite (B2), Ti₃Ni₄ precipitates and martensite (B19') appear in this figure. When the sputtering pressures are 6.0×10^{-2} Pa and 8.0×10^{-2} Pa, there are B2 phase and Ti₃Ni₄ precipitates. There are B2 and B19' phase with the sputtering pressures 10.0×10^{-2} Pa. The result is obtained the indentation hardness of TiNi film versus the displacement into surface under different sputtering pressures. The as-deposited TiNi films is amorphous, Ti₃Ni₄ precipitate appears at heat treatment process. The temperature of martensitic transformation increases with the increase of the sputtering pressure. The mechanical properties are relative to the conditions of the sputtering pressure.

Synthesis of functionalized graphene-based conductive thin films by microwave plasma-enhanced chemical vapor deposition

T14 Thin Films

#TF-P2-21

S. Mori, S. Kaneda, Y. Anekawa, A. Kameyama, M. Suzuki.

Tokyo Institute of Technology - Tokyo (Japan).

In this study, we synthesized functionalized graphene-based conductive thin films by microwave plasma-enhanced chemical vapor deposition in a CO/H₂/N₂ system. In our previous study, we could synthesize carbon nanowalls, which is micrometre-wide freestanding flakes consisting of stacked graphene layers, with very high growth rate. 1) The microwave plasma-enhanced CVD system is a modified ASTeX DPA25 plasma applicator in which the quartz discharge tube of a 15 mm inner diameter is utilized. Silicon single crystal wafers, quartz glass and stainless steel plates were used as substrates with a size of 10×10 mm² square. No catalyst materials were used in this study. The parameters of the CNWs deposition process were as follows: CO flow rate, 46 sccm; H₂ flow rate, 4 sccm; N₂ flow rate, 0-20 sccm; total pressure, 250 Pa; microwave power, 60 W. During the deposition, the substrate is placed at the center of the applicator and heated up by the microwave discharge. Substrate temperature was monitored by the radiation thermometer and was about 700 °C during the deposition. The functional groups in CNWs were evaluated by FTIR as shown in Fig. 1. The intensity of the infra-red absorbance peaks around 1000 to 1200 cm⁻¹ due to C-N stretching vibrations are gradually increased with an increase in nitrogen feed rates. Figure 2 shows SEM images of the CNWs with different nitrogen feed rates. As shown in Fig. 2, the increase in nitrogen feed rates makes the size of individual CNWs smaller. The spaces between the adjacent walls are diminished with increasing nitrogen partial pressure. The sheet resistance of functionalized CNWs thin films was measured with four-probe method with different N₂ flow rates. The applicability of the functionalized CNWs thin films on the counter electrodes in dye-sensitized solar cells is also discussed.

Tissue engineering has emerged as a solution in medicine due to the necessity of local rapid intervention with minimum damage for surrounding tissue and absence of organ implants. It consists in producing of biological structures that resemble closely with the in-vivo mechanical and structural properties of the tissues that have to be replaced. Reconstruction of new tissue via tissue engineering involves: (1) cells which are harvested and dissociated from the donor tissue; (2) materials used as scaffold substrates, where the cells are attached and cultured and (3) scaffolds biofunctionalization with growth factors which promote cell adhesion, proliferation, migration and differentiation [Khang G. et al, 2007].

In this paper deposition of biofunctionalized conducting polymeric thin films on tri-dimensional polymeric and metallic scaffolds is reported. For obtaining polymeric layers with controlled properties Matrix Assisted Pulsed Laser Evaporation (MAPLE) was used.

Polymeric tri-dimensional structures (scaffolds) were obtained by Laser Direct Writing via Multiphoton Absorption (LW-2PP) starting from a mixture containing aliphatic hybrid monomers, Tetrahydrofuran and photoinitiator. Metallic scaffolds were produced by laser irradiation of titanium target. For both experiments a Ti: Sapphire laser with 200 fs pulse duration and 2 kHz repetition rate, emitting at 775 nm was used. Then, the obtained structures were used as substrates for biofunctionalized conducting polymeric thin films blends deposition by Matrix Assisted Pulsed Laser Evaporation. In MAPLE the polymer to be deposited is dissolved in an appropriate solvent (0.1-2 wt % concentration) and frozen in a liquid nitrogen-cooled recipient, forming the frozen target. The frozen target is placed in a vacuum chamber and submitted to laser irradiation. During laser irradiation, the solvent vaporize, the polymer is transported by vapors and collected on the substrate in the form of a thin film while the volatile solvent is pumped away by the vacuum pumps. In the present

case, the receiving substrates will consist of the 3D constructs (inorganic hybrid polymers and 3 D patterned titanium. Desired properties of the polymeric coatings can be obtained by selecting laser fluence, number of laser pulses and composition of the frozen target. The conducting polymer chosen for coating the 3D constructs was polypyrrole (PPy). PPy is a suitable substrate for electrical manipulation of cells due to its environmental stability, lack of toxicity, excellent biocompatibility and low costs [Ahmed El-Said A. et al., 2010; Ateh D. D. et al., 2006]. The coating biofunctionalization was achieved by incorporation of biologically active agents within PPy coatings, using the unique capability of MAPLE to deposit in one step blends of polymers, proteins, drugs, etc. while keeping the functionality of each component [Piqué A. et al., 2002, Paun et al., 2010]. The as deposited structures were tested for their biocompatibility and stimulating tissue growth while inhibiting bacterial infections/inflammations.

TF-4-Or-1

A microstructural investigation of Zr-Cu thin films metallic glass (TFMG) deposited by magnetron sputtering

T14 Thin Films

#TF-4-Or-1

M. Apreutesei ¹, P. Steyer ¹, L. Joly-Pottuz ¹, A. Billard ², J. Qiao ¹, S. Cardinal ¹, F. Sanchette ³, J.M. Pelletier ¹, C. Esnouf ¹.

¹INSA de Lyon, MATEIS Laboratory - Villeurbanne (France), ²LERMPS-UTBM - Montebeliard (France), ³LASMIS, UTT - Nogent (France).

In the recent years, due to their homogeneity and no structural shape the metallic glasses (MGs) have been extensively studied in the bulk form. Their excellent proprieties at room temperature, especially high yield strength and corrosion/wear resistance together with the lack of grain boundary make them interesting structural materials for several applications [1].

The efforts devoted to the continuous development of such materials promoted the formation of thin films metallic glasses (TFMGs). So far, numerous TFMGs based on multicomponent alloys such as Zr-Cu-Al-Ni, Pd-Cu-Si were reported, while just a few are dealing with simple alloy systems [2].

In this study is attempted to form Zr-Cu (within 13 to 90 at% Cu) thin films metallic glasses (TFMGs) by a PVD magnetron co-sputtering method and to investigate their glass forming ability (GFA). The second objective is to perform a detailed microstructural and chemical investigation at the scale of SEM and TEM with emphasis on thermal and mechanical properties.

SEM images on cross-section revealed shear striations and partially vein pattern, implying the typical characteristic of the BMGs as it is presented in figure 1.

XRD analysis revealed that films are amorphous at room temperature within the (33, 85) at% Cu range detectable by XRD. Yet, after a deeper investigation using TEM for some of the as-deposited Zr-Cu thin films two types of features are observed: films are characterized by a fully amorphous structure, or composed of fine crystalline nanodomains embedded into a Zr-Cu amorphous matrix.

In situ XRD were performed under a helium atmosphere every 30°C from room temperature up to 600 °C in order to study the thermal stability of the disordered structure. The first traces of ZrO₂ oxides first appeared from 270°C. Further, the films

crystallize into nanocrystalline Cu₁₀Zr₇ and Cu₅₁Zr₁₄ phases upon exposure at temperatures above 350 °C.

The differential scanning calorimetry (DSC) was used to find out the crystallization parameters, namely T_g (glass transition temperature) and T_x (crystallization temperature) of the TFMG. The supercooled region (ΔT) was then found around 75K. The mechanical general mechanism that governs these films is essentially based on the fact that by increasing Cu content a denser atomic packing state is achieved leading to higher Young's modulus values. Young's modulus and hardness values of films, ranging from 100 to 110 GPa and 5 to 8 GPa are better than those of pure metals.

Titanium dioxide under anatase form is known to present very high photo active properties which can be exploited in several domains of energy and environment. In particular, anti bacterial surfaces can be obtained by deposited crystallized titanium dioxide. In this case, a UV irradiation is necessary to allow the photocatalytic destruction of bacteria. Another way to produce anti bacterial surfaces is to associate titanium dioxide with a noble metal such as Cu or Ag in a composite metal-oxide coating. For such coatings, the intrinsic anti bacterial activity of the noble metal dispersed in the ceramic matrix of titanium dioxide allows the destruction of bacteria even in absence of UV irradiation.

This paper deals with the deposition of composite TiO₂-Cu coatings synthesized by co sputtering of Ti and Cu targets in the presence of reactive Ar-O₂ gas mixtures. In order to allow the full oxidation of titanium while limiting that of Cu, the coatings are deposited using plasma emission monitoring (PEM). After a description of the deposition vessel including the closed loop control PEM system, we investigate the setpoint to be monitored to produce stoichiometric titanium dioxide for different Ar pressures. Hence, the Cu enrichment is studied as a function of the discharge current dissipated on the Cu target for two setpoints yielding stoichiometric and slightly sub stoichiometric titanium dioxide and for different pressures. A special attention will be paid to the amount of copper oxide resulting from these different deposition conditions. In all cases, the structural, chemical and morphological characterizations of the coatings are performed. Finally, some specific formulations of composite TiO₂-Cu coatings are selected and their performance as anti bacterial coatings are investigated using two model bacteria : Escherichia Coli and Staphylococcus Aureus.

ZnO-Ag composite by reactive magnetron co-sputtering: structural and morphological characterisations

T14 Thin Films

#TF-P2-40

R. Francq ¹, A. El Mel ², P.A. Cormier ², R. Snyders ¹.

¹University of Mons - Materia Nova R&D Center - Mons (Belgium), ²University of Mons - Mons (Belgium).

Nowadays, zinc oxide (ZnO) is extensively used as a semi-conductor for gas sensor or solar cell applications. It is accepted that doping ZnO films with Ag is a potential strategy to enhance its photocatalytic and antibacterial activities. Therefore, the controlled synthesis of ZnO-Ag thin films is of particular interest for medical use or for waste water purification. Nowadays, ZnO-Ag thin films are generally synthesized by wet chemistry methods (co-precipitation, sol-gel, hydrothermal, flame spray pyrolysis and electro-spinning) often using toxic solvents. Therefore, the development of less pollutant techniques would be of great interest for a large scale development of such a kind of coatings.

In this work, reactive magnetron co-sputtering is chosen as an efficient method to grow ZnO-Ag thin films. This approach allows a fine tuning of the the cristalline structure, morphology and stoichiometry of the films which are the main criteria defining the efficiency of the material in a given application. Our goal is to investigate the correlation between the experimental parameters of our process (applied power, pressure, target to substrate distance, oxygen flow rate) with the composition and the microstructure of the grown films. In addition their photocatalytic activity is evaluated. The deposited films are characterized in terms of phase constitution (X-ray diffraction), microstructure (scanning electron microscopy), and chemistry (X-ray photoelectron spectroscopy).

The label-free detection using chemically modified nanopores is an emerging research field. Nanopore technique is a promising way for very low concentrated molecule sensing. It has a unique property to electrically detect single molecule. Indeed, biological molecules are electrokinetically driven through a nanopore by an externally applied electric field. This results in a characteristic obstruction of the ionic current across the pore. When the nanopore is functionalized with bioreceptors, information on interactions with biomolecules can be extracted. To ensure the most sensitive detection to a biomarker, an anti-fouling layer should coat the outer surface of the nanopore while the coupling chemistry to immobilize bioreceptors is deposited inside the cavity. In this study, different organosilane based coatings were evaluated for antifouling or bioreceptors grafting. Coatings were characterized by static contact angle, streaming-current zeta potential measurements, Surface-Enhanced Ellipsometric Contrast optical technique, and fluorescence imaging. Effects of activation and functionalization processes on SiO₂ and SiN_x membranes were studied and characterized by Atomic Force Microscopy. As a proof of concept, the surfaces were chemically patterned by lithography technique to demonstrate the compatibility between antifouling chemistry and grafting chemistry. Then a process was developed allowing to sequentially functionalise the outer surface, and then after drilling, the inner surface of nanopores. The antibody immobilization was demonstrated by fluorescence imaging and characterized by Scanning Electronic Microscopy. The preliminary tests are very promising and show that while the control probes practically do not bind cTnI in the nanopores, in the antibody modified nanopores the cTnI binding causes a significant decrease in the trans-pore ion flux. The first results indicate a 10ng/mL cardiac Troponin I detection.

Physical Properties of Reactive RF Magnetron Sputtered Silicon Dioxide Thin Films

T14 Thin Films

#TF/SE-P3-04

F. Cioldin, I. Doi, M.V.P. Dos Santos, J.A. Diniz, E.A. Zambotti, J. Godoy Filho.

University of Campinas - Campinas (Brazil).

In this work physical properties of silicon dioxide (SiO_2) thin films deposited by reactive RF Magnetron Sputtering were studied using different characterization techniques, such as ellipsometry (refractive index and thickness), scanning profiler (thickness), BHF etching (layer quality), infrared spectra (chemical bonds), and Raman Spectroscopy (composition). MOS capacitors were also fabricated to evaluate defects and dielectric constant of these films. The samples were obtained using silicon target (99.999%) in an Ar/O_2 ambient, at deposition pressure of 4-10 mTorr and 200-300 W of sputtering power. The gas flow ratio was changed in the range of 60-100 sccm (Ar) and 12-20 sccm (O_2). The deposition rate as shown Figure 1a it increases with the discharge power and decreases as the total gas ratio is increased. The refractive index of the samples varied from 1.461 to 1.476. The Infrared spectra, Figure 1b, shows the Si-O-Si vibrational band peak around 1072 cm^{-1} and 820 cm^{-1} , corresponding to the stretching and bending mode, which agree well with the band positions of Si-O reported in the literature of the RF sputtered SiO_2 films. No significant changes in IR spectra of the films were observed due to the variations in the deposition pressure. Also no absorption bands in the range of $3300 - 3650\text{ cm}^{-1}$ were observed, corresponding to SiOH group and absorbed water, which indicates low porosity of the obtained SiO_2 films. The Raman spectra showed the SiO_x peak at 193 cm^{-1} and 432 cm^{-1} , for the obtained samples, and that the first band becomes broader with the increase of the Si concentration in the films. Silicon dioxide with thermal grown SiO_2 quality may be obtained by reactive RF sputtering, for instances with 80/16 Ar/O_2 gas ratio, at deposition pressure of 4mTorr and 300 W sputtering power, with relatively high deposition rate of 4.6 nm/min with refractive index and Si/O ratio near to the stoichiometric value.

Figure 1 – (a) Deposition rate and Refractive index x Ar/O₂ Flow. (b) Infrared spectra showing the Si-O bonding.

It yielded that cutting tools are subjected to extreme conditions of temperature, wear, mechanical and friction. Even more, high mechanical stresses are applied on the tools used in aggressive environments and high temperatures. Considering these extreme industrial requirements, alternative solutions had to be developed. Ceramic nitride based coatings could give new functionalities and improve the tools' surface. Their purpose is to increase the lifetime and high oxidation resistance. Recently, new protective materials able to meet these requirements have been proposed, such as Al-Cr-N based coating. A further improvement was obtained by incorporation of yttrium in this system, its beneficial effect being evidenced mainly at high temperature conditions.

This study aims to investigate the oxidation behavior and thermal stability of CrN and AlCrN coatings. Moreover, the effect of yttrium addition on arc evaporated AlCrN coating with emphasis on high temperature behavior is highlighted. Three different coatings of approximately 3 μm thick (CrN, AlCrN and AlCrYN) were deposited on various substrates (M2 steel, Si, glass) in an industrial reactor.

The comparative study of oxidation behavior was performed by thermogravimetric analysis in dry air at selected temperatures from 750 to 950 °C. Thermograms reveal a parabolic evolution of mass gain, suggesting an oxidation process limited by the transport of species. The surface morphology and microstructure of films, oxidized or not, were characterized by means of scanning electron microscopy (SEM), energy

dispersive X-ray analysis (EDX) and transmission electron microscope (TEM). Moreover, films oxidation was observed in real-time at a microscopic scale using a SEM operating in an environmental mode. In situ XRD were performed under protective atmosphere every 30°C from room temperature up to 1000 °C in order to study their thermal stability.

Surface defects density was quantitatively measured by an electrochemical method and was found to be lower than 1% for Y containing films and 0.25 % for Y-free films, respectively.

Films are characterized by a fine grained structure of about 25 nm. Therefore, the aluminum addition into CrN induces a beneficial effect on the thermal stability of the microstructure. At moderate temperature range (800 – 850 °C) oxidation behavior is mainly governed by the intrinsic morphology of the films, while at higher temperatures (950 °C) the beneficial effect of film's composition is emphasized. The oxidation performance of AlCrN films is considerably improved by Y incorporation due to formation of Y₂O₃ phases dispersed into the coating which promote the oxide layer adhesion and hinders grain coarsening.

TiN is historically one of the most employed coatings in the industry for different applications such as cutting tools, dies, bearings, anti-erosion components, etc.

With the aim of enhancing the mechanical properties of titanium nitride, two main ways can be involved. Firstly, a third chemical element, i.e. aluminum, was added to deposit TiAlN coatings with improved mechanical properties and oxidation resistance. Secondly, nano-layered TiN/TiAlN coatings were synthesized in order to enhance their hardness and their tribological behaviour.

Another way to manage properties of nitride coatings is the control of their intrinsic stress. The possibility of controlling the average energy per impinging atoms is the main way to reach this goal. This can be done using highly ionized discharges.

In this study, a comparison between the emerging HiPIMS (High-Power Impulsed Magnetron Sputtering) and the cathodic arc deposition process was performed owing to the deposition of TiN, TiAlN as TiN/TiAlN nanolayers coatings with different periods.

Structural, chemical and morphological characterization of the coatings was systematically performed using X-Ray Diffraction (XRD), X-Ray Energy Dispersive Spectroscopy (EDS), Glow Discharge Emission Spectroscopy (GDOES) and Scanning Electron Microscopy (SEM). The mechanical (Daimler-Benz Indentation Test, micro and nano-hardness) and tribological (pin on disc) characterizations were also realized on the different architectures obtained with both processes to allow the comparison of these two processing routes owing the performance of TiN based nanostructured coatings.

**LSPM-CNRS, Laboratoire des Sciences des Procédés et des Matériaux,
Université Paris 13, Sorbonne Paris Cité - Villetaneuse (France).**

Because of its excellent physical properties and potential technological applications, zinc oxide (ZnO) has recently attracted a lot of attention. In this work, we present the characteristics of ZnO thin films deposited by Spray Plasma device [1,2]. In this process, fine droplets of an aqueous solution of zinc nitrate/chloride/acetate produced in an ultrasonic sprayer, are injected in a low pressure RF inductively coupled Argon/Oxygen plasma. The reactivity of non-thermal plasmas permits the transformation of these salts to zinc oxides. The films were deposited on glass substrate at 200°C. The effect of zinc nitrate and zinc chloride solution, and oxygen ratio in the plasma gas on the structural and optical properties of the deposited films was investigated by X-ray diffraction, atomic force microscopy, transmission electron microscopy and Uv-Vis spectroscopy. Crystallite's size was estimated using Sherrer and Williamson-Hall [3] methods and then compared with TEM images. The results show that nanostructured polycrystalline thin layers are formed with the typical wurtzite structure and a preferred c-axis orientation for the two used solutions (Figure 1). The values of average grain size obtained from the XRD were less similar than those obtained from TEM images, implying the inclusion of strain in the deposited films. The best c-axis orientation and the best transmittance in visible range (80%) were obtained with 5% O₂ in the plasma gas. Radical oxygen emission bands were observed by optical emission spectroscopy indicating that the concentration of oxygen radicals increases first with increasing O₂ ratio in argon plasma until 10% and then decreases. These results confirm that the O radicals concentrations influence the direction of crystal growth.

Ceramic coatings are used extensively in industrial applications mostly to reduce wear on engine and machine components. Large residual stresses develop in coating films due to intrinsic stress or thermal stress produced by a mismatch between the thermal contractions of the film and the substrate, or as a result of other reasons. It is important to elucidate the factors that generate residual stresses in the film since residual stresses exert a strong influence on the mechanical properties of the coated material.

The aim of the present work is to investigate the effect of films thickness on residual stress, resistivity and microstructure. Deposits Cr, Ti-N, Cr-N, Ti-Al, Ti-Si-N and Mo-Cr-N are thus produced by PVD on silicon substrates. The determination of residual stresses and resistivity was made using the devices of "Newton Rings" and "four-point probe", respectively. The compressive stress reaches a peak value of about 5GPa. This stress peak appears to thickness ranging from 200 to 300 nm. . The effect of film thickness has also been highlighted on the resistivity of chromium films. There is a correlation between the variation of the stress, the resistivity and the phenomenon of thin film growth. Stress has also been studied for Mo-Cr-N and Ti-Si-N films.

Words - key: *PVD hard coatings, residual stress, resistivity.*

TF-5-Or-4

Growth of diamond films and other carbon allotropes by surface wave plasma over large areas

T14 Thin Films

#TF-5-Or-4

A. Kromka, O. Babchenko, S. Potocky, B. Rezek.

Institute of Physics AS CR, v.v.i. - Prague (Czech republic).

Attractiveness of carbon-based allotropes (e.g. graphene, fullerenes, carbon nanotubes – CNT, diamond, etc.) reached extremely large interest in nanotechnologically oriented community due to their wide range of applications as smart-multifunctional materials. At the same time, microwave plasma chemical vapour deposition (CVD) techniques have reached outstanding designs which make the growth of CNTs or diamond thin films realistic for industrial uses. Surface wave plasma in the linear antenna configuration is one of the most attractive solution due to scale up capability to large areas (500x500 cm² and larger) [1].

Here we will present the influence of process parameters (temperature, gas composition, total pressure, etc.) on the growth of diamond thin films by modified large area linear antenna microwave plasma CVD process from CO₂ containing gas mixtures [2]. Adding CO₂ facilitates the grain enlargement and improves the film quality as evidenced by electron microscopy and Raman spectroscopy. Next, gas pressure is identified as a crucial process parameter influencing the crystalline character of diamond films. Decrease from 200 to 6 Pa results in enlargement of diamond grains from nanoscale (<20 nm) to polycrystalline character (grain size 500 nm at 570 nm thickness). This result is partially in contrast to other work, where a formation of nano-sized diamond crystals dominated the process due to spontaneous gas phase nucleation [3]. Our growth phenomena are attributed to plasma expansion and change in plasma chemistry (i.e. hydrogen-rich plasma chemistry). The proposed growth model is supported by photographs and optical emission spectra of plasma.

Moreover, we will show that induced surface conductivity of intrinsic diamond thin films due to hydrogen termination can be achieved either by the diamond re-growth in focused plasma or by the CVD growth in linear antenna microwave CVD at lower CO₂ (<5%) [4]. A functional solution-gated FET device based on diamond thin films grown by modified large area linear antenna microwave plasma CVD process.

The modified low pressure linear antenna microwave plasma process will be pointed as a challenging technology which expands the family of diamond uses in i) diamond-based optical elements for effective detection of adsorbed or grafted molecules, ii) the low temperature hydrogen termination (250°C) of diamond films and SGFET devices and iii) the growth of carbon nanotubes and/or carbon nano-sheets. This research was financially supported by the projects P108/12/G108 (GACR), TA01011740 and by the Fellowship J.E. Purkyne. This work occurred in frame of the LNSM infrastructure.

Silicon nanoparticle formation from silicon rich SiO₂ thin films has been investigated as a function of deposition technique, as well as deposition and annealing temperature. The substrate was monocrystalline silicon and annealing was carried out in forming gas. Rotation of the Si substrate during evaporation ensured homogeneity of the films over the whole substrate. Formation of nanoparticles of different sizes after annealing at various temperatures up to 1100 °C was followed by grazing-incidence small-angle X-ray scattering (GISAXS). We have found that significant concentration of 2-3 nm sized particles is established already at 900 °C. The size distribution is broadening with the increment of the annealing temperatures, while the average sizes do not increase substantially. Photo luminescence measurements confirmed nanoparticle photo activity after passivization in hydrogen.

The nano-structural Bi-doped ZnO thin films deposited on glass substrate were successfully fabricated at substrate temperature of 350 °C by an inexpensive spray pyrolysis method. The structural, electrical, optical and photoluminescence properties and the morphology of the surface of films were investigated. X-ray diffraction study revealed the crystalline wurtzite (hexagonal) structure of the films and (100) preferential orientation. The spectral transmittance of all films was higher than 80% and so the doping has no effect on this optical property. The optical band gap energy varies between the value 3.19 eV to 3.24 eV. narrow and broad characteristic photoluminescence peaks emerged. The morphology of surface films was thoroughly rough.

Crystal structure and morphology of tungsten (W) thin films, prepared by magnetron sputtering, were studied by grazing incidence x-ray diffraction and small angle x-ray scattering, x-ray reflectivity, and scanning electron microscopy with compositional analysis. Coexistence of two crystalline phases, α -W and β -W, and formation of amorphous phase (a-W) were observed for various Ar pressures (2-20 mTorr), and flow rates controlled by the applied power (10-90 watt)[1]. Depositions at low Ar pressures (< 5 mTorr) and high powers (> 40 watt) result in compact and smooth layers of crystalline α -W phase only. By reducing the sputtering power (20 watt), along with stable α -W, a metastable β -W phase occurs. For even lower power (10 watt), W film becomes amorphous and exhibits a columnar morphology, like in Fig.1, accompanied with a 25% reduced layer's mass density compared to that of the bulk tungsten [2]. A similar columnar morphology was found also for films deposited at higher Ar pressures (> 5 mTorr), and moderate sputtering power of 20 watt; the columns in high pressure films consist of β -W phase. The columns diameter in the amorphous phase was 3 nm, while for β -W phase the average columns size was 4-6 nm[2]. Columnar aggregations were revealed at wide scale of correlation lengths: up to 10^3 nm (Fig.1.). The highest mass density reduction, of up to 50%, was observed for highest pressure of 20 mTorr. Morphology of W films deposited at high Ar pressures was depth dependent with smaller columns (and inter-columnar voids) closer to the Si substrate. In the amorphous film one observed top surface layer of 3.5 nm which could be attributed to the oxygen rich W or WO_3 phase. The appearance of β -W phase is related to the lowered flux of W atoms, increased film porosity, and correspondingly to the higher probability of oxygen incorporation.

Dual Sensor-based Process Control for High Rate Reactive Zirconium and Hafnium Oxide Sputtering

T14 Thin Films

#TF-3-Or-13

M. Audronis ¹, K. Juskevicius ², R. Drazdys ², A. Matthews ¹.

¹The University of Sheffield - Sheffield (United Kingdom), ²Center for Physical Sciences and Technology - Vilnius (Lithuania).

Zirconia and Hafnia films are often used in multilayer coatings for advanced optical components, such as filters, beam splitters and polarisers. The laser industry has high specification requirements for these components in terms of the laser induced damage threshold. As low extinction as possible in the UV spectral range is highly desirable and significant efforts are spent to advance coating properties on this front. High deposition rate at room temperature (i.e. with no external heating) is also very much sought.

Voltage feedback-based gas flow control is one of the most economical methods to regulate reactive processes and deposit good quality zirconia and hafnia at high rates. It is however very difficult to perform due to multiple transitions in the sensor signal. In this paper we describe a reactive magnetron sputtering technology that exploits the target voltage signal to the full extent yielding a superior deposition process. Zr and Hf oxide films were produced employing a dual sensor-based process control method. We show that the use of this technology can result in improved optical properties, including absorption in the UV spectral range. High quality zirconia and hafnia films at high deposition rates with no external substrate heating were produced. Optical coated sample properties as well as some structural and surface morphology effects were examined and are reported in this paper.

Influence of nitrogen content on CrSiN thin film properties deposited by reactive HiPIMS

T14 Thin Films

#SE-1-Or-13

A. Ferrec, J. Keraudy, F. Schuster, P.Y. Jouan, M.A. Djouadi.

Institut des Matériaux Jean Rouxel (IMN) - Nantes (France).

Although transitional metal nitride films, such as CrN and TiN, have attracted a lot of interests due to the high hardness, high melting point and high chemical stability, their potential applications are limited, especially at high temperature. Recently, many researchers have focused on the development of complex hard film materials such as TiSiN, CrSiN, ZrSiN, nanocomposite films.

It has been proved that the reactive HiPIMS deposition technique enhance the adhesion, the crystallinity and the hardness of the films.

Here, we have have studied the influence of nitrogen content on the CrSiN thin film characteristics and their oxidation behaviour. The CrSiN were deposited using HiPIMS generator (HIP3 Solvix 5K) at floating potential without heating during deposition. The on-time was set at 30 μ s and the frequency was 1000Hz. To obtain films with the same thickness, deposition time was adjusted with nitrogen content injected in the gas mixture. CrSiN thin films have been characterized by XRD, SEM and XPS.

CONTAMINATION CONTROL IN ION BEAM SPUTTER DEPOSITED FILMS

T14 Thin Films

#TF-P1-06

D. Pearson.

Oxford Plasma Technology - Bristol (United kingdom).

Ion beam sputter deposition is used in a wide variety of applications where precision film control and high quality, high performance layer materials are required. However, one of the difficulties of sputtering a target material with an ion beam is the control of the beam shape and collimation so as to avoid any energetic ions following trajectories whereby they could sputter other materials than the desired target material (e.g. from the surrounding furniture and fixtures); this results in a potential contamination of the depositing film with impurity material. The effect of this on the performance of the deposited film will depend on the particular application targeted, on the levels of impurities and on the nature of the impurities.

The conventional wisdom to guarantee high purity thin films in IBD has been to use a large vacuum chamber. The chamber size was important to minimise the effect of reflected high energy particles from the target surface sputtering chamber materials onto the substrate and to allow the use of large targets to avoid beam overspill onto chamber furniture: for example, chambers in excess of 1m³ have been used for the deposition of low loss dielectric mirrors. An improved understanding of beam trajectories and re-sputtered material paths has allowed the deposition of thin films with very low metallic impurity content in a chamber volume below 0.5 m³.

Thus, by optimizing the sputter ion source, target and substrate configuration, and by arranging suitable shielding made of an appropriate material in the process chamber, the levels of contaminants in the deposited films have been reduced to a minimum.

With this optimum hardware arrangement, the ion beam process parameters were then optimized with respect to the ppm levels of contaminants measured in the films by SIMS analysis.

Using the deposition of SiO₂ as a standard material for SIMS composition analysis and impurity level determination, it has been shown that our IBS deposition tool is capable of depositing films with contamination levels of <50ppm for the total of all metal impurities in the deposited films.

SELF-ASSEMBLY OF SEMICONDUCTOR QUANTUM DOTS IN AMORPHOUS DIELECTRIC MATRICES

T14 Thin Films

#TF-4-In-2

M. Buljan.

Ruđer Bošković Institute - Zagreb (Croatia).

Three-dimensional semiconductor quantum dot lattices embedded in dielectric amorphous matrices are increasingly important in various nanotechnology applications. Two simple methods based on self-assembly have recently been developed for controlled preparation of such materials: Self-assembled growth of quantum dots during magnetron sputtering codeposition, and ion-beam irradiation of initially amorphous, semiconductor-rich multilayer films.

Both methods yield various three-dimensional quantum dot lattices, differing by the type of spatial ordering, matrix and quantum dots chemical and phase composition, QD's separation, shape, and size distribution. The prepared materials exhibit very interesting size- and ordering- dependent physical properties, with large potential for various applications.

PST/SE/TF-2-In-1 NANOSCIENCE WITH PLASMAS IN LIQUIDS: DIVING INTO THE UNKNOWN

T14 Thin Films

#PST/SE/TF-2-In-1

T. Belmonte.

Institut Jean Lamour - Nancy (France).

Plasmas in liquids are an excellent way to produce large amounts of nanoparticles. Yields are usually expressed in grams per hour. Furthermore, these nanoparticles are trapped in the liquid phase, which makes them innocuous. Many different processes have been developed, showing pros and cons. However, very little is known about the possible mechanisms leading to the synthesis of nanoparticles. Understanding basic mechanisms would help a lot and processes could be controlled much better than they are today. We shall take stock of the current state in the typical example of nanocarbons. While similar energies can be dissipated in different liquids and electrodes arrangements, nanostructures span a wide range of compositions, shapes and sizes. Thus, it is possible to get nanoparticles, nanotubes, nanooxions and even nanohorns. The production of nanodiamonds (sometimes called UDDs for Ultrafine-Dispersed Diamonds) by plasmas in liquids will be evoked specifically. Results of time-resolved optical emission spectroscopy combined with ICCD imaging of nanosecond-pulsed plasmas will be given to describe important physical and chemical features of plasmas in liquids. Finally, we shall show how to organize nanoparticles into larger structures by controlling intense electric fields.

#TF-1-Kn-1

L. Cohen.

Imperial College London - London (United kingdom).

Magnetic materials play an increasingly important role in our society. Over the last few years the group at Imperial College have built up a suite of novel characterisation tools to study the important physics properties of technologically important magnetic materials. In this talk I will give examples of the use of these tools for the study of spintronic materials, magnetocaloric materials and nanomagnetic artificial spin ice.

TF-1-In-1 GAS PULSING AND OBLIQUE ANGLE DEPOSITION FOR STRUCTURING OF THIN FILMS

T14 Thin Films

#TF-1-In-1

N. Martin.

**Institut FEMTO-ST CNRS UMR 6174, Université de Franche-Comté, ENSMM,
UTBM - Besancon (France).**

Structuring of thin solid films at the micro- and nano-scale is presently one of the most exciting challenges of materials science. I will show various architectures of thin films sputter deposited by RGPP (Reactive Gas Pulsing Process) and oblique angle deposition techniques. The first approach enables an adjustment of the composition and structure (homogeneous or periodic multilayers). The second one plays on the incidence of the particle flux to design the morphology. Both approaches impact on the structuring of the films leading to broaden the range of physical properties compared to the conventional methods. I will present a non-exhaustive analysis of optical, electrical and mechanical characteristics of such films and, in the end, emphasis will be on the RGPP+GLAD combination.

Solid state wetting on nano-pillar arrays : dynamics and elasticity effects

T14 Thin Films

#TF-P1-05

M. Ignacio ¹, P. Smereka ², Y. Saito ³, O. Pierre-Louis ¹.

¹Institut Lumiere Matière, Université de Lyon, UMR5306 Université Lyon 1-CNRS - Villeurbanne (France), ²Univ. Michigan - Ann-Harbor (United states), ³Keio University - Yokohama (Japan).

A challenging perspective in heteroepitaxial growth is to use nanostructured substrates in order to obtain defect free crystals. Several experimental groups have indeed deposited GaN on Si substrates with nano-pores [1] or nano-pillars [2]. These authors showed that (i) islands can stay at the top of nanostructures – with void underneath, and (ii) the density of threading dislocations due to the lattice mismatch can be significantly reduced. These results may have a broad range of applications in optoelectronics.

In this context, we study the morphology and the dynamical evolution of a single crystalline nanoparticle in interaction with an array of nano-pillars [3], using both kinetic Monte Carlo simulations and analytical calculations. Solid islands exhibit several stable or metastable states. Some of these states are already known from the analogy to the literature on liquid-state wetting, such as the Cassie-Baxter (or Lotus) state where the island sits on top of the pillars, the Wenzel state where the island is impaled in the pillars.

We have determined the thresholds of stability of the Cassie-Baxter state depending on the system geometry, and on a parameter called the wettability, which accounts for the wetting properties of the crystal. When the wettability is large enough, the crystal collapses along the pillar until it reaches the base of the pillars. We demonstrate that the collapse dynamics can be decomposed in two phases: a deterministic impalement followed by Brownian motion along the pillar. We show that the dynamics can be controlled either by adatom surface diffusion or by two dimensional nucleation on facets.

Finally, we discuss the consequence of elastic strain induced by a lattice mismatch at

the interface. Elasticity increases the stability of the Cassie-Baxter state. We also find a novel state where the island is partially impaled [4].

TF-7-In-1

LiCoO₂ THIN FILMS: TOWARDS NEW REWRITABLE MEDIA

T14 Thin Films

#TF-7-In-1

I.J. Giapintzakis.

Nanotechnology Research Center and Department of Mechanical & Manufacturing Engineering, University of Cyprus - Nicosia (Cyprus).

Successful integration of oxide thin films in the integrated circuits (ICs) industry could have a major impact in a wide range of applications, such as data storage, spintronics etc. LiCoO₂ (LCO) is a two-dimensional layered compound, which is commonly used as a cathode electrode in rechargeable Li-ion batteries. LCO's interesting electrochemical properties are attributed to redox reactions involving the cobalt-oxygen layers and the intercalation and de-intercalation of Li ions. The growth of high quality epitaxial LCO films on technologically important substrates has been scarcely addressed. This presentation will provide an overview of recent studies designed to explore fundamental aspects of LCO thin film growth by pulsed laser deposition (PLD) as well as the suitability of these LCO thin films as a rewritable media in non-volatile memory applications.

TF-6-In-1

THE IMPACT OF DISORDER ON TRANSPORT IN CRYSTALLINE PHASE CHANGE MATERIALS

T14 Thin Films

#TF-6-In-1

M. Wuttig.

RWTH Aachen University of Technology - Aachen (Germany).

Understanding charge transport in phase change materials is crucial to extend the application range of these exciting materials. The reduction of drift, i.e. the increase of the resistivity of the amorphous phase with time, for example, would facilitate the development of multilevel memories. Tailoring the resistance of the crystalline state could help in reducing the power consumption upon amorphization. With this goal in mind we have studied the resistivity of crystalline phase change materials. A pronounced dependence of the room temperature resistivity upon annealing temperature is observed for crystalline phase change materials such as $\text{Ge}_1\text{Sb}_2\text{Te}_4$ or $\text{Ge}_2\text{Sb}_2\text{Te}_5$. This finding is corroborated by low temperature measurements as well as FTIR data, which confirm that a metal – insulator transition is observed without a change in crystallographic state. This is indicative for an electronically driven MIT [1].

Such an MIT can be achieved if the electron correlation exceeds a critical value (Mott MIT). A second route to insulating behavior has been identified by Anderson, who showed that increasing disorder turns a metal with delocalized electronic states at the Fermi energy into an insulator with localized states. In this talk, arguments for a disorder induced localization of charge carriers will be presented. The observations are compared with doped semiconductors such as Si:P, where both disorder and correlations are crucial to describe the charge transport. Experimental and theoretical attempts to unravel the origin of disorder induced localization will be presented. These calculations reveal that it is the ordering of vacancies into vacancy layers which drives the transition to the metallic state [2]. The potential of this remarkable impact of disorder for applications as well as our fundamental understanding of solids is discussed.

CHALLENGING OF THIN FILM PROPERTIES FOR MAGNETIC RECORDING AT ULTRA-HIGH STORAGE DENSITIES

T14 Thin Films

#TF-8-In-1

D. Suess.

Institute of Solid State Physics, University of Technology - Wien (Austria).

Hard disk media that support high storage densities require small grains in order to obtain high signal to noise ratios. The use of high coercive materials such as alloys in the L10 phase allow for thermally stable grains at grain diameters in the order of 4nm . However state of the art write heads produce too small fields to reverse these extremely hard magnetic grains. Recently composite media and exchange spring media were proposed in order to decrease the write field requirements. In exchange spring media an ultra-hard magnetic storage layer is strongly exchange coupled to softer magnetic layers. It is shown that in exchange spring media the switching field can be completely decoupled from the thermal stability. The high coercive materials can be switched with low fields

Another possibility to write on high coercive materials is to locally heat the media with a laser pulse, known as heat assisted magnetic recording. As a consequence of the heating at temperatures close to the Curie temperature the coercivity significantly decreases and the grain can be reversed. However, errors due to high temperature are introduced. The use of composite media will be presented which allows decreasing these thermal errors.

E.M.C. Fortunato, P. Barquinha, L. Pereira, R. Martins.

CENIMAT/I3N Departamento de Ciência dos Materiais, Faculdade de Ciências e Tecnologia, FCT, Universidade Nova de Lisboa and CEMOP-UNINOVA - Caparica (Portugal).

Transparent electronics has arrived and is contributing for generating a free real state electronics that is able to add new electronic functionalities onto surfaces, which currently are not used in this manner and where silicon cannot contribute [1,2]. The already high performance developed n- and p-type TFTs have been processed by physical vapour deposition (PVD) techniques like rf magnetron sputtering at room temperature which is already compatible with the use of low cost and flexible substrates (polymers, cellulose paper, among others). Besides that a tremendous development is coming through solution-based technologies very exciting for ink-jet printing, where the theoretical limitations are becoming practical evidences. In this paper we will review some of the most promising new technologies for n- and p-type thin film transistors based on oxide semiconductors and its currently and future applications.

Outgassing of Materials Stimulated by Mechanical Stress and Rubbing

T15 Vacuum Science and Technology

#VST-5-Or-14

R. Nevshupa ¹, E. Roman ², J.L. De Segovia ².

¹IETCC-CSIC - Madrid (Spain), ²ICMM-CSIC - Madrid (Spain).

Mechanical elements of ultrahigh vacuum technological equipment, drives and manipulators of space systems may produce significant contamination of ultrahigh vacuum due to emission of gases from materials under stress and rubbing. Composition of emitted gases and behaviour of gas emission were studied for various materials including metals (Fe, Ni, steel, Ti, Ta, elastomers) and surface coatings (amorphous carbon, TiN, Mg, MgH₂, etc.). Various behavior scenarios of mechanically stimulated gas emission which can be ascribed to different physico-chemical mechanisms were identified depending on the type of the material subjected to rubbing and the emitted gas. The hypothesis of thermal desorption due to frictional heating was confidently ruled out. Alternative models of mechanically stimulated gas emission were suggested and discussed.

VST-P2-01

The generalized Hobson-Welch model - Calculation of the propagation behavior of leak induced-pressure gradients in cryogenically cooled accelerator beam pipes

T15 Vacuum Science and Technology

#VST-P2-01

S. Wilfert.

GSI Helmholtzzentrum für Schwerionenforschung - Darmstadt (Germany).

The occurrence of He leaks in cryogenically-cooled vacuum systems of accelerators can cause fatal problems. In consequence of the pumping action of the cold walls and due to a lack of suitable pressure measuring instrumentation, local pressure gradients can be built up without being detected for a long time. Such leak-triggered pressure gradients may not only cause premature beam losses, but also even to quenches of superconducting magnets. The currently only method for calculating time-dependent longitudinal pressure profiles in cryogenically cooled accelerator beam pipes with wall-pumping is described in a theory developed by Hobson and Welch [1,2]. This model predicts the built up of a local high pressure gradient and its strongly delayed propagation in a long, cooled tube in the presence of external H₂ or He loads. The experimentally confirmed model is, however, only applicable to cryogenic vacuum tubes with circular cross section.

The poster presents the extension of Hobson-Welch formalism to the application of cryogenic beam tubes with arbitrary cross-sectional shape. Based on experimental study using a cryogenic beam tube with elliptical cross section, the validity of the generalized Hobson-Welch model is demonstrated successfully.

Transient thermo-molecular pressure difference in a long tube

T15 Vacuum Science and Technology

#VST-7-Or-1

I. Graur ¹, F. Sharipov ².

¹Aix Marseille University - Marseille (France), ²Universidade Federal do Paraná - Curitiba (Brazil).

The thermo-molecular pressure difference (TPD) plays an important role in vacuum systems, e.g. it must be taken into account in calibrations of vacuum gauges [1]. Such a TPD arises because of the thermal creep, i.e. rarefied gas flow due to a temperature gradient. Till now, this phenomenon has been studied only in a stationary state. A critical review of works reporting data on the stationary TPD is given in [2]. However, it is not known the time needed to establish the TPD. The aim of the present work is to model a transient TPD in a long tube connecting two containers. A thermal creep flow due to a temperature drop on the tube ends is considered as the initial conditions. It is assumed that the pressure drop is zero at this moment. When the containers are closed, a pressure drop arises between them which establishes after a certain time. Such a situation was experimentally studied in [3]. The modeling of the transient pressure difference is based on the data obtained from the S-model of the Boltzmann equation subject to the Cercignani-Lampis law of gas-surface interaction which are reported in [4]. As a result, a characteristic time needed to establish the stationary TPD was calculated. It is shown that the numerical results are in a good agreement with the experimental data reported in [3].

**H. Hseuh, A. Anderson, W. De Boer, S. Di Stefano, C. Hetzel, S. Leng,
K. Wilson, H. Xu, D. Ziggrosser.**

Brookhaven National Lab - Upton, New York (United states).

The National Synchrotron Light Source II is a state-of-art synchrotron radiation facility designed with ultra-high-flux and -brightness. It consists of a 200-MeV Linac, a 3-GeV Booster and a 3-GeV, 792-meter circumference storage ring. The Booster vacuum system is made of thin-wall stainless steel chambers and is pumped with ion pumps. The Linac and Booster vacuum systems are completed and have reached ultrahigh vacuum. The storage ring vacuum chambers are mainly made of extruded aluminium with ante-chamber. The synchrotron radiation from the bending magnets in the storage ring is intercepted at discrete photon absorbers made of GlidCop. NEG strips in the ante-chamber provide the distributed pumping, while lumped ion pumps and titanium sublimation pumps at photon absorbers remove the desorbed gas. The 200+ long aluminium chambers were manufactured, assembled with pumps, photon absorbers and diagnostic components, integrated into magnet girders and installed in the storage ring tunnel. Most of the 30 DBA cells have been connected with RF bellows, pumped down, in-situ baked and have reached 10-11 mbar. The narrow gap insertion device vacuum chambers are to be coated with NEG and are currently under fabrication. This paper describes conditioning, installation, integrated testing and commissioning of the NSLS-II vacuum systems. Experience from the large scale production, testing, integration and lesson learned will be summarized.

Development of advanced plasma fueling techniques for EAST tokamak

T15 Vacuum Science and Technology

#VST-3-Or-13

J. Hu, Y. Chen, J. Li, C. Li, X. Zheng, J. Li.

Institute of Plasma Physics, Chinese Academy of Sciences - Hefei (China).

Fuelling system is one of key subsystems of tokamak machine. It is not only providing a fueling source, but also would influence on plasmas performance. The Experimental Advanced Superconducting Tokamak (EAST) is a non-circular advanced steady-state experimental device, which started plasma operation in 2006 in Hefei, China[1]. Long pulse plasmas up to 400s and stationary H-mode plasmas up to 32 seconds have been achieved in 2012 campaign.

Recently, supersonic molecular beam injection (SMBI), and D2 pellet injection at both low field side (LFS) and high field side (HFS) have been successfully developed and applied in EAST for deeper fuelling and fast density feedback control. In the SMBI system, a Laval (0.3mm to 7.5mm in diameter with a taper angle at $\pm 30^\circ$) was used, and the back pressure for injecting D2 is up to 1.5MPa. In theory, the D2 would be driven to a speed of 2200m/s with a max throughput up to 2.47×10^{22} /s. With the cooperation of PELIN Laboratory in St Petersburg, Russia, a new pellet injection system based on a screw extruder has been successfully installed on EAST in 2011. The pellet is 2 mm in diameter and 2mm in the length, which contents 3.78×10^{20} D atoms; it could operated at 10 Hz in 1000s, and pellet velocity could be adjusted from 150 to 300 m/s. The flight tubes which in place to convey the pellets toward the plasma either from low field side or from high field side. And the length of LFS flight tube is nearly 4.5 m while the HFS flight tube is 9.5 m. The injection line is able to pump the propellant gas effectively to make sure no influence to the vacuum of the plasma vessel during the long steady pellet injection.

In the campaign of EAST in 2012, SMBI and PI system has been firstly and successfully tested. And the test showed that both fuelling system have quite high feasibility, stability and reliability. The tested showed that both systems could be used not only for advanced core fueling, but also for ELMs control. SMBI produces a rapid travelling gas jet with a speed exceeding 1 km/s and pulse length ranging from 2 to 20 ms. This leads to a much shorter density response time (2-4 ms) than the conventional gas puffing (16 ms and 77 ms for LHS and HFS, respectively). SMBI has been also successfully employed as a fast density feedback tool to maintain

plasma density for steady-state operations, and it seems much better than gas puffing. The present pellet injection system is mainly used for core plasma fuelling. As expected, pellet injection from HFS exhibits a higher fuelling efficiency with deeper penetration into the core plasma than from LFS, i.e., 18-30% for LFS and 30-60% for HFS, respectively, which much higher than that of SMBI or GP. Both SMBI and pellet injection have also been employed for active control of ELMs. This research was funded by National Magnetic confinement Fusion Science Program under Contract No.2010GB104002 and No.2013GB114004 and National Nature Science Foundation of China under Contract No.11075185 and No.11021565.

VST-7-Or-2

End effect corrections for rarefied gas flows through long capillaries of finite length

T15 Vacuum Science and Technology

#VST-7-Or-2

D. Valougeorgis ¹, S. Pantazis ², F. Sharipov ³.

¹Department of Mechanical Engineering, University of Thessaly - Volos (Greece), ²Physikalisch-Technische Bundesanstalt - Berlin (Germany), ³Universidade Federal do Parana - Curitiba (Brazil).

Fully developed gas flows through long capillaries in the whole range of the Knudsen number have been extensively considered with remarkable success on the basis of linearized kinetic theory. The assumption of the fully developed flow is based on the fact that the capillary is adequately long and that pressure varies only in the flow direction. This assumption permits the simplification of the kinetic formulation leading to precise analysis with very accurate results.

However, the main hypothesis that the capillary is sufficiently long, in order to achieve the fully developed state, is not always true in practical situations, leading to a significant impact on the accuracy of the results because of the capillary inlet/outlet effects. For the case of short capillaries the end effects can be taken into account by including additional regions before and after the capillary. In the case of long capillaries this type of investigation becomes computationally expensive and therefore in most applications only empirical approaches are applied.

The objective of the present investigation is to quantify the influence of the capillary ends by applying the effective length concept in order to extend the applicability of the infinitely long capillary theory to capillaries of moderate length. This concept has been initially applied in slow viscous flows and later on, in rarefied gas flows in an approximate manner. The main idea is to extend the length of the channel by additional length increments for the purpose of calculating the correct pressure profile and flow rate.

Here, the effective length concept has been introduced to investigate the end correction for rarefied gas flows through capillaries of finite length by splitting the flow

domain in the inlet, middle and outlet parts. A kinetic solution of the developing flow in the inlet and outlet parts based on the BGK model equation subject to proper boundary conditions is provided to compute the effective length increment, which depends only on the gas rarefaction parameter (not on the channel length). The kinetic solution is properly combined at the level of the distribution function for the inlet and outlet regions with the typical fully developed solution in the middle part of the capillary. The inlet and outlet length increments are added to the capillary length and then, the well known fully developed approach is applied to compute quantities of practical interest, such as the flow rate. A comparison with the typical (without end correction) fully developed solution as well as with the solution of the complete domain has been performed to demonstrate the superiority of the proposed approach compared to previous ones.

Results for the effective length increment in terms of the Knudsen number are tabulated for flows between parallel plates and through circular tubes. A detailed view of the inlet and outlet flow fields is also provided by plotting the pressure and velocity distributions. The effective length increment values given here can be used in practical applications with minimal computational effort.

Numerical simulation of rarefied gas flow through a thin orifice based on the ab initio potential.

T15 Vacuum Science and Technology

#VST-7-Or-3

J. Strapasson, F. Sharipov.

UFPR - Curitiba (Brazil).

Rarefied gas flow through a thin orifice is well studied on the basis of the direct simulation Monte Carlo (DSMC) method, see e.g. Ref.[1]. However, all previous calculations are based on molecular models like hard sphere, variable hard sphere etc. Such molecular models contain fitting parameters usually extracted from experimental data. For vacuum metrology, it is important to obtain numerical data without any fitting parameter. Recently, the ab initio potential was implemented into the DSMC method [2]. The aim of the present work is to calculate ab initio the mass flow rate and flow field the whole range of the rarefaction parameter for various values of the pressure ratio. A comparison of the present numerical results with those based on the hard sphere and variable hard sphere models published previously, and also with experimental data available in the open literature is performed.

A profile of the gradational lead rotor with equal axial addendum width in dry twin-screw vacuum pump

T15 Vacuum Science and Technology

#VST-P1-16

S. Zhang, J.L. Zhao, Y.F. Zhang, Z.J. Zhang.

School of Mechanical Engineering and Automation, Northeastern University - Shenyang (China).

The profile design of the screw rotor is one of the most key technologies in dry twin-screw vacuum pumps. The single-thread and variable-pitch rotors has won the good graces and much concern of both manufacturers and users in recent years because of its outstanding advantages of energy saving and noise reduction.

All of the previous profiles of the gradational lead screw rotors have the same structural characteristics, i.e., the axial addendum width of the rotor changes to narrow gradually along with the lead becoming narrow gradually from the inlet towards the outlet. This kind of structure leads to the performance of pump descending.

Aiming at the above problems, a new profile of the gradational lead screw rotor with equal axial addendum width is introduced in the article. The end profile of it consists of 4 curves connected in order. As shown in Fig. 1, they are dedendum circle (1), involute (2), addendum circle (3) and a self-meshing transitional curve (4) in turn. When this end profile is expanded by gradational pitch along with the axial, a single-thread and gradational-pitch screw rotor is formed which includes 4 tooth surfaces corresponding respectively to 4 curves, as shown in Fig. 2, the dedendum surface (5), the trapezoid surface (6), the addendum surface (7) and the transition tooth surface (8). The main feature of this profile is that the screw lead of the rotor gradually get larger and larger ($P_1 < P_2 < P_3$) along with the rotor axis from inlet towards outlet, the axial length of trapezoid surface also gradually become larger ($L_1 < L_2 < L_3$), but the addendum width remains the same ($B_1 = B_2 = B_3$). The entire equations of this profile are presented in the article and its advantages are analyzed in detail. This work can be taken as a useful reference for technical personnel in the design of screw rotors.

The non-rotating piston gauge usage in vacuum metrology

T15 Vacuum Science and Technology

#VST-2-Or-4

J. Wang.

National Institute of Metrology - Beijing (China).

The non-rotating piston gauge(FRS5) have been used in vacuum lab of NIM for the calibration service within range 100Pa to 11kPa. The FRS5 is also been used to improve the static expansion primary standard performance both in the volume ratio measurement and the vacuum pressure calibration. The reference gauge method is been used to measure the volume ratio in which the reference gauge would be calibrated immediately by FRS5 after the expansion. The result show that the volume ratio has no relation with the initial pressure which from 10kPa to 130Pa

The evolution of the gas characteristics in time is an important topic from the scientific and practical points of view. In the design and development stages of Pirani gauges [1], the heat flux and the pressure evaluation in time is vital information for adjustment of sensor characteristics.

A Pirani sensor is simulated by two coaxial cylinders. The time-dependent heat transfer of a gas between two coaxial cylinders is studied on the basis of kinetic model equation [2] over a broad range of the gas rarefaction. The response time is determined as a time needed to establish a steady state heat transfer averaged over the distance between the cylinders. As an initial state of the system, a instantaneous increase of the internal cylinder temperature from room temperature to 110 °C is considered. It was found that the response time varies very slightly for the low pressures and increases then drastically when the pressure increases, passing through a minimum between the two regimes. The influence of the gas nature on the response time is analysed.

Abstract: The vacuum spray jet atomization of plain-orifice nozzle is simulated using the Fluent and Gambit softwares. The influence of spray parameters including chamber pressure, injection pressure and nozzle diameter on the cavitation performances, atomization structure and the Sauter mean diameter (SMD) are systematically investigated. We present the effect of cylindrical, conical and fan-shaped nozzles on the performances such as the jet velocity, initial spray angle, dynamic pressure and TKE. Our results show that high injection pressure (> 10 MPa) has less effect on the vapor volume inside the nozzle. The TKE outlet the nozzle increases with increasing the injection pressure (see Fig. 1). The spray beam width decreases, while the spray jet penetration distance and the SMD increase with the decrease of the chamber pressure. As the injection pressure increases, the spray beam width increases quickly in the range of 1 to 10 Pa. The SMD changes very little, while the jet penetration distance increases linearly with increasing of the injection pressure. The nozzle with smaller diameter tends to produce longer spray jet penetration distance and smaller SMD. We find that the conical nozzle has a higher dynamic pressure conversion efficiency and larger spray angle than that of the other type of nozzles (see Fig. 2), which is in well agreement with previous experimental observations.

Keywords: Vacuum spray method; Plain-orifice nozzle; Atomization; Cavitation; Sauter mean diameter

On the Joule heat cutting and welding for various metallic nanowires under vacuum environment

T15 Vacuum Science and Technology

#VST-6-Or-3

H. Tohmyoh.

Tohoku University - Sendai (Japan).

To effectively use and create a new function from metallic nanowires (NWs), welding technique for NWs must be vital. Among the reported techniques, the welding technique utilizing Joule heat, where a constant direct current is supplied to a NW system comprising two NWs in contact, is one of the promising ways [1]. The contacting portion of two wires are successfully welded in self-completed manner with Joule heat [2] provided that suitable amount of constant direct current is supplied, see the picture. On the other hand, if the current supplied to the wires is over the upper limit value, the wire is cut out after the welding due to over Joule heating. The lower limit value for welding current was found to be about 70% for the upper limit value, i.e., the current required to cut the wire. Therefore, if the current to cut the wire is identified, the condition for successful Joule heat welding is also know. Generally, the thermal boundary condition around the wire is unknown, and therefore predicting such current is a difficult task.

In this presentation, currents required to cut various mtallic NWs under vacuum environment are estimated from a heat conduction model [3]. Most of the cases to use the NWs, the NWs are need to be observed with high magnification, and such wire is thermally insulated under vacuum. In the experiments for cutting the ultrathin Pt wires with Joule heat in vacuum, only the small region around the middle of the wire was melted and most part of the wire remained solid, see the picture. Thus in the theoretical modeling, we only considered the sensible heat and does not consider the latent heat of melting. The total heat applied to the NW system until the system reaches a steady state is determined. From the theoretical model, we found that the current required to cut the wire depended on the physical properties, i.e., thermal and electrical conductivities, density, specific heat and melting point, and the geometry of the wire, i.e., cross sectional area and length. Moreover, metallic NWs are cut in vacuum with Joule heat and the results are compared with the predicted one.

Survey of primary standards of atmospheric leaks

T15 Vacuum Science and Technology

#VST-1-Or-7

D. Pražák ¹, L. Peksa ², T. Gronych ², F. Staněk ¹, J. Tesař ¹.

¹Czech Metrology Institute - Brno (Czech republic), ²Charles University - Prague (Czech republic).

The halogenated hydrocarbons were widely used in the last century as volatile cleaning liquid, refrigerant gas and also for leak testing of vacuum systems. Majority of these applications were abandoned due to the environmental reasons but replacing them as refrigerator gas proved to be a difficult and long term task. This is caused not only due to large amount of the devices working with them at present (utilizing mainly R134a, i.e. 1,1,1,2-tetrafluoroethane), but also due to the safety and technological difficulties that are brought by their possible substituents. As the living environment friendly refrigerant media, the most promising are HFO-1234yf (2,3,3,3-tetrafluoropropene) and carbon dioxide. The first is flammable and slightly toxic; the second requires nearly ten times higher pressures during refrigerator cycle than the halogenated hydrocarbons. Hence, even if the halogenated hydrocarbons will be successfully replaced, the need for good leak testing will remain to secure the reliability of the refrigerating and air-conditioning systems.

Thus, the hot topic for metrology will be the measurement of the refrigerant leaks with sufficient accuracy and with traceability to the primary standards. The traceability in the field of leak measurement is performed usually via the secondary standards, so-called calibrated leaks, standard leaks or reference leaks.

Although the regulations of European Union impede the need of the reference leak calibrations, there are only a few national metrology institutes in Europe having a primary standard of this kind and the situation in the World is not much better. This is in contrast with the well established metrology of the helium vacuum leaks.

One reason is the fact that no method of conversion from leak-into-vacuum to leak-into-atmosphere is available, thus, the leaks-into-atmosphere must be determined in these cases which is a more complicated problem than the measurement of leakage into vacuum. At the other hand, the situation is rather simplified by the fact that usually mainly two orders of magnitude of the leak rates have to be covered in contrast to approximately seven orders of magnitude of the leak rates in the case of helium vacuum leaks.

An overview of the primary standard principles applicable for this purpose – used or under consideration – is given in the presentation. They can be classified into two groups: those being sensitive to the leaking gas species and those being insensitive to it. The problem of the first group standards is that they can work with a limited number of the gas species only, the problem of the second group standards is that they measure depleted volume of gas into a space under the atmospheric pressure, i.e. a very small change of a relatively large quantity which brings many experimental obstacles. The solution of CMI will be discussed in detail.

This work benefited from support of the European Metrology Research Programme under Joint Research Project IND 12 – Vacuum metrology for production environments. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union.

Fabrication and gas permeation properties of ultra-thin PolyDiMethylSiloxane (PDMS) membranes

T15 Vacuum Science and Technology

#VST-6-Or-2

G. Firpo, E. Angeli, L. Repetto, V. Ierardi, F. Buatier De Mongeot, U. Valbusa.

University of Genoa - Physics Department - Genova (Italy).

The polymeric membranes technology is a dynamic growing field, exploited in several areas of application like gas separation,^[1] sensors, and vacuum technology.^[2] It is based on well-known selective permeation process of gas through a polymer, whose selectivity for two different gas is the ratio of their permeability coefficients P . In the last years have been developed methods to fabricate ultra-thin membrane,^[3] but there's no estimation of P . Moreover, even if for thick membrane there is some results, the dependence of P from the thickness is generally poorly investigated.

Here we present a novel method to fabricate stable and resistant ultra thin PDMS membranes, and we show their gas permeation characteristics as function of the membrane thickness and the type of gas: CO_2 and He. The membranes have been fabricated by spin coating with thickness in the range between few micron and 500 nm. Afterwards, in order to guarantee the necessary mechanical stability, they have been transferred on SiN membrane previously drilled by focused ion beam with a number of apertures such that to have an appropriate permeation area (Fig. 1). Permeability measurements have been performed in high vacuum chamber, where the membranes have been exposed to 10^5 Pa of pressure differential without rupturing or stretching, proving their high strength.

The results confirm the higher permeability of the carbon dioxide respect to those of helium, whereas the value of P decreases unexpectedly with the membrane thickness, on the contrary of the CO_2/He selectivity that remains constant. Studies on thickness-dependence of the gas permeability are scarce, but our data (Fig. 2) are in good agreement with a model that considers non-equilibrium reactions at gas-

membrane interface. This make it possible the evaluation of the adsorption and desorption rates, and in conjunction with mechanical properties of the membranes, suggests new technological solutions in the devices miniaturization.

Design and construction of the LCLS-II vacuum system

T15 Vacuum Science and Technology

#VST-3-Or-14

M. Ferreira, D. Gill.

SLAC National Accelerator Laboratory - Menlo Park (United states).

The Linac Coherent Light Source - II (LCLS-II), now under construction at SLAC National Accelerator Laboratory in California, will be an x-ray free electron laser to increase the capacity and capabilities of the operating LCLS. The vacuum system includes a new RF gun and injector, two km of the SLAC linac (sectors 10-20), a new transport line, Undulator hall, X-ray transport optics and diagnostic (XTOD) and end-stations. The vacuum requirements for the different sub-systems need to be addressed taking into account the desired flexibility and technical limitations. We will show the mix of simulations techniques and results used to define the engineering solution for each section of the accelerator including the RF-gun and the injector, representing the most demanding region, and its coupling to the more than 50 years old LINAC section. The system is required to operate with dynamic isolation over a 12 order of magnitude pressure range.

Physisorption of hydrogen: a mean residence time, an adsorption energy, and a condensation coefficient deduced from the observation of transient states approaching equilibria

T15 Vacuum Science and Technology

#VST-5-Or-2

I. Arakawa, H. Shimizu, N. Inose, W. Kato, K. Yamakawa.

Department of Physics, Gakushuin University - Tokyo (Japan).

Considerable data on the physisorption characteristics of hydrogen on a variety of substrates have been accumulated with the intention of applying them to cryopumping in the various fields of vacuum engineering [1-5]. In the present study, equilibrium and transient properties of hydrogen physisorbed on a cold metal surface were investigated in ultra and extremely high vacuum. Electron stimulated desorption (ESD) technique was applied to measure the adsorption density of hydrogen molecules. Hydrogen was adsorbed on a copper substrate in the temperature range of 3 - 4.2 K and was irradiated with a pulsed electron beam of a few hundreds ns pulse width. ESD ions, H^+ , H_2^+ , and H_3^+ , were mass-separated by a time-of-flight measurement. In submonolayer range, the signal intensity of ESD H^+ was a useful measure for the amount of hydrogen physisorbed. The monolayer completion, which was accompanied by a two dimensional phase condensation, was observed in the rapid rise of H^+ intensity followed by its saturation. An adsorption isotherm was obtained as the ESD signal intensities of H^+ as a function of the hydrogen pressure, which was gradually increased from 10^{-9} to 10^{-4} Pa so as to keep adsorption equilibria. The observable lower ends of the isotherm were 1×10^{-8} Pa of the equilibrium pressure and 0.001 of hydrogen coverage, which was limited by background signal of H^+ originated from water or hydrocarbons adsorbed on the metal substrate. A transient state measurement was also applied to derive the mean residence time of physisorbed hydrogen. A time development of ESD H^+ intensity was monitored after a stepwise hydrogen pressure rise to a certain value. The time constant of the increase of ESD H^+ intensity is the direct measure of the mean residence time, τ , of hydrogen, which leads to the adsorption energy, E_d , and the

condensation coefficient, α . At 4.2 K of the substrate temperature, τ , E_d , and α were systematically measured as a function of coverage, θ , of hydrogen; 550 ± 50 s, 1.27 kJ, and 0.018, respectively, at $\theta = 0.18$, and 53 ± 2 s, 1.18 kJ, and 0.075, respectively, at $\theta = 1.0$, under the assumptions of $\tau_0 = 1 \times 10^{-13}$ s and 7.39×10^{18} m⁻² of the monolayer density of hydrogen.

Effect of sealing time of anodic aluminum oxide (AAO) film for vacuum parts

T15 Vacuum Science and Technology

#VST-P1-17

J. Kim ¹, J.B. Song ², J.S. Shin ², J.Y. Yun ¹.

¹KRISS - Daejeon (Korea, republic of), ²Daejeon Univ. - Daejeon (Korea, republic of).

The damage to the surface structure of Anodic Aluminum Oxide (AAO) caused by plasma and heat is evaluated with respect to the sealing time (0, 10, 30, 60 minutes). With a short period sealing of the oxide layer, the leakage current is abruptly reduced, while the breakdown voltage and permittivity are rapidly improved. Longer sealing becomes less efficient after 10 minutes. An evaluation of resistance to plasma and heat shows that the resistance is best with a sealing time of 10 minutes. In the samples sealed for 30 or 60 minutes, more cracks were formed by plasma and heat treatments, which further reduce the breakdown voltage. In addition, measurement of contamination particles generated in plasma treatment reveals that sealing longer than 10 minutes produces more particles.

Monte Carlo simulation of a Vapour Diffusion Pump

T15 Vacuum Science and Technology

#VST-4-Or-2

X. Luo, T. Giegerich, C. Day.

Karlsruhe Institute of Technology - Karlsruhe (Germany).

The vapour diffusion pump was the very first ultrahigh vacuum pump in vacuum history and it is exactly 100 years ago since W. Gaede patented his mercury diffusion pump made of glass in 1913.

Although turbomolecular pumps are the most commonly used high speed UHV pumps nowadays, vapour diffusion pumps do still play a role, especially in harsh applications where a robust and reliable pump is needed. In present applications, mercury has been completely replaced by synthetic oil. However, a new programme is currently underway to develop a mercury diffusion pump for applications in nuclear fusion power plants, because mercury is known to be perfectly tritium compatible. This type of pump would be an ideal alternative for the cryopumps used in present fusion devices, because it is much less demanding in operating cost and complexity and has no need for regeneration. This is the reason why Karlsruhe Institute of Technology (KIT) has started a new effort to develop a vapour diffusion pump using modern molecular modeling efforts.

The code which was correspondingly modified is ProVac3D (Profile of the Vacuum system of 3D complexities), which is a well validated Test Particle Monte Carlo simulation code developed by KIT [1-3]. In this paper, the simulation of a linear mercury diffusion pump will be presented. This also picks up an old pump design formerly used in the 1950s in US.

Diffusion pumps operate by directing a jet of vapour towards the walls of the pump shell where it condenses. On the way, when vapour molecules collide with molecules of incoming gas, the gas molecules are deflected in the direction of the pump exhaust. The vapour stream is created by boiling the pump fluid at the base of the pump and directing the vapour through a series of nozzles which accelerate the vapour molecules.

The modeling approach is as follows. First, we calculate the background density of the mercury molecules established by the mercury jets. Secondly, the gas molecules of the gas load coming from the pump inlet will be simulated. However, the collision between the gas load with the background jet has not been included yet. This step is necessary for checking the influence only from the pump geometry and the backing pump. Thirdly, the collisions between the molecule of the gas load (probe particle A) and the mercury molecule in the background (target particle B) will be considered. This approach has been newly implemented in ProVac3D. In order to achieve a high simulation precision, the code has been parallelized for optimum use of the powerful supercomputers. Compare the simulation results in the second step and the third step, the pumping effect of the mercury gas jet has been clearly revealed.

Atomic level surface characterization of vacuum fired stainless steel

T15 Vacuum Science and Technology

#VST-5-Or-1

M. Leisch.

Graz University of Technology - Graz (Austria).

Stainless steel (SS) is one of the most commonly used constructional materials for vacuum chambers and components. Special applications like accelerator and storage ring facilities make need for extreme high vacuum (XHV). In the XHV regime a reduction of the outgassing rates of the materials used is essential. Beside surface treatment high temperature vacuum firing became a widely accepted practice of reducing the amount of hydrogen dissolved in SS. For the description of the outgassing rate basically two models common as diffusion limited model (DLM) and recombination limited model (RLM) have been discussed [1,2]. It is well established that the rate of recombination depends strongly on the atomic structure of the surface. In order to gain atomic level information on the real morphology of a surface after common bake-out and vacuum firing SS samples were imaged in the atomic force microscope (AFM) and the scanning tunnelling microscope (STM).

The main experimental work has been carried out on a combined STM – atom probe field ion microscope (AP-FIM) apparatus [3]. A unique feature of the particular instrument is that it allows a fully-predictive preparation of STM probe tips which is important for a reliable imaging of complex surfaces. After the thermal treatment surface inspection by Auger electron spectroscopy (AES) gives reason for a composition change indicated by a reduction of the chromium signal in relation to the iron and nickel. Since the atom probe allows measuring the chemical composition on the surface atomic layer by layer it has been used to study the segregation behaviour on SS samples after bakeout and vacuum firing.

The surface after vacuum firing shows the formation of large flat (111) terraces bounded by bunched steps and facets corresponding in orientation to (110) and (100) planes. The deep grooved grain boundaries and facets represent very active sites for adsorption and recombination. A close up view by STM shows that there are a lot of vacancies too. Theoretical studies on the interaction of hydrogen with lattice imperfections [4] may provide a new insight in hydrogen outgassing. The energy calculations using the ASED method (Atom superposition and Electron Delocalization) result in lower energy levels in Fe vacancies. It supports the picture

that surface and subsurface defects form traps with different energetic levels. From these results a more complete description of the outgassing process may be given. The design of accelerator vacuum chambers requires input from different scientific disciplines such as surface science, material science. Vacuum gas dynamics allows joining them to the vacuum science for particle accelerators. The most time-efficient way of beam vacuum optimization is using a 1D diffusion model where all parameters are defined as a function of a longitudinal coordinate [5]. This theoretical approach corresponds very well with the results of this atomic level surface study.

Development of a Gas-sheet Target for Monitoring the High Intensity Proton Beam

T15 Vacuum Science and Technology

#VST-P2-22

N. Ogiwara, Y. Hikichi, J. Kamiya, M. Kinsho.

JAEA - Tokai (Japan).

The 3 GeV Rapid Cycling Synchrotron (RCS) in the Japan Accelerator Research Complex (J-PARC) project accelerates a proton beam up to 3 GeV. At a 25-Hz repetition rate, the RCS is planned to generate a high-power beam of 1 MW. Until now, the beam power of 400 kW has been obtained. In order to supply continuously the beam of 1 MW it is important to reduce the beam loss thoroughly. Thus the non-disruptive and fast-response beam diagnostic tools for extensive researches have been strongly required.

An idea to realize the fast non-disruptive beam profile detection is to introduce a gas target so as to increase the ionization yields with the beam. Luminescence lights (or ions) from the target yielded by the collision with the synchrotron beam are easily observed and utilized to obtain the beam profile. The gas density of about 10^{10} molecules/cm³ and the thickness of 2-3 mm are required for the measurement in the RCS in the J-PARC.

Therefore, we intended to apply the molecular beam technique for making the compact and large-scale gas-sheet target. First of all, we examined the angular distributions of the outgoing molecules from the exit of the rectangular slits by using the Monte Carlo simulation. The molecules emitted from the slit can be shaped into a sheet. To do so, the following two conditions need to be satisfied: $L \gg b$ and $a \gg b$. The letters a , b , and L represent the lengths of the long and short sides, and the length of the slit, respectively. With the parameter set of $L : a : b = 100 : 50 : 0.1$, the fraction of outgoing molecules collimated within the azimuth of 0.01 rad becomes 25% of all molecules[1]. Next simulations demonstrate the generation of large-scale gas-sheet targets in a vacuum by a thin concentric slit with a large aperture. Here gas is introduced from the outside toward the center, leading to the appearance of a large-scale gas sheet around the center. In the case of the circular slit, with inner and outer diameters of 200 and 400, respectively, and a gap of 0.1, the generated gas sheet had a diameter of 130 and thickness of less than 0.4 (half width), where all the

valuables are expressed in ratio. The uniformity of the gas density, which is the ratio of the minimum to the maximum peak value of gas density, was more than 85%. According above results, the experiments have been now under taken. The molecules from the rectangular slit have been found to focus into a sheet. The results for the circular sheet will be presented.

Capacitance Diaphragm Gauges for Very Fast Processes

T15 Vacuum Science and Technology

#VST-1-Or-1

M. Wüest ¹, F. Mullis ¹, K. Jousten ², J. Buthig ².

¹INFICON - Balzers (Liechtenstein), ²PTB - Berlin (Germany).

Calibration of a vacuum gauge according to ISO 3567 requires stationary conditions in pressure and temperature. In industry however, highly cyclical, non-equilibrium processes with rapid pumping and venting are found. In order to enable the calibration of vacuum gauges for very fast processes, a new calibration system has been developed at PTB. We report on a specially developed fast CDG measuring system that was tested for the fast transient pressures in the new calibration system in the pressure range 10^5 Pa to 10^2 Pa.

Support through the EMRP IND12 project is gratefully acknowledged. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union.

VST-P1-18

Large-scale Hydro-formed Bellows with Inner-surface Polishing, as Flexible as Welded Bellows

T15 Vacuum Science and Technology

#VST-P1-18

O. Koizumi ¹, M. Inoue ², N. Ogiwara ³, J. Kamiya ³, M. Kinsho ³.

¹Sun-tech limited - Kobe (Japan), ²Neos Co., Ltd. - Higashimatsuyama (Japan), ³JAEA - Tokai (Japan).

In the 3 GeV Rapid Cycling Synchrotron (RCS) in the Japan Accelerator Research Complex (J-PARC) project, large-scale bellows were needed to adjust the gap between the ceramic ducts and between the ceramic ducts and the transport ducts. The space for setting the bellows are so narrow that the requirements for the bellows were severe. Typical free length and inner diameter of the bellows were 100 mm and 300-400 mm, respectively; nevertheless, the spring rate of less than 100 N/mm was needed. Then pure Ti and SUS 316L steel were selected as materials for bellows; Ti bellows were set in the high radiation field because of its small residual radioactivity, and the SUS 316L bellows in the other area.

By the way, the formation of oxide scale and surface-roughening are sometimes observed on and/or near the melted parts. As they lead to the increase of outgassing and accumulation of dusts, the long welding trace should be avoided. Furthermore, the long welding trace of Ti is risky for vacuum leak because the penetration of a small amount of oxygen into the melted part under the welding causes the welded part to be brittle. Therefore, we have developed the hydro-formed bellows as flexible as welded bellows. In addition, the technique for polishing inner-surface of hydro-formed bellows has been developed.

In order to make flexible bellows the thin plates and a lot of convolutions are preferred. From this viewpoint, the welded bellows have an ideal structure. Therefore, we have developed the hydro-formed bellows with the almost same structure as the welded bellows. To realize Ti bellows, we had to resolve 2 tasks: 1) Necessary elongation for close contact bending is nearly 100% although the permissive elongation is only 27%; 2) It is difficult to keep the close contact after bending or pressing because of large spring-back effect. The repetition of combination of bending process with annealing enabled us to make sure the close contact of Ti plates.

Then, we have developed the new polishing method “wet mechanical polishing”. Using the fluid containing the minute particles of abrasive we have succeeded to polish the inner-surface of the complicated shape such as corrugation tube. The bellows for the RCS have been polished with this technique after the first bending process, that is, under the ordinary shape of the hydro-formed bellows. Then the bellows have been pressed into the final shape, which are almost the same as the welded bellows. The average roughness factor Ra of 0.02 μm changed to the value of 0.05 μm after the final pressing. The surface flatness just after the polish has been well maintained after the final pressing.

After assembling, mainly to reduce the hydrogen inventory in the bellows, all the bellows have been vacuum-fired for 10h at 650°C for Ti bellows, and at 750°C for SUS316L bellows, respectively.

Thus we have succeeded in developing the large-scale hydro-formed bellows with the inner-surface polishing, as flexible as welded bellows.

Transient rarefied gas flow through a slit

T15 Vacuum Science and Technology

#VST-P2-23

A. Polikarpov ¹, I. Graur ².

¹Ural Federal University - Ekaterinburg (Russian federation), ²Aix Marseille Université - Polytech Marseille - Marseille (France).

Transient gas flow through a slit into vacuum and at arbitrary pressure ratio was investigated basing on the unsteady S-model kinetic equation. Different gas flow regimes lying from free molecular to continuum regime were considered. The time necessary to reach the steady-state flow conditions was obtained, which varies from 10 to 100 as a function of the pressure ratio between the reservoirs and flow regime. The evolutions of the macroscopic parameters, the number density, the temperature and the bulk velocity in time were analyzed.

J. Wolf ¹, S. Görhardt ², N. Kernert ², L. La Cascio ², T. Thümmeler ².

¹KIT, IEKP - Karlsruhe (Germany), ²KIT, IKP - Karlsruhe (Germany).

The objective of the Karlsruhe Tritium Neutrino experiment (KATRIN) at the Karlsruhe Institute of Technology (KIT) is to measure the electron neutrino mass from the beta-decay of tritium with an unprecedented sensitivity of 200 meV. A central component is the electro-static main spectrometer (MS), where the energy of the beta-decay electrons at 18.6 keV will be measured with high precision. It consists of a large ultra-high vacuum vessel with a volume of 1240 m³ and a surface of 690 m², which is instrumented with a complex inner wire-based electrode system with more than 120000 individual parts, which almost doubles the inner surface of the MS. The pumping system of the MS consists of 6 turbo-molecular pumps (10000 l/s), a large-scale getter pump (3000 m NEG strips, St707) and three cryo-baffles (6.8 m²) at LN₂ temperature. It has three major goals: (I) the ultimate pressure, dominated by

H₂, has to be kept in the range of 1 × 10⁻¹¹ mbar in order to maintain a low background rate. (II) In conjunction with a differential pumping section and a cryogenic pumping section of the electron beam line, which connects the gaseous tritium source with the spectrometer, it has to keep the partial pressure of tritium in the MS below 10⁻²¹ mbar. (III) The NEG strips are known to emanate a small amount of radon atoms, increasing the intrinsic background rate. The cryo-baffles, which have been installed in front of the NEG strips, are expected to capture most of the radon atoms, before they can enter the sensitive volume of the MS. The objective is a reduction of the decay rate in the MS of the order of one decay per day. This paper describes the design of the vacuum system and the properties of its major components.

VST-P1-01

Low negative gauge pressure comparison between CMI and INRIM

T15 Vacuum Science and Technology

#VST-P1-01

Z. Krajíček ¹, M. Bergoglio ².

¹Czech Metrology Institute - Brno (Czech republic), ²INRiM - Torino (Italy).

The precise étalonnage of the border areas of vacuum is problematic – both its lower (XHV) and its upper (low negative gauge pressure) ends. The digital non-rotating pressure balance FPG8601 manufactured by Fluke/DH-Instruments is based on a 10 cm² non-rotating tungsten-carbide piston-cylinder with a conical gap. It is normally used for gauge and absolute pressures in the range from 1 Pa to 15 kPa, but with some modifications it can be used also for the upper vacuum range, i.e. negative gauge pressures down to 15 kPa.

Étalonnage of the negative gauge pressures has been a neglected branch of primary metrology with the lack of international interlaboratory comparisons [1]. Recently an intercomparison (EURAMET.M.P-S8) was performed [2] and two others are in progress (EURAMET.M.P-S9, SIM.M.P-S5). However, none of these covers the negative gauge pressures lower than 10 kPa, and as a consequence an intercomparison confirming its metrological quality was necessary.

During the preparation of the visit of INRIM at CMI for the last comparison within the framework of EURAMET.M.P-K4.2010, it was agreed to perform an additional comparison in the range from 300 Pa to 15 kPa in negative mode. It was registered as a supplementary comparison (EURAMET.M.P-S12) and it is aimed to verify the equivalence of the national low negative gauge pressure standards of Czech Republic and Italy.

In this case a digital pressure controller Fluke/DH-Instruments PPC3-200K was used for pressure regulation of both FPGs instead of Fluke/DH-Instruments Very Low Pressure Controllers (VLPCs) normally utilized. When measuring in negative mode the VLPCs of both FPGs were connected only electrically but pneumatically disconnected. A capacitance diaphragm gauge with a set of valves were used as a zero indicator and separator between both standards. The nominal negative gauge pressure points were 300 Pa, 1 kPa, 3 kPa, 10 kPa and 15 kPa. Measurements were performed in 2 cycles in different days. Nitrogen was used as pressure transmitting medium.

The paper will show the details of the experimental setup, the procedure used and the obtained results of this comparison.

Temperature sensing of fast gas expansions

T15 Vacuum Science and Technology

#VST-1-Or-2

J. Buthig, S. Pantazis, K. Jousten.

PTB - Berlin (Germany).

In processes involving fast gas expansions, it is often important to observe the change of temperature. Ongoing experiments in the Physikalisch-Technische Bundesanstalt include a dynamic system, performing an expansion of ratio 1:1800 within 1 s. In this case, a temperature drop of more than 150 K from room temperature may be expected. Assuming room temperature in theoretical calculations of conductance may in this case lead to significant errors. Thus, a temperature sensor should be placed inside the atmospheric pressure vessel. A thermocouple of type T, consisting of copper-constantan wires, has been selected to deal with this low temperature range.

The response time of the sensor is the most important property determining the accuracy of the measurement in fast processes. For this reason, thin wires of 25 μm diameter, which is the smallest possible size commercially available, are used. Several challenges are involved in the process of using a wire of this size, such as the building of a new connection with the 200 μm wires of the vacuum lead through. Various possibilities have been considered, such as laser welding, crimping, bonding and partially modified factory produced connectors. The characterization of the sensor for a rapid temperature change is also discussed. The influence of various factors such as the wire diameter, the gas temperature and velocity on the response time is estimated through simulations. Preliminary results are presented for simplified experiments, as well as the validation of experimental data with simulations.

Capacitance Diaphragm Gauges with highest measuring rate

T15 Vacuum Science and Technology

#VST-1-Or-3

C. Berg, F. Mullis, H. Hanselmann, M. Wüest.

INFICON AG - Balzers (Liechtenstein).

Capacitance Diaphragm Gauges (CDG) are used in many pressure control applications in industry. In such a typical application the CDG pressure signal is used in the butterfly valve controller to regulate the pressure in a vacuum chamber. The faster the control loop, the quicker the desired pressure value can be achieved. At present, the fastest commercially available CDGs have a time constant of 8 ms, while the majority of the CDGs have time constants of 20 to 30 ms. In this talk we will present CDGs that can deliver a new pressure value at less than 1 ms.

VST-5-Or-3

Comparison of diffusion and recombination limited model of experimental results for outgassing of hydrogen from a stainless steel vacuum chamber

T15 Vacuum Science and Technology

#VST-5-Or-3

S. Avdiaj¹, J. Šetina², B. Erjavec².

¹University of Prishtina, Faculty of Natural Sciences and Mathematics - Prishtina (Kosovo), ²Institute of Metals and Technology - Ljubljana (Slovenia).

Outgassing from the walls of vacuum chambers limits lowest achievable pressure. Austenitic stainless steel is the most common construction material for ultrahigh vacuum (UHV) and extremely high vacuum (XHV) chambers. Hydrogen is the predominant residual gas at very low pressures in stainless steel vacuum systems, i.e., in the UHV and XHV range. Therefore, the reduction of the hydrogen outgassing rate remains a challenging problem in the achieving pressures in those ranges. In this work, a vacuum chamber with a wall thickness of 2.62 mm and made from AISI type 304L stainless steel was examined with the aim of mitigating the outgassing rate. The heat treatments were carried out at 250°C for 380 hours and at 350°C for 140 hours. After baking at 250°C for 380 hours (corresponding to a dimensionless time $F_0 = 3.09$), an outgassing rate $q = 1.5 \times 10^{-10} \text{ Torr} \cdot \text{cm}^3 / \text{s} \cdot \text{cm}^2$ was achieved at room temperature. This room temperature outgassing rate was further reduced to $q = 0.5 \times 10^{-10} \text{ Torr} \cdot \text{cm}^3 / \text{s} \cdot \text{cm}^2$ after baking for another 140 hours at 350°C ($F_0 = 8.66$), resulting a total dimensionless time $\sum F_0 = 11.75$).

Diffusion limited model governs the initial removal of hydrogen from stainless steel, whereas hydrogen surface recombination plays an important role in the outgassing rate at lower hydrogen concentration. Numerical calculations based on diffusion limited model (DLM) and recombination limited model (RLM) of the same outgassing

data as a function of bake-out time are presented and compared with our measured data.

Rarefied gas flow between parallel plates of finite length at any pressure ratio

T15 Vacuum Science and Technology

#VST-7-Or-5

S. Misdanitis ¹, S. Pantazis ², D. Valougeorgis ¹.

¹University of Thessaly, Department of Mechanical Engineering - Volos (Greece), ²Physikalisch-Technische Bundesanstalt - Berlin (Germany).

Due to the enlarged interest in the numerical solution of rarefied gas flows in vacuum applications, it is important to identify the most suitable and computational efficient methods as well as to be able to judge the accuracy to expect from these approaches. In this framework, very recently, in an IUVSTA workshop [1], few benchmark problems have been selected and a comparison between the results obtained by various methodologies has been performed [2]. During this effort it was realized that results for the rarefied gas flow through a channel are very limited and for that reason the comparison for this specific flow configuration has been abandoned.

In the present work, an effort is made to fill this gap by solving the channel flow problem and providing results for the three parameters, namely the reference gas rarefaction parameter δ , the downstream over the upstream pressure ratio Π and the dimensionless channel length L/H , which completely define this problem. This is achieved by numerically solving the nonlinear BGK model equation subject to Maxwell boundary conditions via an upgraded discrete velocity algorithm, which has been optimized by massive parallelization and memory handling techniques [3]. Results are provided for the dimensionless flow rates and the macroscopic distributions of the flow field for $0 \leq \delta \leq 10$, $0 \leq \Pi \leq 1$ and $0 \leq L/H \leq 10$. Furthermore, a comparison is performed with the corresponding linear solution in the case of small pressure differences as well as to the fully developed solution in the case of long channels in order to investigate the extend of validity of these theories. It is hoped that the provided solution will be used for benchmarking purposes as well as for comparison with experimental data.

A live calibration method of the leak detector of change pressure and experimental research

T15 Vacuum Science and Technology

#VST-P1-02

J. Shi, J. Zhao, L. Sun, F. Qi.

BISEE - Beijing (China).

This paper deals with an easy live calibration method using rise pressure for calibration the leak detector of change pressure. A given model detector is used in the calibration, and five leaks of different leak rate achieved by adjusting a micro-adjustable valve are calibrated. The minimum experiment relative error can arrive at 0.92% using the method in the calibration. The best merit of the method is easy and that the volume of the calibrating container is not introduced into the calculating course. It's needless to found the calibration system of specific size. The effect of the temperature and the leak rate on the result of the test using the leak detector of change pressure is also detailed by calculating. And the calculating result indicates that the biggish error would be introduced into the test result because of lesser change of the temperature if the leak rate and weight of leak are both lesser.

Evaluation Design of Reliability Engineering of Vacuum Pumps in the Semi-conductor Industry

T15 Vacuum Science and Technology

#VST-P1-19

J. Lim ¹, W.J. Kim ², S.Y. In ³, D.Y. Koh ⁴, W. Cheung ¹.

¹KRISS - Daejeon (Korea, republic of), ²LOT Vacuum - Ansung (Korea, republic of), ³KAERI - Daejeon (Korea, republic of), ⁴KIMM - Daejeon (Korea, republic of).

Methods of the characteristics evaluation of vacuum pumps are well-defined in the international measurement standards such as ISO, PNEUROP, DIN, JIS, and AVS. The Vacuum Center in KRISS has recently designed, constructed, and established the integrated characteristics evaluation system of vacuum pumps based on the international documents by continuously pursuing and acquiring the reliable international credibility through measurement perfection.

Recently advanced industrial processes such as semiconductor and display manufacturing continuously require very precise evaluation of reliability engineering of vacuum pumps including the lab level of characteristics and endurance evaluation via the control of the mass flow of gases. The requirements include very low mass flows of less than 1 sccm or 2×10^{-2} mbar·l/s up to 10^5 mbar·l/s.

Utilizing the combined mass flow systems in KRISS, the measurement of pumping speed has been performed with the throughput and orifice methods dependent on the mass flow regions. However, in the HV range of the molecular flow region, the high uncertainties of the gauges, mass flow rates, and conductance are too critical to precisely accumulate reliable data. In order to solve the uncertainty problems of pumping speeds in the HV range, we introduced an SRG with 1 % accuracy and CVFMs to measure the finite mass flow rates down to 10^{-3} mbar·l/s with 3 % uncertainty for the throughput method. In this way we have performed the measurement of pumping speed down to less than 10^{-6} mbar with an uncertainty of 6 %.

Based on the measurement of perfection developed we are supposed to develop the evaluation design scheme of reliability engineering of vacuum pumps with mapping the database accumulated in the lab, process, and factory sites. In this article we briefly introduce the current developmental stage of reliability engineering in vacuum

community.

Acknowledgements: Results are partially attributed to two national projects (Contract Nos. 10031858 and 10031836) sponsored by the Korean Ministry of Knowledge Economy, and KRISS main project 13011040.

VST-P1-03

Evaluation of the influence factors on vacuum helium mass spectrum leak detecting system sensitivity

T15 Vacuum Science and Technology

#VST-P1-03

W. Sun, D. Meng, L. Sun, Z. Li, R. Ding.

Beijing institute of spacecraft environment engineering - Beijing (China).

The sensitivity of the existing total leak rate detection methods for the large-scale seal structure was limited at present, and the vacuum helium mass spectrum leak detection system sensitivity is higher, hence evaluating some effect factors of the vacuum helium mass spectrum leak detection system sensitivity was useful for large-scale seal structure total leak rate detection and provided some references for vacuum system design. With large-scale space environment simulator as researching leak detection system, the sensitivity and influence factors of vacuum leak detection method was analyzed by the theory and experimental study. the study conclusions indicate the main influencing factors of vacuum leak detection system include the performances of leak detector, the vacuum system design, the scheme of leak testing system and the Helium background of the vacuum container. The large-scale seal structure vacuum leak detection sensitivity can achieve $5 \times 10^{-9} \text{Pa} \cdot \text{m}^3/\text{s}$. And the molecule pump in series mode can attain a little large response and sensitivity. Cryopump can effectively improve the degree of vacuum, but it affects the Helium background. The heat sink has little affection for leak detection but is disadvantage for reducing Helium background. These conclusions provide some references and rational advices for improving vacuum leak detecting system.

VST-6-Or-5

Review and measurement of outgassing rates of stainless steel and polymers

T15 Vacuum Science and Technology

#VST-6-Or-5

K. Battes, C. Day, V. Hauer.

**Karlsruhe Institute of Technology (KIT) - 76344 Eggenstein-Leopoldshafen
(Germany).**

The investigation of the outgassing of stainless steel was started a couple of decades ago. Many literature values for different types of steel and polymers are available showing a broad range of outgassing rates depending on pre-treatments and measurement methods even for the same material. The first part of this work is the review of available data and the presentation in a more general way. The Fourier and the Knudsen number are used to decouple temperature dependent from gas specific quantities.

The second part of the work is the experimental investigation of outgassing by using the difference method (a modified throughput method). The Outgassing Measurement Apparatus (OMA, Fig. 1) at KIT was used for the measurement of pre-treated (electro-polished, air-baked) and gel coated stainless steel as well as for different polyimides and Viton[®].

The review of literature data including own measurements shows that the hydrogen outgassing from stainless steel can be reduced very effectively by surface treatment whereas the reduction of chemical bound water needs higher efforts especially in polymers and if baking cannot be performed at higher temperatures.

A Portable Vacuum Gauge Calibration Apparatus

T15 Vacuum Science and Technology

#VST-P1-04

L. Yaowen ¹, C. Xu ¹, Q. Jing ², L. Bo ³, C. Liangzheng ².

¹(1.Tsinghua University - Beijing (China), ²(1.Tsinghua University - Beijing (China), ³(2.Xi'an aerospace Institute of metrology - Xi'an (China).

A portable vacuum gauge calibration apparatus has been developed in order to meet the increasing demands of the on-site vacuum gauge calibration with wider pressure range. Three methods are integrated on this apparatus to expand the calibration pressure range, which are the static comparison method, the static expansion method and the dynamic flow method. The calibration chamber of the apparatus is a spherical container with 200mm diameter, where two capacitance diagram gauges (CDG) with full range of 1.33×10^5 Pa and 133 Pa are used as the reference standards.

The achieved calibration range of this apparatus is $1 \times 10^5 \sim 4 \times 10^{-6}$ Pa, and the combined standard uncertainty is 1.3%~4.7%, which are shown by the experimental results. The size of this apparatus is 450 mm × 400 mm × 750 mm, and its total weight is less than 40 kg. The advantages of this developed apparatus are small volume, light weight, portable and low cost etc, which is suitable to do on-site vacuum gauge calibration with wider pressure range.

TRIUMF - Vancouver (Canada).

The new Advanced Rare Isotope Laboratory (ARIEL) is TRIUMF's flagship facility that will expand Canada's capabilities to produce and study isotopes for physics and medicine. ARIEL Phase I have been funded and include the construction of conventional facilities and the first stage of high-power electron linear accelerator (e-linac) using superconducting radio-frequency niobium cavities. Additional phases of ARIEL will add two full target stations and an additional proton beam line from TRIUMF's main cyclotron.

ARIEL's e-linac will drive photo-fission of actinide target materials to produce exotic isotopes which will be extracted and separated on-line (ISOL) and delivery to TRIUMF's existing ISAC facilities. Employing a 300 keV electron gun (e-gun), the e-linac will deliver 5 mA beams at 25 MeV from an injector cryomodule and 5 mA, ~25 MeV beams at the output of the first accelerator cryomodule by year 2014.

To minimize the collision of electrons with air molecules, the pressure in the e-gun and the section before the injector cryomodule has to be at less than $1\text{E-}9\text{mbar}$, in the accelerators and the section between the accelerators at $\sim 1\text{E-}7\text{mbar}$, and in the beam transport lines which deliver beam to the targets or beam dump at level less than $1\text{E-}6\text{mbar}$. To achieve this goal, the e-linac vacuum system has to comply with ultra-high vacuum design, manufacturing and assembly standards.

This document describes the vacuum system of ARIEL E-linac. It identifies all vacuum components as pumps, valves, gauges, and elaborates on the effort spent in finding a cost efficient solution. The document also provides information about the control system and interlocks for the operation of e-linac vacuum system.

Study on Diagnostics of Dry Vacuum Pumps Using the Adaptive Parametric Model of State Variables

T15 Vacuum Science and Technology

#VST-P1-20

S. Nam ¹, W. Cheung ², J.Y. Lim ².

¹UST - Deajeon (Korea, republic of), ²KRISS - Deajeon (Korea, republic of).

This paper introduces statistical features extracted from the measured state variables of dry vacuum pumps in the semiconductor processes. They were found to have three distinctive means and overlapped distributions unlike a single normal distribution. Specifically, two distinctive distributions near the upper and lower asymptotic bounds are obviously observed from the gas-loaded states of the vacuum pump and the third one from the idle states. These observations have provided new motivations of not only separating the pump operation state into the gas-loaded and idle states but also modeling the upper and lower bounds as a separated distribution. A linear adaptive parametric model (APM) is addressed to map their linear trends of each state variable onto their corresponding model parameters. Estimated model parameters are used to construct the batch data for each process. The APM-based batches are also exploited to construct the reference batches under the normal operating conditions (NOC) such that the principal components of the NOC (reference) batches are used to diagnose each process batch data in real-time. The APM-based batch is shown to provide a dramatic reduction of memory usage and computation time (1 ~ 2 % memory usage and 10 times faster computation time) in comparison to the conventional dynamic-time wrapping algorithms. Four cases of test results are demonstrated to examine the feasibility of the proposed APM for the diagnostics and predictive maintenance of dry vacuum pumps.

This paper proposes the use of two statistics, the Hotelling's T^2 and the sum of squared residuals, in order to improve the reliability of the self-diagnostics and predictive maintenance of dry vacuum pumps. The first one is exploited to examine what amount of similarity the current process batch has in reference to the normal operation conditions and, furthermore, the second is to examine what contribution the current process batch makes to the noise space. The two proposed statistics are examined to quantitatively analyze the reliability and improvement of the predictive maintenance and self-diagnostics developed in this work.

Pumping Speed Measurement Capability of Dry Vacuum Pumps Using a Block of Six Calibrated Sonic Nozzles

T15 Vacuum Science and Technology

#VST-P1-05

W. Cheung ¹, S. Nam ², J.Y. Lim ¹.

¹KRISS - Daejeon (Korea, republic of), ²UST - Daejeon (Korea, republic of).

This paper addresses the capability of measuring the pumping speed of dry vacuum pumps using a built-up block of multiple calibrated sonic nozzles [1-2]. The first challenging issue comes from the technical limit that their calibration capability of sonic nozzles [3] established by the flow measurement standard laboratories do not fully cover the low vacuum measurement range of 10 through 1000 mbar. In order to tackle the first technical issue, the constant volume flow measurement method [1-3] dedicated for the vacuum range of 10 through 1000 mbar is exploited to calibrate the discharge coefficient multiplied by the cross-section area of each sonic nozzle used in the built-up block of sonic nozzles. On the other hand, the discharge coefficient multiplied by the cross-section area of each sonic nozzle in the upstream pressure range of 2 through 10 bar is calibrated in the gas flow standard laboratory in KTISS. These combined calibration methods are illustrated to enable each sonic nozzle to cover the three decade measurable range of 10 mbar through 10 bar. The second technical issue comes from a logical way of stacking multiple sonic nozzles to expand the capability of measuring the pumping speed of dry vacuum pumps. On the onset of this work, sonic nozzles of 5 mm throat diameter were machined to expand the upper limit pumping speed by stacking three or four nozzles in the built-up block. Of course, small sized nozzles (0.1, 0.16, 0.5, and 1.0 mm throat diameter) were also machined to cover the low and mid range of the throughput of 0.1 through 100 mbar-l/s. A prototype of the built-up block with the capacity of installing six sonic nozzles was tested to investigate its performance. As shown in Figure 1, a maximum pumping speed was realised to be 5,000 m³/h at the 50 mbar inlet pressure (.equivalent to 67,500 mbar-l/s). This prototype is expected to provide a possible 'on-line pumping speed tester' with the capability of 5,000 m³/h or more, applicable to the pumping speed measurement at the on-site flat display and semiconductor processes.

Simulation study of sensitivity on ionization gauge with carbon nanotube cathode

T15 Vacuum Science and Technology

#VST-P2-16

Y. Xiao ¹, D. Li ¹, Y. Cheng ¹, C. Dong ², H. Zhang ¹.

¹Science and Technology on Vacuum & Cryogenics Technology and Physics Laboratory, Lanzhou Institute of Physics - Lanzhou, 730000 (China), ²Institute of Micro-nano Structures & Optoelectronic Devices, Wenzhou University - Wenzhou, 325000 (China).

In this paper, the sensitivity of carbon nanotube (CNT) cathode ionization gauge based Leybold IE514 extractor gauge structure is simulated using SIMION 8.0 ^[1] software extended by additional code. The simulation and analysis results are as follows:

(1) For the commercial IE514 thermionic cathode ionization gauge, all movement electrons emitted from the heated filament electron source are been restrained inside anode grid, no escape, as shown in Fig.1 (a). However, to the CNT cathode ionization gauge, the area of electron source is larger than thermionic cathode, and requiring high applied gate voltage ($V_{\text{gate}} > 400\text{V}$) in operation, which results in a few escaped electrons that cannot be collected by anode, as shown in Fig.1 (b). These escaped electrons account for about 4%~10% of total electrons from CNT field emission cathode, and influence the effective electron path length (L_e) in the CNT source ionization gauge. Considering the theory relation between sensitivity and L_e in ionization gauge, the escaped electrons possibly give rise to the instability of sensitivity. With regard to the sensitivity instability of CNT source ionization gauge is also discovered in some experimental data reports ^[2, 3].

(2) As the ratio between anode voltage and gate voltage ($V_{\text{anode}}/V_{\text{gate}}$) increases, the L_e increases before, and then almost keeps constant after $V_{\text{anode}}/V_{\text{gate}} > 1.6$. However, the sensitivity of CNT cathode ionization gauge declines with the anode voltage rising, which is primarily attributed to the decrease on ionization proficiency of gas-phase molecules ^[4]. Therefore, the reasonable voltage values on the electrodes will be propitious to increase the L_e , and improve the sensitivity, further extending the vacuum measurement lower limit.

As is mentioned above, the simulation results are contributed to penetrate the operation mechanism of CNT source ionization gauge, and provide important theoretical guidance to develop the new-type extreme high vacuum ionization gauge with CNT cathode.

Abstract: A super-huge steel artificial climate environmental test facility with diameter of 22m and volume of 12000m³ is used for the simulation of natural climate at different elevations below 6000m in southwestern China to carry on the characteristic research of the external insulation for ± 800 kV direct current transmission insulators and provide necessary facility and condition for design specification and technical standard. The key technology of this facility is the acquisition of stable low pressure plateau environment. The facility utilizes three sets of large scale liquid ring pump as prime vacuum pump and one set of lower pumping speed liquid ring pump as holding vacuum pump to evacuate the chamber in steps. Based on the principle of dynamic flow balance, a vacuum regulating valve is used to control the effective pumping speed of holding vacuum pump to achieve a stable experimental vacuum degree. The result of the experiment is as follows : the vacuum degree of 0.05MPa obtained within 15 minutes ,and the control accuracy of vacuum degree at 0.5% .

Capacitance Diaphragm Gauges with very high full scale stability

T15 Vacuum Science and Technology

#VST-1-Or-6

P. Kappenberger, C. Strietzel, M. Wüest.

INFICON AG; Alte Landstrasse 6 - 9496 Balzers (Liechtenstein).

It has been shown that ceramic capacitance diaphragm gauge technology has achieved a great deal of maturity. Long-term stability of those production line gauges with analog electronics have been demonstrated to be within 0.005-0.04% depending on full scale[1] and rivaling the reproducibility of a static-expansion primary standard. Taking advantage of the developments in the electronics industry we have developed a new reference design using digital electronics optimized for high stability. Initial data will be presented.

VST-P1-06

An Analysis of Gas Flow and Pressure Differences for a High Vacuum Measurement Standard

T15 Vacuum Science and Technology

#VST-P1-06

H. Song, W. Khan, S.S. Hong.

KRISS - Daejeon (Korea, republic of).

A flow-control system has set up at vacuum laboratory, KRISS, which can be used for the calibration of vacuum gauges by comparison method in the pressure range from 0.1 ~ 133 Pa. The system mainly consists of a large vacuum process chamber and a high vacuum pumping system separated by a pneumatically actuated gate valve. To achieve homogeneous pressure inside the chamber, a square-shaped baffle plate of area 289 cm² is installed at a distance of 30 mm from the top of the chamber. Two mass flow controllers (MFCs 1 and 2) are installed on top of the chamber with flow controls of 1 slm (1 slm = 1000 sccm = 1.69 Pa m³ s⁻¹) and 3 sccm (1 sccm = 1.69 × 10⁻³ Pa m³ s⁻¹) range, respectively. In this work, we studied the following characteristics of the flow-control system; generating stable pressure points in the chamber of the system, the effect of baffle plate on pressure distribution, analysis of gas flow through the conductance-reducer (CR), and measurement of time constant and equilibrium times for various gases. The stable pressures can be generated in the turbo-molecular pump region as well as the scroll pump regions in the range 6.53×10⁻⁴ Pa ~ 6.27 Pa and 11.2 Pa - 493 Pa, respectively. In order to reduce the pressure non-uniformities, the effect of a baffle plate was investigated by comparison of the pressure ratios in the presence an absence of the plate. The pressure ratios of the four CDGs were close to the mean value of 1.00 in the presence of baffle plate. The gas flow through the conductance-reducer (CR) was analyzed by calculating the Knudsen number K_n for the three gases Ar, N₂ and He. It was observed that initially the flow was molecular which shifted to transitional with rise in pressure across the ends of the CR. The time constant (τ) and 95 % equilibrium time (3τ) we experimentally calculated for Ar, N₂, and He by delivering same flow rates of each gas through the mass flow controller(s). The values of 3τ for Ar, N₂, and He gases were 28 ~ 12, 24 ~ 10, and 10 ~ 6 minutes respectively. It was observed that, equilibrium time for heavy gases were longer and vice versa. From

this we conclude that equilibrium time is dependent on molar mass and size of the gas in the pressure range of nearly 1 Pa ~ 133 Pa.

A dynamic vacuum pressure standard to test the response time of fast vacuum gauges

T15 Vacuum Science and Technology

#VST-1-In-1

K. Jousten ¹, S. Pantazis ¹, R. Model ¹, J. Buthig ¹, J. Iwicki ², M. Wüest ³

¹PTB - Berlin (Germany), ²VACOM GmbH - Jena (Germany), ³Inficon AG - Balzers (Liechtenstein).

In several industrial applications, such as leak testing, CD metallization or coating processes, fast processes are often involved, requiring rapid changes of pressures in the vacuum regime. Vacuum load locks are typically being used for coating processes, where the pressure changes from atmospheric to medium vacuum within 1 s or less. The control of such vacuum systems is triggered by vacuum gauge readings. Therefore, vacuum gauge manufacturers are interested to know how fast their gauges can follow such rapid changes of pressures.

In order to study the response time of vacuum gauges to rapid pressure changes, the Physikalisch-Technische Bundesanstalt has developed a dynamic vacuum standard where the pressure may change from 100 kPa to 100 Pa within 1 s or less in a predictable manner. This is accomplished by an expansion of gas at 100 kPa from a very small volume of less than 0.1 L into a large volume of 180 L through a well defined orifice. The process is started after the activation of a fast opening gate valve DN40, reaching its final state within less than 6 ms. The flow rate through the orifice needs to be calculated versus time through simulations. Furthermore, the temperature inside the small volume may drop by more than 150 K and therefore needs to be calculated and measured to avoid uncertainties in theoretical calculations. Finally, the pressure in the small chamber found by the simulations will be used as a reference for the indicated pressure of the attached vacuum gauge.

To validate this standard, in a first step, the pressures have only been changed to the extent that the gas flow remains viscous, i.e. the pressure has been decreased from 100 kPa to 1 kPa. Hydrodynamic flow simulations have been carried using the

commercial code ANSYS CFX and compared to experimental results. In a second step, simulations for the case where the pressure changes down to 100 Pa have been performed by a hybrid continuum particle solver. This is a challenging task, due to the fact that the low pressure dictates an approach based on the kinetic theory of gases, but also due to the non-stationary nature and extreme characteristics of the flow, such as the geometrical features and pressure range.

First results of tests regarding the response time of fast vacuum gauges are presented and discussed.

Support through the EMRP IND12 project is gratefully acknowledged. The EMRP is jointly funded by the EMRP participating countries within EURAMET and the European Union.

Devices based on permeation leaks and physical leaks are used in order to calibrate leak-detection instruments. For many type of leak devices, the conductance is not predictable based on dimensional, gas species and temperature data, for this reason no estimates or only rough estimates of leak rates are possible for conditions under use where they differ from those of the calibration. Unfortunately, permeation leaks are very sensitive to small temperature fluctuations and can be used only with those gases for which permeating materials are available. While, physical-leaks that overcome these restrictions are susceptible to clogging. Here we present the characterization and the performances of a new kind of physical-leak devices based on nano-holes, namely holes with nanometric size, which overcoming the drawbacks of the physical and permeation leaks [1]. These devices work in the molecular-flow regime up to atmospheric pressure. The nano-holes with diameter of the order of 200 nm are manufactured by milling a silicon nitride membrane 200 nm thick by means of Focused Ion Beam (FIB) [2]. An example of a nano-hole with diameter of 200 nm is shown in figure 1. The geometrical dimensions were determined by Scanning Electron Microscopy (SEM), Scanning Transmission Electron Microscopy (STEM) and Atomic Force Microscopy (AFM) [3]. The performances of the leak devices have been studied using a primary gas flowmeter [4]. The measurements are carried out by a direct comparison of the unknown flow rate from the leak devices based on nano-holes with the known flow rate from the primary gas flowmeter [5]. By direct simulation Monte Carlo method the conductances of these short tubes were calculated from the measured dimensions. The calculated conductances agreed with the values measured by comparison with a primary gas flowmeter within their respective uncertainties.

Acknowledgements-This work is funded by EMRP (European Metrology Research Programme). The EMRP is jointly funded by the EMRP participating countries within EURAMET and European Union.

Development of new materials and ultra clean processes using the vacuum – plasma – levitation technique

T15 Vacuum Science and Technology

#VST-P1-24

Y. Shin, S. You.

Korea Resear Institute of Standards and Science - Daejeon (Korea, republic of).

It has been known that a lot of new and noble materials which is hard to be synthesized in the earth can be made in the space. We have tried to make space simulated environment system in the laboratory by developing the system conversing the representative elements of the space, such as a vacuum, a plasma and a non-contact status from any other things. The space simulated environment system has been designed and developed. This system was consisted with the precisely controllable vacuum - plasma system, the sample levitation equipment and the temperature control system. Levitation technique can reduce the contamination from the container and the contact effect during the heating process. If we can feed ultra clean material during the well controlled vacuum – plasma – temperature process, we can develop new materials or new processes. In this system, we made the pure particles and tried to use as the evaporating materials immediately without any contact with container. Not only the design and the development processes of the system, but also its application results will be presented. This technique can be expected to be applied in the development of the next generation processing equipment in manufacturing as well as new material synthesis.

Nano particle synthesis and control in the vacuum-plasma-levitation chamber.

Mass spectrometry residual gas analysis: a key tool to optimize the packaging of MEMS

T15 Vacuum Science and Technology

#VST-1-Or-8

P. Nicolas, P.L. Charvet, D. Bloch, B. Savornin.

CEA, LETI, MINATEC Campus - Grenoble (France).

A vacuum packaging process is required for most of MEMS sensors or actuators such as accelerometers, gyroscopes, resonators, RF switches, micro bolometers. Indeed, the MEMS devices operation and reliability are critically dependent on the vacuum level inside the MEMS cavity after sealing (fig 1). This vacuum level can be improved by using porous absorbing materials, namely getter materials which are deposited inside the MEMS cavities before sealing. Their pumping properties are however gases dependent and it is then important to be able to identify and quantify the different residual gases inside the very small MEMS cavities (~1mm³ or less, at pressure level usually in the 10⁻² to 10⁻³ mbar range. Although different methods have been explored [1], the Residual Gas Analysis (RGA) method -however destructive- reveals to be an interesting one to determine the possible sources of gaseous species present in the MEMS package cavities, in order to assess their reliability.

This paper introduces results recently achieved with a specific RGA test bench, developed at the CEA-LETI (fig 2). This equipment operates with a residual background pressure level in the 10⁻¹⁰ mbar range and uses a quadrupolar mass spectrometer (QMS) for gas analysis.

Experimental results confirm that the RGA technique may be successfully used to identify the nature and proportions of gaseous species [2], trapped in cavities as small as 1 mm³ under a residual pressure lower than 10⁻² mbar.

Effects of the photon stimulated desorption from the surfaces cleaned with ozonized water

T15 Vacuum Science and Technology

#VST-P1-25

G. Hsiung, C.M. Cheng, Y.T. Cheng, C.K. Chan, C.C. Chang, J.R. Chen.

NSRRC - Hsinchu, Taiwan.

The significant pressure burst, typically rising up to more than 3 orders of magnitude, due to the photon stimulated desorption (PSD) from the fresh surface of vacuum beam ducts irradiated by the synchrotron radiation in a large accelerator is a major problem to the beam instability and the limitation of the beam life time. In previous studies [1] in the 1.5 GeV synchrotron accelerator Taiwan Light Source (TLS) the typical outgas molecules of the PSD emitted from the OFHC copper (Cu) or aluminum (Al) alloys contain hydrogen (H₂), carbon monoxide (CO), carbon dioxide (CO₂), methane (CH₄), and water vapor (H₂O). Those outgas molecules comprised of three atoms: H, C, O, were formed on the surface through the complex of recombination or dissociation processes prior to desorption. Any effective surface treatment to reduce the quantity of contamination-atoms in the surface oxide layers will dramatically reduce the rate of PSD-outgas. A cleaning process with ozonized water applied to the pre-cleaned surfaces of Al and Cu has been studied. The Al-chambers were machined with pure alcohol as the coolant and lubricant to protect the surface from oil contamination. A further cleaning with the high purity ozonized water was applied to the machined pieces for thoroughly cleaning of the surface residual contaminants, e.g. C, Cl, Na, F, etc. The thermal outgassing rate of the Al samples after oil-free machining and the ozonized water cleaning (with a concentration of 30 ppm) reaches to a value of $\sim 6.4 \times 10^{-12}$ Pa·m/s after a 24-hours baking at 150 °C.[2] The yield of PSD for Al or Cu samples measured at the 19B(PSD) beam line of the TLS is lower than 5×10^{-5} molecules/photon at the beginning of the photon exposure period which is more than ten times lower than those treated with conventional surface cleaning process. The surface characterization for both Al and Cu samples after the cleaning process presents a lower surface contamination and the consequent lower rate of PSD-outgas. More photon exposure experiments for various materials, e.g. Al, Cu, or stainless steel, are

performed and the effects of the PSD for the samples with or without ozonized water cleaning will be analyzed and described in this paper.

VST-P2-05

Development of a fast mask for Diamond Light Source beamlines

T15 Vacuum Science and Technology

#VST-P2-05

H. Shiers, M. Cox, S. Omolayo, J. Emmins.

Diamond Light Source - Didcot (United kingdom).

Diamond Light Source is the UK's national synchrotron light source. In order to protect the storage ring ultra-high vacuum from a vacuum incident in a beamline, vacuum valves and fast closing valves (10ms) are installed in each of the 22 operating beamlines which close automatically in the case of a vacuum excursion. The main water-cooled photon absorber in each beamline can take several seconds to close and, to avoid photon beam damage to the vacuum valves, it has been necessary up until now to dump the electron beam in the storage ring in case any valve is required to close across the "hot" photon beam. This can result in nuisance x-ray beam trips of the whole facility. A fast mask has recently been developed and tested which is guaranteed to close within 100ms and which can protect downstream vacuum valves by withstanding the "hot" photon beam during the time required to close the main photon absorber in the beamline. This removes the need to dump the stored electron beam in many circumstances with a consequent benefit on facility uptime.

The development and evaluation of the new fast mask, material selection, incorporation into the Diamond Light Source control system and some challenges which had to be overcome will be described.

VST-P2-06

In-house development of PLC controlled vacuum systems for experimental stations at Diamond Light Source

T15 Vacuum Science and Technology

#VST-P2-06

S. Omolayo, P. Amos, H. Shiers, J. Emmins, M. Cox.

Diamond Light Source UK - Didcot (United kingdom).

Diamond Light Source is the UK's national synchrotron light source currently with 22 operating beamlines each with an associated endstation. Some of these endstations are complex ultra-high vacuum systems in their own right, which have to be operated by non-expert users and which have a windowless interface to the x-ray beamline and the electron storage ring. A complex endstation control system with a large number of different dynamic states is therefore required and a PLC-based solution was selected and developed. As well as having an intuitive user interface, the endstation control system has to prevent inappropriate user operations, to provide automated functions for pump down, baking out, venting, sample transfers and valve operation as well as providing interfaces to the main Diamond Light Source EPICS control system. In addition some end stations need complex gas inlet systems for sample dosing combined with regulated pumping speed using PID controlled valves.

The design and development of these end stations, the hardware chosen and its integration into the PLC system as well as into the main EPICS control system will be described. The development and testing of the PLC code for automation of routine operations and for protection against incorrect operation and fault conditions will also be discussed.

Absorption of noble gases by sputter-ion pumps: investigating synergetic pumping mechanisms for a better integration with non-evaporable getters

T15 Vacuum Science and Technology

#VST-P1-22

T. Porcelli, A. Bonucci, F. Siviero, A. Conte, L. Caruso, P. Manini.

SAES Getters S.p.A. - Lainate (Italy).

Ultra-high vacuum (UHV) conditions, corresponding to pressures lower than 10^{-9} mbar, are nowadays essential for a large variety of technological applications, ranging from large vacuum systems for particle accelerators to small equipment for portable analysers and devices. The achievement and maintaining of the required vacuum performances, as well as strict constraints in terms of design, size and weight of the vacuum components, led to the development of a novel combination pump, called NEXTorr[®], whose functioning is based on the synergetic integration of a non-evaporable getter (NEG) cartridge, representing the main pumping element, and a small sputter-ion pump (SIP) [1]. After having been activated, the NEG cartridge is able to adsorb on its surface all the chemically reactive gases normally present in a vacuum system, i.e. H₂, O₂, N₂, H₂O, CO and CO₂; on the other hand, the SIP is responsible for pumping inert gases and hydrocarbons (especially CH₄), which are not pumped by NEG. The compact and integrated design enhances the synergy between the two pumping elements, providing pumping efficiency for methane and noble gases higher than the one ensured by the sole SIP. A deeper understanding of the sorption mechanisms of sputter-ion pumps for noble gases is a key factor to further develop the combination pump technology, aiming to enhance its overall pumping efficiency. A series of sorption tests has been conducted for different SIPs; data will be presented with special focus on the pumping of helium, neon, argon and krypton, which are employed in several imaging and analytical instruments. Furthermore, important side effects – such as gas regurgitation during pumping of these species – will be shown and discussed. Lastly, the interactions of certain gases with the inner surfaces of a SIP have been studied and the positive effects of this *purging* mechanism on pumping efficiency will be described.

High-Vacuum Metrology at NIST

T15 Vacuum Science and Technology

#VST-1-Or-4

J. Fedchak.

National Institute of Standards and Technology - Gaithersburg (United states).

The vacuum calibration laboratory at the National Institute of Standards and Technology (NIST; USA) is responsible for realizing and disseminating the SI for pressure covering the range of 10^{-7} Pa to 1 Pa, and for low gas flow from 10^{-6} mol/s to 10^{-13} mol/s, in addition to performing research and development related to metrology in vacuum and low gas-flow. Standard calibration services are offered for ionization gauges, spinning rotor gauges, and He leak artifacts. The heart of the laboratory is the constant pressure flowmeter, which is used as a low gas-flow standard and is also used as a source of a known gas-flow for the dynamic-expansion systems that are the NIST high-vacuum standards. Recent projects include long-term ionization gauge stability studies and developing an orifice flowmeter that can produce low gas-flow based upon a flow calibrated laser-drilled pin-hole orifice. In this talk, an overview of the vacuum lab standards will be given and the results of recent research projects will be presented.

ASTeC, STFC Daresbury Laboratory, Warrington, WA4 4AD, U.K

Author: mark.pendleton@stfc.ac.uk

The ASTeC Vacuum Science Group, based at the Cockcroft Institute STFC Daresbury Laboratory, primarily focus on the design and operation of large vacuum systems for particle accelerators. One of the main interests is accurate total and partial pressure measurements.

Utilising the existing secondary vacuum gauge comparison facility it has been upgraded to perform accurate RGA comparative measurements in the range between 10^{-10} and 10^{-5} mbar to an extractor gauge calibrated against a primary standard.

In a reported study initial background measurements were taken and recorded for the three instruments which include a Granville Phillips Ion trap 1-145amu, and two standard RGA units from different manufacturers' (Hiden Analytical and MKS) with 1-50amu and 1-200amu respectively. Gas injections at two points per decade are

performed within the pressure range along with separate stage gas mixtures to also study the cross influence of masses, particularly those of interest found within the accelerator.

The presentation will highlight the comparative data obtained using the three instruments which will include the gas species studied over the cited pressure range, calibration coefficients, linearity of the instruments over time and also the influence in which common gases found within the accelerator have upon each other.

Theoretical and experimental investigation of metal foil vacuum pumps for pumping and separating hydrogen

T15 Vacuum Science and Technology

#VST-4-Or-4

T. Giegerich, C. Day.

1 - Karlsruhe (Germany).

At KIT Karlsruhe, a new vacuum pump based on the physical principle of superpermeation is under development. This 'metal foil pump' shall be used in the fuel cycle of fusion power plants. This pump provides two major functions, separating and pumping, simultaneously for hydrogen and its isotopes. It separates a hydrogen and impurities containing gas flow sharply into a pure hydrogen flow that is also being compressed. The remaining impurity (i.e. non-hydrogen gas species) enriched gas flow passes the pump without being pumped.

For superpermeability, a source of molecular hydrogen is needed. This can be achieved by different methods and directly inside the pump. Most important are plasma based or hot rod (atomizer) based methods. For safety reasons (low temperatures in a hydrogen environment) and to be more energy efficient, the plasma method is favored in technical applications though it still needs a high development effort.

An experimental arrangement was set-up to investigate the pumping behavior of metal foils and to produce data for scaling. This asks for an experimental device where atomic hydrogen with clearly defined parameters and at a known flux can be produced and accelerated towards the metal foil. Furthermore, the metal foil has to be heated to investigate it at different temperatures and in a schematic way. It must be easily demountable and withstand the pressure difference during a helium leak test.

In this paper, first results are presented and the physical working principle including modeling of such a metal foil pump is discussed. Furthermore, the development towards a technical-scale pump is shown up.

Status of the Spiral 2 project - Overview of the vacuum system

T15 Vacuum Science and Technology

#VST-3-Or-3

P. Dolegieviev.

CEA / GANIL - Caen (France).

The Spiral 2 facility is a rare isotope accelerator that will be installed on the GANIL site at Caen (Grand Accélérateur National d'Ions Lourds). This machine is dedicated for the production of high intensity radioactive ion beams using ISOL technique (Isotope Separation On Line). Spiral 2 facility is based on a high power superconducting driver LINAC delivering a deuteron beam (5 mA / 40 MeV) and heavy-ion beams (1 mA / 14.5 MeV/u). Radioactive beams are produced by fission reactions of a Uranium target (UCx) maintained at 2000°C and subjected to a high neutron flux. Fission products of different reactions are then scattered out of the target, ionized, separated on line and post-accelerated into the existing CIME cyclotron at GANIL.

The construction of the facility is organized in two phases. First phase including the superconducting driver accelerator and its associated experimental areas, and a second phase including the radioactive ion beams production, the low energy experimental area and the connection to GANIL existing facility. The Spiral 2 facility is now in its construction phase, with the objective of obtaining the first beams with the first phase during 2014.

This paper presents an overview of the project and a status of the construction. A general presentation of the Spiral 2 vacuum system is given, with a focus to the constraints due to the radioactive environment. The specific vacuum systems designed for safety functions are briefly described (storage exhaust gas system, fast valves system and specific trap to limit the radioactive transfer of volatile contamination in the beam lines).

A. Rauch.

graduate of diploma program - Feldkirch (Austria).

Penning Gauges Revisited

Albert Rauch^{1,2}, Hans K. Pulker¹, Martin Wüest³

¹ Institute for Ion Physics and Applied Physics, University of Innsbruck, 6020 Innsbruck, Austria

² now at ThyssenKrupp Presta AG, Essanestrasse 10, LI-9492 Eschen, Liechtenstein

³ INFICON AG, Alte Landstrasse 6, LI-9496 Balzers, Liechtenstein

The plasma in a Penning gauge has been studied in depth with optical emission spectroscopy, Langmuir probes and a retarding field analyzer.

A Langmuir double probe was used to measure the plasma parameters at the center of the discharge. The obtained results are the electron temperature and plasma density. The temperature was found in the range of 1-4.8 eV at a discharge voltage of 1600V. It shows that changing the type of gas has little effect on the electron temperatures. Temperature versus neutral density (pressure) indicates that electron temperature decreases with increasing neutral density, due to the increase of the collision frequency and therefore increases the amount of cooling (electron lose a certain amount of energy through inelastic collisions with neutrals).

Optical Emission Spectroscopy (OES) provides a non-evasive probe to investigate discharge plasma. The optical emission from the Penning gauge was viewed across the anode ring, parallel to the cathode plates. To examine the influence of gas type on the performance of the gauge, different pressures were set and the various spectra were recorded, yielding the dependence of the different emission lines on the discharge current. The observed N₂ rotational temperature is almost the same as the gas temperature.

Retarding field analyzer(RFA) were used to estimate directly the ion energy distribution (IED) of the incident ion flux on the gauge cathode material. The observed mean ion energies have values in the range of 150-525eV and the energy spread is in the range of 5-45eV as the pressure drops from $p = 1 \cdot 10^{-2}$ mbar to $2 \cdot 10^{-6}$

mbar, while the maximum ion energy is in the range of 300-630eV. It is shown that at constant anode voltage, a decrease in gas pressure is accompanied by a monotonically increase in ion energy.

Novel design for ultralow magnetic stray fields in cold cathode gauges

T15 Vacuum Science and Technology

#VST-5-Or-9

B. Andreaus.

Inficon AG - Balzers (Liechtenstein).

Electromagnetic interference from low-intensity static magnetic fields has been observed to affect the operation of pacemakers and other medical electronic devices. The ICNIRP Guidelines [1] recommend that those devices are not adversely affected by static magnetic fields below 0.5 mT. These recommendation have been incorporated into the Semiconductor Manufacturing Standard SEMI S2-0302 [2] and requires that the magnetic field at exterior surfaces of the equipment (2 to 3 cm from the surface) has to be smaller than 0.5 mT or a pacemaker warning needs to be posted. This is why presently available cold cathode gauges should (but most do not) carry a pacemaker warning label, because they do not fulfill the SEMI S2 standard.

Moreover, from a technical point of view, the presently available cold cathode gauges' magnetic stray fields may impede their usage in applications sensitive to such fields as in the case of analytical instruments.

We have developed an inverted magnetron with a novel magnetic field design, keeping exterior magnetic stray fields below the threshold set by the SEMI norm, and thus extending the usefulness of cold cathode gauges to applications where magnetic stray fields are critical. In this paper, the magnetic design of this inverted magnetron is presented in detail.

A simplified vacuum system for the new PC gun in the FERMI@Elettra project.

T15 Vacuum Science and Technology

#VST-P2-07

L. Rumiz, I. Cudin, E. Mazzucco, G. Pangon, M. Trovò, F. Zudini.

ELETTRA Sincrotrone Trieste S.C.p.A. - Trieste (Italy).

The construction of the FERMI@Elettra machine, the single-pass FEL user facility located in Trieste (Italy), started in May 2009. The first installed part was the photoinjector. It was designed to work at a repetition rate of 10 Hz. Its vacuum system is able to keep the pressure lower than $1 \cdot 10^{-9}$ mbar at the photocathode. To reach the 50 Hz rep-rate target, a general upgrade of all the RF plants has been implemented. A new PC-Gun has been also developed with a new and more compact mechanical design that requires a new pumping system. The main challenge was to simplify it, preserving the good vacuum performance of the first gun.

A comparison of the vacuum system designs between the previous and the new gun is discussed.

Simulation of electron stimulated desorption ion effect based on Axial-symmetric transmission gauge

T15 Vacuum Science and Technology

#VST-P2-24

D. Li ¹, H. Zhang ², C. Dong ³, Y. Feng ⁴, Y. Cheng ⁴, Z. Xi ⁴, Y. Xiao ⁴, Y. Wang ⁴.

¹Teacher - Lanzhou (China), ²Student - Lanzhou (China), ³Teacher - Wenzhou (China), ⁴colleague - Lanzhou (China).

The effects of electrode voltages and structure on the collection rate of electron stimulated desorption (ESD) ions in axial-symmetric transmission gauge (ATG) were studied by the theoretical simulation, which was in favor of providing theoretical basis and experimental guidance for analyzing the ESD ion effect, and the study possesses significant meaning to minimize the ESD ion effect and develops new types of extreme high vacuum gauges. Based on Axial-symmetric transmission gauge (ISX2), a physical model was constructed, and the influence of energy analyzer voltage (V_{be}) on ESD ions collection ratio was investigated with the aids of the ion & electron optic simulation software SIMION 3D 8.0. Meanwhile, the experimental study of the ESD ion effect was carried out. Excellent agreements were demonstrated between the theoretical simulations and experimental results. Namely, after crossing the energy analyzer, the energy difference of the ESD and gas phase ions was about 40eV in the ultimate vacuum (1.0×10^{-9} Pa) in both cases. The energy difference between the ESD and gas phase ions would be increased to about 60eV via optimizing the model structure. Consequently, by considering that the effect of gauge structure on the collection ratio of gas phase ions is relatively little, energy difference between two kinds of ions will increase by optimizing the structure reasonably, which was in favor of minimizing the ESD ion effect.

Comparison of the standards for high and ultrahigh vacuum at LIP laboratory

T15 Vacuum Science and Technology

#VST-P1-07

Y. Cheng, D. Li, Y. Feng, W. Wei, Z. Xi, L. Zhao.

colleague - Lanzhou (China).

A comparison of standards based on different principles for high and ultrahigh vacuum was carried out by the Lanzhou Institute of Physics (LIP) of China. The static expansion standard (SES) ^[1] and separated flow standard (SFS) ^[2] were used in the present comparison. Two commercially available gauges, a Bayard-Alpert gauge (BAG) and an extractor gauge (EXG), were chosen as transfer standards. The argon

pressures generated by the standards from 4×10^{-7} Pa to 1×10^{-3} Pa were compared by measuring the sensitivity of the two ionization gauges. The deviation

was used to describe the agreement of the two standards. The BAG results show an agreement of 0.72% and the EXG results show an agreement of 0.64%. The SES-SFS differences are all within the combined uncertainties of the standards. By this intercomparison, the method to extend the lower limit of the SES by using non-evaporable getter pump to eliminate the outgassing influence has been demonstrated. The SES is to be used in China as a primary standard of ultrahigh vacuum.

Electrohydrodynamic microflows in a ring-type mixing chamber

T15 Vacuum Science and Technology

#VST-P2-17

Y. Kim ¹, H.S. Seo ².

¹School of Mechanical Engineering - Suwon (Korea, republic of), ²Graduate School of Mechanical Engineering - Suwon (Korea, republic of).

Micro/nano-scale mixing is emphasized in various applications such as homogenization solutions of reagents in chemical and biological reactions, synthesis of nucleic acids and nano drug delivery system, etc. [1]. Especially, electrokinetically driven flow such as electroosmotic flow (EOF) is a highly attractive alternative to pressure-driven flow for fluidic handling and reagents transportation in microfluidics and nanofluidics [2].

In this study, the electrokinetic microchannel with a ring-type mixing chamber was investigated to fast mixing of the species. The three dimensional modeled micromixer that is applied for the electroosmotic effect takes two fluids from different inlets and combines them in a ring-type mixing chamber, and then these are mixed by forming a vortex flow due to applied electric potential at electrodes. The schematic of modeled micromixer applied to this study is shown as Fig. 1. We numerically investigated flow characteristics with electrode dispositions in the ring-type mixing chamber using a commercial code, COMSOL Multiphysics.

Effective mixing basically involves repeated combinations of stretching and folding of fluid elements and small scale diffusion. They were influenced by the electric fields that were produced by each electrode. Also, the vortex flow fields were formed around the electrodes in the mixing chamber and its configurations formed differently caused by electrode dispositions. Through these phenomena, the fluid particles that stayed in the central loop stretched and folded for a long time before they entered the outlet section of the microchannel (see the Fig. 2). In additions, we will discuss the concentration distributions of the dissolved substances in the working fluid and three dimensional flow fields, and compare the mixing performance in the modeled micromixer with various operating conditions.

Time dependent gas mixture flow through a short tube in a wide range of the Knudsen number

T15 Vacuum Science and Technology

#VST-7-Or-8

M. Vargas ¹, S. Naris ¹, D. Valougeorgis ¹, S. Pantazis ², K. Jousten ².

¹University of Thessaly - Volos (Greece), ²Physikalisch-Technische Bundesanstalt - Berlin (Germany).

Steady-state gas flows through channels of various lengths and cross sections under low, medium and high vacuum conditions have been successfully modeled based on kinetic theory. Reliable results for the conductance, as well as for the flow field have been obtained with moderate computational effort in the whole range of the Knudsen number [1].

In important industrial applications like coating processes, however, fast pressure changes are required and the time response of the vacuum gauge and the vacuum system becomes important. In many of these applications, gas mixtures are involved. In spite of their high practical interest, time dependent flows of gas mixtures have attracted little attention, which is limited so far to unsteady single gas flows [2,3], while the corresponding problems for gas mixtures have not been investigated yet. It is noted that compared to single gases the computational effort for solving gas mixture flows is significantly increased due to the large number of parameters involved in the simulations.

Recently, in order to examine the time response characteristics of gas mixtures compared to single gases, an investigation of rarefied time-dependent binary gas mixture flows through short tubes has been initiated. Within this framework, in the present work the unsteady flow of a gas mixture, namely He-Xe, through a short tube is investigated based on the DSMC method. Preliminary results are provided for one molar fraction of the mixture at typical values of the downstream over the upstream pressure ratio and for some values of the reference Knudsen number covering the free molecular and transition regimes. The critical time needed to reach the steady-state flow conditions is computed and its dependency on the flow parameters

(pressure ratio and Knudsen number) is examined. A detailed view of the flow field is also presented by plotting the transient velocity and density distributions of each species of the mixture. Furthermore, the time dependency of the separation effect, which is always present in gas mixture flows due to the different molecular velocities of the species is considered. A comparison with the corresponding single gas time dependent flow is provided to point out the main differences between the flow conditions in unsteady single and gas mixture flows.

VST-P2-08

Protection of the HIE-Isolde superconducting linac against air inrush

T15 Vacuum Science and Technology

#VST-P2-08

G. Vandoni, M. Hermann.

CERN - Geneva (Switzerland).

The High Intensity and Energy ISOLDE (HIE-ISOLDE) project aims at upgrading CERN present ISOLDE and REX-ISOLDE facilities to increase the energy and intensity of the delivered radioactive ion beams [1]. Energy up to 10 MeV/amu is reached by means of a new post-accelerating, superconducting linac, consisting of quarter wave resonators housed in 6 cryomodules. Three beam drift lines transport the accelerated beam to the three experimental stations. In order to avoid cold-warm vacuum transitions and thus better cope with effective space limitations, the cryomodules feature a common beam and insulation vacuum, imposing the high standards of cavity beam vacuum to the ensemble of the cryostat [2]. Protection against sudden air inrush from the experimental stations is achieved by a fast closing valve, built in the line close to the last cryomodule of the linac, following a scheme generally applied to beam lines in synchrotron light sources [3]. With a short distance between the potential leak source – the experimental station – and the valve, and with particulates swept along the transfer lines at the same speed as the pressure front, even the reported very short reaction time of the valve may not be sufficient to prevent particulate contamination of the cryomodule volume. Delay of the pressure front progression may be achieved naturally by the series of expansion volumes and restrictions naturally embedded in the transfer lines layout in the form of beam transport and diagnostics elements. To evaluate the propagation speed in the real lines, as well as to assess the efficiency of short acoustic delay devices, a Finite-Element simulation of the air inrush dynamics has been performed. A test stand has been set up, with the scope of measuring the valve's reaction time and to experimentally validate the delay effect of a small expansion volume, a stack of diaphragms, a cold section, a deflector.

Numerical analysis of the non-isothermal gas flow through a packed bed of spheres

T15 Vacuum Science and Technology

#VST-P2-25

E. Afrasiabian, L. Marino, C.M. Casciola.

Department of Mechanical and Aerospace Engineering, University "La Sapienza" - Rome (Italy).

The advent of micro-devices with high specific power raises the important challenge of how to dissipate the heat fluxes produced by the active components inside the micro-systems. In this frame, gas flows through porous and/or fibrous media is particularly appealing due to their potentially high capability to transfer the heat. While the gas flow through simple micro-devices, like micro channels and micro tubes, has been widely investigated and quite well understood, the physics of rarefied gases through porous matrices is still matter of discussion. Though the literature on transport phenomena through porous media is very large, most of the published papers deal with the flow of an incompressible fluid. Concerning the analysis of the temperature effects in porous media, a great attention has been devoted to convection but, again, in the continuum regime. The influence of the compressibility of a gas flow through a porous matrix can be re-conducted to the prediction of the Klinkenberg law, which actually applies to isothermal flow. To take into account the effects of a possible rarefaction of a gas flow some investigations have been done. Some efforts have been carried out to establish simple numerical models based on DSMC (Direct Simulation Monte Carlo) simulations, as in Ref. [1]. DSMC shown to be a very efficient method to simulate rarefied gas flows, in particular at high speeds (more generally, at high values of the signal to noise ratio). On the other side its computational cost increases dramatically when the typical values of the molecular velocities are comparable with the thermal speed. As a consequence, simulations of low speed flows, like those at micro and nano scales, can be really expensive from the computational point of view. Although some efforts have been done to reduce the statistical errors for the molecular simulation methods and low-noise Monte Carlo simulations have been presented. Alternative approaches to simulate the gas dynamics near the equilibrium state are based on the solution of the kinetic equations, in particular by means of BGK or S

models, and some results have been preliminary carried out for the analysis of flow through porous medium. In this paper we present numerical results concerning the gas flow through a porous medium made of a packet bed of spheres. Our approach is based on the Boltzmann equation considering the effect of porous matrix as an additional parameter inside the collisional term proposed by Pavan et al. [2]. This problem, already studied in the isothermal case in [1] by means of DSMC, is here extended to a physical situation where the heat transfer plays an important role, by solving the above mentioned homogenous kinetic equation. We analyzed the case of the gas flow through an annulus between two concentric cylinders filled of porous medium and constant surface temperature or a known heat flux as boundary conditions on the internal cylinder. The corresponding flow is characterized by a Knudsen number (Kn) that spans from the almost continuum flow to nearly free molecular regime.

Stainless steel is one of the main materials used for particle accelerator vacuum chambers and components. The surface preparation, history and condition of use strongly affect the outgassing rate and particle-induced gas desorption. The electron stimulated desorption (ESD) was studied for 316L stainless steel as a function of electron dose, electron energy, and wall temperature. The effect of duration of pumping before the bombardment was also studied. The surface preparation can also affect the results. The ESD yields were compared for polished and TiN coated surfaces. The experimental details and results will be reported.

Optimisation of Non-Evaporable Getter Coatings for Particle Accelerator Vacuum Chambers

T15 Vacuum Science and Technology

#VST-5-Or-5

R. Valizadeh ¹, O. Malyshev ¹, B. Hogen ¹, A. Hannah ¹, R. Jones ².

¹STFC Daresbury lab - Warrington (United kingdom), ²university of Bath - Bath (United kingdom).

The pressure in particle accelerator vacuum chamber bombarded with energetic particles (photons, electrons, ions, etc.) is defined by the desorption induced by these particles and the available pumping speed. When the non-evaporable getter (NEG) coating is applied, the pumping speed is close to ideal for CO and CO₂. To reduce the pressure further the main attention was devoted to reducing the particle induced desorption from the NEG coated walls. The dense coating provides lower pumping speed compared to the columnar one but reduction in desorption yields is much more significant, therefore the net effect is a lower pressure in a vacuum chamber. Use of dual layer coating NEG coating allows desorption yields to be reduced with a dense NEG base layer and have increased pumping speed with a columnar NEG as a second layer applied over the base. These results allows reaching the required UHV/XHV conditions at lower cost and, in some cases, is the only solution. In the reported experiments, the samples were 38-mm diameter and 0.5-m long stainless steel tube with the entire internal surface coated. The pumping speed of the sample was measured by H₂, CO and CO₂ injection. The desorption properties were evaluated by measuring the electron stimulated desorption yield with 500-eV electrons emitted from a filament placed along the tube axis bombarding the tube walls. The experimental details and results will be reported.

VST-2-Or-3

Evaluation of efficient use of molecular drag pumps in vacuum coating systems

T15 Vacuum Science and Technology

#VST-2-Or-3

J. Bhatti, S. Qaiser, K. Chaudhary.

The Islamia University of Bahawalpur - Bahawalpu (Pakistan).

The beginning of the twentieth century has seen an increasing use of high vacuum in the industrial processes such as thin films, plasma displays, PVD, sputtering, ion etching, simulators and fusion research. These applications greatly depend on the clean environment that requires oil-free pumping. Molecular drag pumping is a rather new and quite good technique for the creating of high vacuum. The present studies represent a real model of a molecular drag pump with an emphasis on its design, theoretical development and vacuum characteristics. Although a complete theory of molecular drag pumps has never been published and theoretical studies are also a few in numbers, yet effort has been made to evaluate a complete theoretical and practical picture of a molecular drag pump. Using a prototype, potential capabilities of a molecular drag pump in vacuum coating processes have been experimentally explored. The results are in quite good conformity to the theoretically computed values.

At the end some applications and use of these pumps in various industrial and technological areas have been high lighted

Gallium Arsenide (GaAs) photocathodes have in recent years been widely used and have become the focus for use in modern accelerators and light sources such as the Accelerators and Lasers in Combined Experiments (ALICE). Once activated to a Negative Electron Affinity (NEA) state and illuminated by a laser, these materials can be used as a high-brightness source of both polarised and un-polarised electrons. Activated GaAs is extremely sensitive to the vacuum environment and its performance can be compromised if the presence of particular gas species are not minimised. This paper will present the influence of O₂, CO₂, CO, N₂, H₂ and CH₄ gas injections on the stability of the quantum efficiency (QE) of a negative electron affinity (NEA) gallium arsenide (GaAs) photocathode activated with caesium (Cs) and oxygen (O). This is the first time this has been demonstrated under an extreme high vacuum (XHV) condition, with a base pressure of 6.0 E-12 mbar, where the influence of the background gas is minimised. It was found that exposure of a GaAs photocathode to N₂, H₂ and CH₄ does not affect the QE, whereas exposure to O₂, CO₂ and CO leads to a substantial reduction in photocathode QE. It was also found that the QE of photocathodes which have been degraded under O₂ exposure can be recovered to 95% of their initial QE level by the re-caesiation process, while those which have been degraded under exposure to CO and CO₂ can only be partly restored to 60 - 70% of their initial QE levels.

RAREFIED HELIUM DYNAMICS SIMULATION IN THE “ITER” CRYOSTAT FOR LEAK MAPPING AND DETECTION

T15 Vacuum Science and Technology

#VST-7-Or-9

D. Gordillo ¹, A. Kumar ², A. Kumar ², S. Claude ¹, T. Amita ¹, W. Liam ³,
P. Robert ³, A. Alexander ³.

¹FLUIDYN France - Saint-Denis (France), ²FLUIDYN India - Bangalore (India),
³ITER Organization - St Paul Lez Durance (France).

Currently under construction in the South of France the ITER project will be, on completion, the largest superconducting fusion device in the world capable of operating with tritium. Key to the success of ITER is the reliable operation of its vacuum systems and it is expected that

Helium leaking from cryogenic components installed in the ITER cryostat will be a cause of significant delays to the ITER program unless the leaks can be localized and repaired in a timely fashion.

It has been proposed that by the use of multiple sensors permanently installed in the cryostat the location of a leaking component can be identified by the creation of a concentration map derived from the sensor signals. In order to the feasibility of this concentration map technique, simulations of gas expanding into cryostat geometries have been performed details of which are described in this paper.

At pressures inside the domain ($\sim 10^{-4}$ Pa), the mean free path of molecules is larger than the characteristic dimensions of the Cryostat. The equations for continuous media are no longer applicable, and the system behavior is in the molecular regime.

Therefore simulations are performed by tracking the molecules inside the domain by Direct Simulation Monte Carlo (DSMC), using the PI-DSMC numerical software.

The Maxwell speed distribution is used for each speed component in the space. The mean thermal velocity is found to be 650 m/s. The global flow is directed outwards from the injection point, the mean flow velocity calculated and added to the thermal speed, in the direction in which the leak is pointing.

It is shown that for leaks with small magnitude (0.01 Pa.m³/s), the steady state distribution in the cryostat is reached in approximately 3 s. The oval shaped gas plume bounded in space by a steep concentration gradient beyond which the

background concentration is continuous reducing the possibility of detecting the leak beyond this space.

The results of simulating small leaks expanding into a “large” open free volume of the cryostat vacuum show that the cryostat vacuum scarcely affected as there are a low number of molecules leaking to occupy the space and therefore, change the background pressure.

For the cases in which the leak expands into a smaller, packed, free volume (full geometry), the number density increases quickly and vacuum is may be perturbed. In this case, the plume may be better detected on surfaces opposite to the leak location, as the molecules near the opposite surface can accumulate over it or may be reflected back towards the leak location. Additionally the plume size will be affected by the surface temperatures surrounding the leak and detection may be further enhanced.

Simulations performed using a cryostat geometry which includes all geometric characteristics at representative temperatures are presented an, based on these results, preliminary design requirements will be drawn for gas detection systems which may be installed in the cryostat.

VST-P2-09

Pumping system of neutral beam injectors.

T15 Vacuum Science and Technology

#VST-P2-09

A. Dranichnikov, V.V. Anashin, A.A. Ivanov, V.S. Khrestolyubov, V.V. Kobets, V.A. Polukhin, D.K. Toporkov.

BINP - Novosibirsk (Russian federation).

A review of different types of vacuum pumping systems for injectors of neutral hydrogen beams is given. The pumping systems based on a cryo condensation allow to obtain the final pressure between the injection better than 10^{-6} Pa and may to operate under the typical flow rate more than 10 Torr*l/sec with a pumping speed up to 100 m³/sec for hydrogen. Such kind of pumping system is operated in injectors of many plasma systems e.g. in Louzanne (TCV), Boston (ALCATOR), Padova (RFX), Irvain (TAE), Prague (CAMPAS). Another one of injector for tokamak (W-7) for Germany is ready now and will be delivered on site in February this year.

VST-1-Or-9

Calibration of leak artefact for sniffer test by constant volume type flow meter

T15 Vacuum Science and Technology

#VST-1-Or-9

K. Arai, H. Yoshida, T. Kobata.

NMIJ/AIST - Tsukuba (Japan).

A sniffer test, where a leak measurement is performed under atmospheric pressure conditions, is often used for a tightness inspection of objects, for example, air-conditioners. The response of a leak detector against a magnitude of leaks is calibrated by a known-gas flow, which is generated by a leak artefact. To trace the indication of the leak detector to SI-unit, the flow should be calibrated against SI-unit. In this study, a constant volume type flow meter for the measurement of flows into the atmospheric pressure has been designed and fabricated. The calibration system of a leak artefact for a sniffer test was established by using the flow meter.

A measurement principle is based on the pressure rise method. A gas flow rate Q is given by

$$Q = V \frac{\Delta P}{\Delta t}, \quad (1)$$

where ΔP and V are an amount of the pressure change during the time duration of Δt and a volume of a chamber, respectively. A key point of the measurement is the detection of a small pressure increase (about 100 Pa) at the atmospheric pressure (100 kPa). In this flow meter, a pressure change is measured as a differential pressure between two chambers, which are connected by a valve and a differential type diaphragm gauge (FS: 133 Pa) (inset of figure 1).

A change of a differential pressure during a measurement is plotted in figure 1. A leak artefact to be calibrated was a cramped type metal capillary and the test gas is nitrogen. Prior to the measurement, the pressure inside the flow meter was set at 100 kPa and the pressure at the upstream side of the artefact 200 kPa. After the valve was closed at the elapsed time of 0 s, the differential pressure increased with a rate

of 0.22 Pa/s. The volume of the main chamber was 32.33 ml [1]. In case of figure 1, the gas flow from the artefact was calibrated to be 7.1×10^{-6} Pa m³/s with an uncertainty of 2.0 % ($k=2$). By changing the pressure in the upstream of the artefact from 110 kPa to 250 kPa, flows into the atmospheric pressure was calibrated ranging from 1×10^{-6} Pa m³/s to 3×10^{-5} Pa m³/s.

The Vacuum System Design Of A New Electron Beam Test Facility (EBTF) at Daresbury Laboratory

T15 Vacuum Science and Technology

#VST-3-Or-12

J. Herbert, K. Middleman, A. Hannah, O. Malyshev, M. Pendleton, R. Valizadeh.

STFC Daresbury Lab - Warrington (United kingdom).

Recent UK government funding has facilitated the construction of a unique accelerator test facility which can provide enabling infrastructures targeted at the development and testing of novel and compact accelerator technologies, specifically through partnership with industry and aimed at addressing applications in medicine, health, security, energy and industrial processing. The infrastructure provision on the Sci-Tech Daresbury Campus will permit research into areas of accelerator technologies which have the potential to revolutionise the cost, compactness and efficiency of such systems. The main element of the infrastructure will be a high performance and flexible electron beam injector facility using a metal photocathode, feeding customised state-of-the-art testing enclosures, and associated support infrastructure.

This paper will look specifically at the vacuum system design of this unique accelerator detailing the challenging design of the photoinjector, the requirement for shielding of all total pressure gauges and how a differential pumping scheme has been implemented to separate two vacuum systems with 3 orders of magnitude pressure difference over 50 cm. Many other aspects of the accelerator design will be described and data showing the 'real' performance of the accelerator presented.

MEMS Pirani sensor with increased sensitivity for pressure measurements in the fine and high vacuum

T15 Vacuum Science and Technology

#VST-P2-18

F. Voelklein, M. Grau, A. Meier, G. Hemer, L. Breuer.

University of Applied Sciences Wiesbaden, Institute for Microtechnologies - Rüsselsheim (Germany).

Users require inexpensive, reliable sensors compatible with modern signal processing. One answer to this demand may be provided by microsensors, notably based on silicon by using the integrated circuit (IC) technology. On-chip circuitry, high reliability and low cost batch-process fabrication are the advantages offered by IC technology for the realization of MEMS. This approach has been demonstrated also for MEMS Pirani sensors with resistive or thermoelectric detection principle[1-4]. However, up to now, these sensor chips have not demonstrated an increased sensitivity in comparison to conventional hot wire pirani gauges. We analyse the crucial design parameters which determine the pressure response of MEMS Pirani sensors. Based on this analytical thermal model we have optimized the chip design in order to increase the sensor sensitivity, especially in the pressure range between 10^{-3} to 10^{-5} mbar. Furthermore, the analytical calculations are compared with Finite Element Methods (FEM) simulations, which support and confirm the analytical results. The calculated thermal conductances of the optimized microchip are in good agreement with the measured parameters. The signal Voltage $U(p)$ as function of pressure p has been calculated for applying the sensor in a Wheatstone bridge circuit with constant voltage supply. The theoretical voltage-pressure response is in very good agreement with the measured curves. This response shows a significantly increased pressure sensitivity in the high vacuum range (from 10^{-3} to 10^{-5} mbar) compared to conventional Pirani vacuum gauges. Finally, the fabrication steps of the sensors based on batch-process technologies are presented.

MODELLING OF THE RESIDUAL GAS IONIZATION LEADING TO DARK CURRENT CREATION

T15 Vacuum Science and Technology

#VST-7-Or-6

L. Caillault, B. Seznec, T. Minea.

LPGP UMR 8578 CNRS-Université Paris Sud XI, bât. 210, rue Becquerel, 91405 Orsay Cedex - Orsay (France).

In the field of controlled fusion, the high-energy neutral beam injector device which is used as additional heating source to sustain fusion reactions in the tokamak plasma bulk, consists in the acceleration by several electrostatic grids under vacuum of negative ions before their neutralization on a gas target.

The set of grids are connected to high voltage power supplies through an insulating feedthrough - called bushing. Unfortunately, experimental campaigns carried out at IRFM, Cadarache, France have shown that the grid voltage holding was limited by breakdown occurrences (depending on the grid separating distance) and by the creation of an unwanted non negligible electron current (100 mA at 400 kV), usually called dark current. The dark current is the result of electric field emission appearing at the micro-tips at the high voltage electrode surface due to the roughness of the metal (micro-protrusions).

In order to improve the grid voltage holding, a self-consistent modelling of the physical processes occurring in front of micro-protrusions has been developed. This modelling accounts for electron emission as well as heat transfers within micro-protrusions, Joule and Nottingham heating effects and the emitted electron multiplication through ionization collisions with the residual gas, in real three dimension space. Numerical results are presented and discussed.

The present achievement should help designing a new concept for the busing system of the future Neutral injector device useful for the next generation of fusion reactors, like DEMO.

Experimental and computational investigation of rarefied gas flows through bellows and very short tubes

T15 Vacuum Science and Technology

#VST-7-Or-11

C. Day ¹, C. Saglietti ², S. Varoutis ¹, R. Zanino ³.

¹Karlsruhe Institute of Technology (KIT) - Karlsruhe (Germany), ²Karlsruhe Institute of Technology / Politecnico di Torino - Karlsruhe (Germany), ³Politecnico di Torino - Torino (Italy).

Gas flows under vacuum conditions represent one of the main scientific fields in rarefied gas dynamics with many engineering applications, e.g., nuclear fusion. The main characteristic of such flows is that in rough, medium, and high vacuum conditions, the whole range of the Knudsen number (Kn) from the free molecular through the transition and slip regimes up to the hydrodynamic limit may be covered. Typical components of vacuum systems are ducts with various lengths and cross sections, where the estimation of overall macroscopic quantities as mass flow rate, conductance and pressure is of vital importance.

In this context, an experimental investigation of flows through bellows and several very short tubes (with length/diameter ratios in the range from 0.01 to 0.1) in the whole relevant range of Kn (from 0.01 to 50) was performed. The flow is due to a pressure gradient imposed in the longitudinal direction. The experimental work has been performed at the TRANSFLOW experimental facility at KIT [1]. The TRANSFLOW facility represents a reliable tool for measuring the conductance of various geometrical configurations over the whole range of Kn. The main principle of this facility is the dynamic measurement of the pressure difference across the duct by setting a constant mass flow rate through the test channel.

The measured conductance in the aforementioned geometries is compared with available analytical solutions in the free molecular and viscous regimes as boundary cases for validation. Moreover, for the whole range of the Knudsen number, a computational study was conducted based on an open DSMC (Direct Simulation Monte Carlo) code, the results of which are used for additional comparison.

VST-P1-15

Detailed investigation of a CNT emitter-based extractor gauge for pressure reading in the cryogenic beam vacuum system of SIS100

T15 Vacuum Science and Technology

#VST-P1-15

M. Lotz, S. Wilfert, A. Krämer, O. Kester.

GSI - Darmstadt (Germany).

The new main accelerator system of the FAIR project, which is built at GSI in Darmstadt (Germany), will be the SIS100 with a circumferential length of about 1.1 km. This heavy ion synchrotron machine uses superconducting magnets to bend and focus the beam. Consequently, about 80% of its beam line vacuum will be operated at cryogenic temperatures between 5 and 15 K. In order to generate sufficiently low UHV conditions in these sections, cryopumping will be used. To guarantee a long beam lifetime, the vacuum pressure during beam operation may not exceed 5×10^{-12} mbar (H₂). For this reason the assembly of pressure measuring devices in the cryogenic sections have to be taken into account. However, in consequence of the extreme low-temperature conditions the pressure measurement in cryogenic vacuum systems is not a simple undertaking. With the exception of some very special measuring methods, such as particle life time-based measurements, pressures down to $\sim 10^{-12}$ mbar can only be measured by ion gauges of extractor type. Commercially available extractor gauges, however, are equipped with a hot-filament cathode whose operation would introduce an immense heat load to the cryogenic system. Although it is known that these gauges can be operated at LHe temperatures [1,2], nevertheless, their use is commonly avoided. To overcome this problem we developed and investigated an extractor gauge whose hot filament was substituted by a CNT field emitter. Compared to a thermionic cathode, this cathode type does not cause a noticeable heat load.

We will present some emission characteristics of the CNT cathode used and results on its long-term emission stability. Further, we investigated theoretically the operating performance of the CNT emitter-based extractor using AMaze simulation calculations. Finally, results on experimental investigations of the measured behavior and characteristics of the modified gauge in both room temperature and cryogenic

vacuum environments are shown. The low emission current yield of the cathode (~150 μ Amp) appears to be disadvantageously, since it causes a significant increase of the lower measure limit. Nevertheless, the results clearly imply that CNT emitter-based ion gauges seem to be generally suitable for local pressure measurements in cryogenic vacuum systems.

Vacuum Calculations of the FAIR Collector Ring

T15 Vacuum Science and Technology

#VST-P2-10

J. Kurdal.

GSI Helmholtzzentrum für Schwerionenforschung - Darmstadt (Germany).

The Collector Ring (CR) of FAIR (Facility for Ion and Antiproton Research in Europe) is characterised by a circumference of 225m and due to the beam life times a required vacuum pressure in the range of 10^{-9} mbar. The CR is a dedicated storage ring; its architecture is governed by the stochastic precooling of secondary particles, rare isotopes or antiprotons. To reach the required beam life times an in-situ bake-out of the ring is not required. Due to space constraints there is no space for large pumping stations, therefore new pumping solutions were studied. The pumping concept is now based on NEG cartridge/ion getter combination pumps. To define the required pumping speed and positions of the pumps vacuum calculations of the CR were carried out by means of three different programs. The analysis of pressure profile of the whole ring was performed with VAKTRAK (a transfer matrices program), which allowed us to optimise the pumps positions. The conductance of every chamber was simulated with Molflow+, a Monte Carlo Simulation program. Additionally, using VAKDYN, which calculates the dynamic pressure, the dynamic pressure profile in the ring was determined. The results obtained in these calculations will be presented and discussed.

VST-P1-08

A R&D program on Leak localization concepts for actively cooled fusion machines

T15 Vacuum Science and Technology

#VST-P1-08

A. Durocher ¹, D. Anthoine ², V. Bruno ¹, M. Chantant ¹, L. Gargiulo ¹, J.C. Hatchressian ¹, M. Houry ¹, D. Mouyon ¹.

¹CEA - St Paul Lez Durance (France), ²Bertin Technologies - Aix-En-Pce (France).

High vacuum conditions are required for the fusion machines operation. Any leak in the vessel, even micrometric (down to 10^{-6} Pa.m³/s) doesn't allow their operation. The conditions for the leak localization in the next step actively cooled machines like ITER will be more severe and human intervention will no longer be possible. Thus the techniques used in the current actively cooled tokamak like Tore Supra will not be relevant. These techniques consist mainly in pressurization/depressurization cycles of the sub circuits feeding the Plasma Facing Components (PFC). From the Tore Supra experience, some statements can be made. The localization process must be considered in early stage of the cooling circuit design in order to be able to mitigate the leaky PFC. Leak Localization diagnostics which could be quickly deployed as soon as a leak appears are needed.

A R&D program on this last topic has been launched at CEA/IRFM since 2009. Its objective is to define the best experimental conditions and to select the most efficient concepts or diagnostics to localize helium or water leaks quickly maybe by remote operation. Their performances should allow detecting in a few seconds traces of helium or water close to the first wall, corresponding to a micro-leak. Leak sensors would have to be light weight devices in order to be integrated on a carrier or as small as possible to be integrated into the first wall, both of these options should be taken in consideration. The specifications for the Leak Localization concept will depend on the constraints of each machine.

The concepts must be selected among the available technologies and the specific conditions for their implementation. In this framework, a compliance matrix concept

was used. Two test-beds have been erected to validate the concepts in relevant conditions.

The paper will describe some of the most promising concepts and the selection methodology.

VST-P1-09

Development of a low cost, rugged, precision Capacitive Low Pressure Gauge for Cryogenic use.

T15 Vacuum Science and Technology

#VST-P1-09

L. Manceron ¹, L. Lago ², C. Herbeaux ², P. Roy ², M. Bol ².

¹CNRS - Paris (France), ²Synchrotron SOLEIL - Saint Aubin (France).

The precise measurement of Infrared absorption cross sections and line profiles of molecules and organic volatile compounds of relevance for atmospheric chemistry in planetary and upper earth atmospheric layers imposes precise pressure measurements between 10^{-3} and a few mbars in the 80 to 300K temperature range. Measurements using room temperature thermostated capacitive gauges outside the cryostatic cell are possible only when thermomolecular effects (which can offset the pressure reading by as much as 90%) have been empirically modeled, which is only the case for a few rare or inert gases [1]. Thus, measurements on various compounds with unknown thermomolecular correction factors have to be made in situ in the operating conditions of temperature. If various prototypes of precision capacitive cryogenic gauges have been built in different laboratories around the world [2, 3], they all rely on high cost, precision capacitive bridges for the read out electronics. A prototype, rugged, precision capacitive pressure gauge for cryogenic use has been designed and built at SOLEIL, and finally tested down to 77K. The design includes corrosion-resistant materials and has been tailored to operate on a differential measurement scheme based on the low cost, high precision AD7747 Σ - Δ capacitance-to-digital converter [4]. The design, realization and performances are presented here, illustrated by a precision better than 1% in the 0.2-40 mbar range with a resolution of $2 \cdot 10^{-3}$ mbar. The gauge can be, however, tuned for a higher precision and resolution, at the expense of the maximum high pressure range.

Reinventing Pressure and Vacuum Metrology: Development of an Optical Vacuum Standard

T15 Vacuum Science and Technology

#VST-2-Or-1

J. Hendricks, J. Stone, G. Strouse, D. Olson, P. Egan, J. Ricker, G. Scafe.

NIST - Gaithersburg (United states).

We propose to fundamentally change the method for realizing and disseminating the SI unit of pressure. The underlying metrology behind this advance is the ultra-accurate determination of the refractive index of gases by picometer optical interferometry. An optical-based primary pressure standard will improve accuracy and allow the complete replacement of all mercury-based pressure standards which are expensive to operate and have environmental and health hazards. Mercury manometers currently serve as primary standards at 11 National Metrology Institutes (including NIST and PTB). Developing an optical-based pressure and temperature standard is central to the NIST measurement science mission, as it will improve NIST realization and dissemination of important SI units. For pressure and vacuum, the technique will provide a needed improvement in accuracy (3X to 10X) across many industrial sectors in aerospace, energy, advanced manufacturing and government agencies. The primary goal of the ongoing research is to develop a laser-based, SI-traceable pressure standard (1.5 ppm, $k=1$) along with a transportable version that can be deployed to industry covering a range of 1 Pa (vacuum) to 360 kPa (~4 atmospheres pressure). The two instruments under development are the variable-length optical cavity (VLOC) and a fixed-length optical cavity (FLOC). The primary technical challenge involves building an apparatus to generate and precisely measure equal displacements of Fabry-Perot interferometer mirrors in vacuum and in a helium environment to picometer accuracy, thus determining refractive index in a manner that allows absolute measurement of pressure or temperature if one of these two quantities is known. More specifically, the refractive index, n , is intrinsically related to density such that $n-1$ depends on P/T , where P is the pressure and T is the temperature. The current state of primary mercury manometers in use at NIST will be

discussed along with technical challenges and recent developments in designing an optical based primary standard.

VST-P2-11

Analysis of a CF500 flange for the Collector Ring of FAIR

T15 Vacuum Science and Technology

#VST-P2-11

L. Urban, A. Krämer, C. Will, I. Schurig.

GSI - Darmstadt (Germany).

The Collector Ring (CR) is a storage ring of the accelerator complex of the Facility for Antiproton and Ion research (FAIR). Its purpose is the stochastic precooling of rare isotope and antiproton beams and the measure of the nuclear masses in an isochronous mode. Following the results of some vacuum simulations the use of DN500CF Flanges are foreseen in some parts of the CR.

In the technical specification ISO/TS 3669-2 are no flanges with a larger dimension than DN400CF.

In order to ensure the tightness of the flange, the idea was to design and construct a CF flange which can be baked or cooled and has a lower leak rate compared to rubber-sealed flanges. Furthermore the dimensions of the CF flange are smaller compared to COF flanges.

To perform leak tests of a DN500CF flange a setup was designed and commissioned at GSI, and it consists of an extractor gauge, a residual mass spectrometer and a pumping station. The flange was mounted in vertical position and screwed with different torques. The final pressure and the leak rate were determined and the corresponding mass spectrum was recorded. Through further measurements, the behavior and the tightness of the flange was detected also during the bakeout. The results obtained in these measurements will be presented and discussed.

Surface and material treatments for XHV vacuum components - An industrial approach for achieving low hydrogen-outgassing rates

T15 Vacuum Science and Technology

#VST-5-Or-8

A. Müller, O. Posth, H. Wunderlich, M. Flämmich, U. Bergner.

VACOM Vakuum Komponenten & Messtechnik GmbH - 07749 Jena (Germany).

Stainless steel has been and still is the most commonly used raw material for ultra-high vacuum (UHV) components. However, the requirement of going beyond the critical total pressure of 10^{-11} mbar has become stronger over the last years, especially driven by research institutions and accelerator facilities. The challenge of suppressing hydrogen outgassing from the bulk material has extensively been discussed in literature resulting in some well-established methods and few new approaches to achieve extremely low hydrogen outgassing rates needed for extremely high vacuum (XHV) applications. Some approaches seem to be promising, but simultaneously they are quite expensive and economically not viable. Industry is always faced with the challenge of producing high quality products for appropriate and affordable costs, often resulting in compromises regarding the applicable processes.

This talk will present an industrial approach to reliably and cost-efficiently manufacture XHV components with hydrogen outgassing rates below 10^{-14} mbar·l/s·cm². An appropriate sequence of cleaning and surface treatment methods is introduced and its correlated effects on surface structure and outgassing behaviour are analysed.

VST-5-Or-10

Improved cold cathode gauge for UHV / XHV

T15 Vacuum Science and Technology

#VST-5-Or-10

J. Iwicki, I. Pongrac, P. Gottschalk, R. Bauer, M. Flämmich, U. Bergner.

VACOM Vakuum Komponenten & Messtechnik GmbH - Jena (Germany).

Ionization vacuum gauges are currently the preferred sensors for total pressure measurements in high-, and ultra-high vacuum (UHV). The two most widely-used types of ionization gauges are hot cathode and cold cathode gauges. While in the first case ionization occurs due to thermionic electrons, in the latter case crossed electromagnetic fields are responsible for the ionization. Such a gauge is mechanically robust, insensitive to accidental venting as well as to vibrations. Mostly cited disadvantages of this sensor type are residual stray magnetic fields and increasing contamination of electrodes after long term operation. Moreover, the plasma discharge is difficult to initiate and maintain at low pressures.

In order to optimize the properties of this gauge type we investigated different penning cell elements, geometries and materials experimentally and by means of theoretical calculations. In this contribution, we present experimental and simulation results and the design of an optimized cold cathode gauge. Major improvements are proven by the experiments. They include enhanced ignition characteristics, a lower magnetic stray field, a better long term operation and a lower pressure limit with pressure readings down to the extremely high vacuum (XHV) region ($1E-12$ mbar).

VST-4-Or-5

Quantification of IGP pumping speed for different gases

T15 Vacuum Science and Technology

#VST-4-Or-5

A. Schlotter, J. Iwicki, T. Rietmann, O. Posth, A. Müller.

VACOM Vakuum Komponenten & Messtechnik GmbH - Jena (Germany).

Ion getter pumps (IGPs) are well known devices in terms of stability and long term operation. IGPs are preferably used in vibration-free environments and in high and ultra-high vacuum. The pumping mechanism itself is described by ionization of gas particles in a crossed electromagnetic field and the subsequent capture of the particles in terms of implantation, chemisorption, and sputter-induced trapping. Since the quantification of the underlying mechanisms concerning the pumping speed for different gases is not yet fully described by theory, ion getter pumps are predominantly used in air, nitrogen and argon atmospheres.

In order to deepen the understanding of these pumping processes, the pumping speed of several gas species, e.g. CO₂, CH₄, Ar and He, was systematically investigated conforming to standard DIN 28429. In this contribution we will present and interpret the results of pumping speed measurements for several different gases and the resulting deduction for the quantification of the respective pumping speeds.

VST-6-Or-6

Influence of joining inherent stress birefringence on polarization maintaining capabilities of vacuum optical assemblies

T15 Vacuum Science and Technology

#VST-6-Or-6

T. Rietmann, S. Gottschall, C. Sahib, M. Flämmich, U. Bergner, A. Becker.

VACOM Vakuum Komponenten & Messtechnik GmbH, Gabelsbergerstraße 9 - 07749 Jena (Germany).

The major challenge in the field of vacuum optics is to balance the diverse product requirements for the two different industries optics and vacuum technology. Tackling this challenge requires identifying parameters of critical importance to the manufacturing process as well as choosing materials that are suitable for both, ultra-high vacuum (UHV) and precision optics. Because the components have to be joined in a manner that ensures UHV compatibility, appropriate joining technologies have to be identified, developed, optimized and finally applied. Eventually, the component's significant technical parameters are to be characterized and specified for both the user's vacuum and optics requirements.

A significant parameter in optical applications is the polarization of light, which can be affected by a vacuum optical element. In order to evaluate the suitability of the four common joining methods for creating vacuum optical assemblies for optical applications, the joining inherent effect on polarization was investigated by the analysis of stress birefringence. The investigated joining methods are elastomer fitting, bonding, brazing and thermal fusion. In this contribution we will present and interpret the results of stress birefringence measurements and identify high potential joining methods for the two vacuum regimes high vacuum (HV) and ultra-high vacuum (UHV).

A. Krasnov.

BINP - Novosibirsk (Russian federation).

The installation provides time resolved measurements of secondary emission yield and secondary electron velocity/energy distribution in the presence of strong magnetic field. The measurement system is designed to be installed into superconducting solenoid with maximum field of 10T. The experimental data would help to improve computer codes developed for simulation of electron clouds behaviour in a cold beam pipe of particle accelerators. At present time the installation under commissioning at room temperature. The structure and performance capabilities of the setup are described, first experimental results are presented.

VST-3-Or-4

Design Status of the radioactive production area pumping system of SPIRAL2

T15 Vacuum Science and Technology

#VST-3-Or-4

R. Levallois.

GANIL - Caen (France).

SPIRAL2 is a radioactive Ion beam accelerator under construction now at GANIL dedicated to fundamental and applied research in nuclear physics [1]. This machine aims essentially at producing high intensities of exotic nuclei issued from the interaction between a Deuteron beam ($E= 40$ Mev, $I =5$ mA) delivered by a superconducting Linac and a carbide uranium target placed in a special zone named production area. Reaction between beam and target in the production area produces a large amount of radioactive gaseous that must be stopped and retained because it may cause a danger for users and also may generate an uncontrollable contamination of machine equipments. That's why, vacuum pumping system in this special area is considered as a major issue for global machine safety.

In this presentation, we will describe the vacuum system design of the production area in order to obtain a pressure lower than 10^{-6} hPa and to ensure a strong limitation of radioactive gas transmission.

Firstly, main characteristic of proposed pumping system for which a Monte Carlo Code named MOVAK3D [2] has been used to optimize conductance, will be presented. An additional Cryogenic trap system (named "cryotrap"), handled by robots, will be used if necessary to reinforce pumping capacity.

Secondly, a description of a special experiment using a prototype of Cryotrap, performed recently, will be exposed and the main experimental results with three different gaseous (H_2 , CO_2 , N_2) will be given. Modelisation with a Monte Carlo Code named Molflow+ [3] with sticking coefficient determined with experimental data will be also showed.

Finally, global status of pumping system will be presented with an illustration of its main specificities in managing radioactive gaseous in the production area where human interventions are forbidden

Quantitative residual gas analysis: industrial methods

T15 Vacuum Science and Technology

#VST-5-Or-6

O. Posth, A. Müller, H. Wunderlich, M. Flämmich, U. Bergner.

VACOM Vakuum Komponenten & Messtechnik GmbH - Jena (Germany).

In both, science and industry, mass spectrometry is a very common tool for the qualitative analysis of the residual gas in vacuum. Main applications are the control of leak tightness of vacuum components and the control of processes where the composition of the residual gas has to be guaranteed because it may interfere with the executed process. Another application is the investigation of desorption behavior of different materials e.g. as the function of temperature or the preceding surface treatment.

Frequently, mass spectroscopy is also utilized for quantitative residual gas analysis of vacuum components after the wet-cleaning or an additional vacuum bake out process in order to estimate the outgassing behavior of the components during the final application. For these investigations there are several different approaches and setups depending on the desorption rate of the components and the dominating gas in vacuum.

In this presentation we will exemplify the necessity of residual gas analysis of vacuum components after surface and cleaning treatments. Three types of methods and measurement setups (the throughput method, the so called box-in-box method and the accumulation method) will be presented with dedicate focus to the advantages and limits of each method and their fundamental reasons. For each method we will compile common applications where the setup fully proves its superiority.

VST-3-Or-5

Large industrial dry vacuum systems for vacuum metallurgy and other applications

T15 Vacuum Science and Technology

#VST-3-Or-5

S. Bruce ¹, A. Teeuwsen ².

¹Edwards Ltd - Burgess Hill (United kingdom), ²Edwards GmbH - Munich (Germany).

Very large industrial dry vacuum pumping systems are required for processes ranging from steel degassing in the metallurgy industry, and special vacuum coating systems, to large space simulation chambers used for satellite testing. Possibly the largest current industrial dry vacuum system operating provides a nominal 1 million cubic metres per hour pumping capacity for a 230 tonne Ruhrstahl-Hereaus steel degasser in Chongqing, China (Figure 1). The assembly of such very large pumping systems requires a combination of large primary dry pump mechanisms with large mechanical vacuum boosters. In such cases multiple parallel sets of these combinations are used. The major challenge is to provide very high pumping capacity in the most compact and energy-efficient way, to minimise space and power consumption, and to create a large vacuum system which is still simple to install, easy to integrate into the process control system, and has low maintenance requirements.

Significant challenges facing global industry are the requirements to increase energy efficiency and to minimise environmental impact. There are also increasing needs to improve productivity and reliability in vacuum processes, to reduce installation and operating costs, and to enable more technological advances to satisfy market demands for increasing functionality and performance. Vacuum pump manufacturers have made significant technological strides in new vacuum pumping mechanisms to provide advanced pumps capable of fulfilling these requirements.

Such developments not only assure the user of excellent vacuum performance and reliability, but also offer significant savings in energy use and a dramatic improvement in ease of integration into vacuum control systems. These advances are typified by new, compact, high capacity, intelligent dry vacuum pumps which are

fitted with on-board controllers to undertake process control functions themselves, and provide easy integration into the vacuum process control system. Large vacuum pumping capacity can be simply provided by mounting such pumps together in a modular fashion, as illustrated by the new steel degassing system (Figure 2) which will be described.

VST-P2-12

Magnetic field shielding by vacuum chambers of soft magnetic materials for beam loss reduction in J-PARC RCS

T15 Vacuum Science and Technology

#VST-P2-12

J. Kamiya, N. Ogiwara, H. Hotchi, M. Nishikawa, Y. Hikichi, T. Yanagibashi, M. Kinsho.

JAEA (Japan).

One of the reasons of beam loss in the 3 GeV synchrotron of J-PARC (Japan Proton Accelerator Research Complex) is unwanted stray magnetic field originating from magnets at the beam extraction line, which distorts the beam orbit so that the beam partially hit a vacuum chamber wall. In this area, the magnetic flux density is about $1 \cdot 10^{-3}$ T along the beam line of 10 m. In such circumstances it is required to shield the unwanted external magnetic field to less than one-tenth. The most effective way to shield such magnetic field is to cover the beam region by magnetic materials. We've developed a vacuum chamber of soft magnetic materials with high permeability [1]. In the previous paper [1], we reported outgassing rate, magnetic shielding characteristics, and heat treatment condition of a vacuum chamber, whose pipe is made of permalloy PC. As a result, such vacuum chamber of soft magnetic materials is applicable to the magnetic shield in 3 GeV synchrotron of J-PARC from the vacuum and magnetic shielding point of view. Considering the read availability of a material and fabrication yield, we decided to make the beam ducts and the bellows by a combination of permalloy PC, SUS430 and SUS316L. The magnetic shielding characteristic of these vacuum equipments is measured by taking the magnetic field mapping inside. As shown in shows a typical result of Fig. 1, the required magnetic shielding performance was achieved. After installing these vacuum equipments in the accelerator, the beam loss measurement was performed. Fig. 2 shows the beam current just after beam injection period before and after magnetic shielding. We achieve the beam loss reduction by the vacuum chambers of magnetic materials.

The Bilateral Comparison of the Helium Leak between Slovene Institute of Metals and Technology and Czech Metrology Institute

T15 Vacuum Science and Technology

#VST-P1-10

M. Vicar ¹, J. Šetina ².

¹Czech Metrology Institute - Brno (Czech republic), ²Institute of Metals and Technology - Ljubljana (Slovenia).

The International Key Comparison CCM.P-K12 has been finished in 2011.

After failing in this comparison, CMI located and corrected the source of the systematic error and proposed the Subsequent bilateral comparison CCM.P-K12.1 linked to the finished CCM.P-K12 key comparison.

The helium leak of the similar leak rate as the L1 in the key comparison was used for circulation as the transfer standard.

The Institute of Metals and Technology Laboratory for Pressure and Vacuum has successfully participated in the Key Comparison CCM.P-K12 and agreed to act as pilot laboratory in the bilateral CCM.P-K12.1 comparison.

The comparison was done in 2012 using the procedure close following the K12 protocol. The basic principles and metrological characteristics of the compared primary standards are described together with the comparison procedure.

The CMI laboratory raw measurements results evaluation is explained in details, focusing on the avoidance of the potential systematic deviation sources.

VST-P2-13

Surface preparation for the electron beam vacuum system of the European-XFEL

T15 Vacuum Science and Technology

#VST-P2-13

S. Lederer, L. Lilje, T. Wohlenberg.

Deutsches Elektronen-Synchrotron (DESY) - Hamburg (Germany).

The future European X-ray Free Electron Laser, build at DESY, will generate ultra-short pulses of coherent X-rays with wavelengths down to 0.1 nm with extreme brilliance. An electron beam traveling through undulator sections of up to 250 m length produces the light by means of Self-Amplified Spontaneous Emission (SASE). The electron bunches with variable charges between 20 pC and 1 nC are generated in a laser-driven RF-gun, accelerated in superconducting modules and compressed in three bunch compressors to peak currents of several kA. After compression the ultra-short electron bunches are accelerated in a superconducting linac to their final energy of up to 17.5 GeV, transported through a collimation section and distributed to different SASE sections. To preserve the beam quality during transport to the undulators, wake fields, generated by the interaction of the electron bunches and the vacuum system, have to be minimized. To reduce the effects of wake fields to an acceptable level, several countermeasures are applied, e.g. RF-shielding of bellows, pumps and valves but also the oxide layer thickness and roughness of beam pipes have to be in accordance with the impedance budget of the machine. In this contribution we describe the preparation techniques applied to fulfill the requirements for oxide layer thickness and roughness on standard copper beam pipes as well as for the aluminum undulator vacuum chambers.

VST-5-In-1

Vacuum Improvements for the Jefferson Lab Polarized Electron Source

T15 Vacuum Science and Technology

#VST-5-In-1

M. Stutzman.

Jefferson Lab - Newport News, Va (United states).

Long operational lifetime at the Jefferson Lab high polarization electron source requires vacuum approaching XHV (1×10^{-10} Pa). Electron sources proposed for future efforts will require higher average current, and vacuum improvements are critical for these projects. The work to improve vacuum at Jefferson Lab have focused on three critical aspects: chamber material selection and processing to minimize the outgassing rate, pumping system configuration and protocol for maximizing pump speed at near-XHV pressures, and accurate measurement of pressure through careful understanding of the background factors in gauges. This presentation will include an investigation of the effect of adding a bakeable cryopump to the non-evaporable getter and ion pump system of a test chamber, and a comparison of pressure measurement using three XHV gauges: the Leybold extractor gauge, the Ulvac AxTran gauge, and the Watanabe bent belt beam (3BG) gauge. Finally, progress on reconciling the persistent discrepancies between calculated and measured pressure will be presented.

VST-4-Or-6

Increasing Reliability and Extending Service Intervals of the dry High Vacuum Pump, which Works Against Atmosphere

T15 Vacuum Science and Technology

#VST-4-Or-6

A. Shirinov, S. Oberbeck.

Pfeiffer Vacuum GmbH - Asslar (Germany).

OnTool Booster is a dry high vacuum pump, which works against atmosphere and achieves a final pressure of less than $10E-5$ hPa. This pump has a maximal pumping speed of more than 130 m³/h at 0.1 hPa and 20 m³/h at 1000 hPa.

The pump consist of several in series connected side channel stages, which work against atmosphere, and five in series connected holweck stages, which generate a high vacuum.

The rotors of the side channel and holweck stages are placed on one shaft, which rotates with 1000 Hz frequency. The circumferential velocity of side channel and holweck rotors varies from 150 m/s till 310 m/s.

The shaft has two ball bearings on its both sides, which are lubricated with vacuum oil by two pumps. The inlet of the pump is dry and free of hydrocarbons. The lubricating pumps shall be filled with lubricating oil on a regular basis, because it is being used during the operation of the pump. The service interval of the pumps depends strongly on the application in which the vacuum pump works.

The current work describes changed made in the pumping system of the pump and in its lubricating system to increase reliability of the pump, improve its manufacturability and to extend its service intervals.

The results of investigation of the lubricating pumps at different operating pressures, temperatures and with different vacuum oils are demonstrated.

VST-P2-19

Qualification of Liquid Dye Penetrant for use on ITER Vacuum Systems

T15 Vacuum Science and Technology

#VST-P2-19

L. Worth, R.J.H. Pearce, D. Laugier, F. Burdeau.

ITER Organization - St Paul Lez Durance (France).

ITER will comprise one of the largest and most complex vacuum systems yet to be built. Situated in Southern France, the ITER facility covers approximately 190 hectares and is designed to demonstrate the scientific and technological feasibility of magnetic confinement nuclear fusion. Liquid Penetrant Testing (LPT) is extensively used to find surface defects in welds in the manufacture of pressure vessels; however LPT is not effective in detecting leak paths which would be considered large for Ultra High Vacuum (UHV) applications but insignificant for pressure applications. Hence in many UHV applications the use of Liquid Dye Penetrant (LDP) has been forbidden due to concerns over potential issues of surface contamination and temporary vacuum leak blocking. In the ITER vacuum systems, due to the large number of systems components which use high pressure water for cooling there are many cases where vacuum and pressure boundaries are shared. Many boundaries also provide nuclear confinement dictating manufacturing to pressure codes. As an example the design and manufacture of the ITER Vacuum Vessel shall be in accordance with the RCC-MR 2007 code. Among others the code specifies the surface inspection of weld preparations and welded joints either by LPT or by Photo-Thermal Camera (PTC) examination.

In this paper the experimental work to determine the acceptable limits of application of LDP in ITER manufacturing of vacuum components is presented. This includes: the methodology to manufacture samples covering a range of calibrated vacuum leaks with magnitudes representative of potential cracks through ITER welds; the testing of the leak blocking potential of different LDP product families; the cleaning methods applied to determine the unblocking potential of different cleaning techniques.

Finally the policy on the application of LDP product families on ITER vacuum systems as derived from the experimental work is presented.

VST-P2-14

Experience on the vacuum system of SOLEIL synchrotron light source

T15 Vacuum Science and Technology

#VST-P2-14

C. Herbeaux, N. Béchu.

Synchrotron SOLEIL - Gif-Sur-Yvette (France).

The SOLEIL synchrotron light source has been on operation for about six years. SOLEIL was the first storage ring using NEG coating (TiZrV) in an extensive way with about 60 % of the circumference treated [1]. This poster will present the evolution of the storage ring vacuum system. The vacuum conditioning is still improved with the integrated beam dose as for standard stainless steel vacuum chambers. In particular the behavior of the NEG coating will be discussed for cells which have been vented several times in order to install new devices (beam diagnostics, insertion devices...). After intervention for maintenance, the vacuum system presents a fast recovery of the vacuum conditions. Efficiency of NEG coating has been demonstrated at the occasion of activation with an electron beam stored in the storage ring. A beam loss monitor placed in the vicinity of the straight section where the activation was made presented a fast decay of the radiation rate as soon as the minimum activation temperature has been reached. Finally, the comparison of the behavior of a cell pumped only with NEG coating (except in front of primary absorbers) with other cells equipped with standard pumping demonstrated that the quantity of traditional pumps can be reduced.

[1] : Herbeaux, C., Béchu, N., & Filhol, J. M., Vacuum Conditioning of the SOLEIL Storage Ring with Extensive Use of NEG Coating, EPAC-08 European Physical Accelerator Conference 23-27 June 2008, Genova (IT) - THPP142

Vacuum performance of glassy carbon

T15 Vacuum Science and Technology

#VST-P1-23

C. Garion, C. Meynier, C. Pasquino, I. Wevers, P. Chiggiato.

CERN - Geneva (Switzerland).

In high-energy particle accelerators, radiation-transparent vacuum chambers are required to maximise particle detection at the collision points and to reduce the material activation and the consequent residual radioactivity. A possible alternative to beryllium, which is the material of choice at present, might be glassy carbon. This material is obtained by high temperature pyrolysis of a highly reticulated resin. In this paper, the compatibility of glassy carbon for UHV applications is addressed. The vacuum performance of two commercial grades is assessed. Thermal outgassing and permeation tests have been carried out and the results are presented.

VST-3-Or-6

Design Principles and Test Results for a Conduction Cooled Beam Pipe for Fast Ramped Accelerator Magnets

T15 Vacuum Science and Technology

#VST-3-Or-6

A. Mierau, E. Fischer, P. Schnizer, S. Wilfert, J. Macavei, F. Walter.

GSI Helmholtzzentrum für Schwerionenforschung GmbH - Darmstadt (Germany).

The heavy ion synchrotron SIS100 of the Facility for Antiproton and Ion Research (FAIR) at GSI Darmstadt will be the world second synchrotron utilising fast ramped superconducting magnets. The high current operation of the machine with heavy ions of intermediate charge state requires maximum vacuum pressures of $5 \cdot 10^{-12}$ mbar under dynamic machine conditions. Such low pressures can be effectively produced when the beam pipes of the sc magnets act as a cryopump. The design of the beam pipe has to fulfill the opposite requirements of safe mechanical stability and low eddy current production despite the fast ramped magnetic field. Beside the minimized field distortion, a sufficient cooling of the beam pipe must be provided to keep its temperature below 15 K in all operation modes. We present possible design versions of the beam pipe for fast ramped superconducting magnets, which were studied using simplified analytical models, FEM calculations and test models.

VST-1-Or-5

Calibration of reference leaks in a wide pressure range

T15 Vacuum Science and Technology

#VST-1-Or-5

O. Teodoro, A. Fonseca, A. Matos, A. Barreto, A. Moutinho.

METROVAC—CeFITec, Department of Physics, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa - Caparica (Portugal).

There are many kinds of reservoirs where tightness has to be checked by sniffer leak detectors. These leak detectors include not only those based on He mass spectrometry but also the refrigerant leak detectors commonly used in the refrigeration and air conditioning industry. In the case of refrigerant circuits, recent requirements as the European Regulation EC 842/2006 (and the subsequent ones) established tightness procedures with a limit of 5g/year of maximum allowable refrigerant fluid loss. Therefore, calibration of reference leaks in this range became mandatory.

In this work we describe a primary standard developed at METROVAC in Lisbon to calibrate leaks of any gas in a typical range of $\approx 4 \times 10^{-6}$ mbar.L/s to 4×10^{-4} mbar.L/s (for R134a ≈ 0.5 g/year to 50 g/year). The calibration pressure is adjustable by the user in a range defined by the absolute gauge used (in our case 750 mbar to 1300 mbar). With this approach calibration repeatability is increased since the leak delivering pressure may be kept constant, independently of the local atmospheric pressure. Typical calibration pressure is 1013.25 mbar.

The calibration method is based in an expandable volume at constant pressure. As soon as the gas flowing into the closed volume produces a detectable pressure increase (< 1 Pa) a gas tight syringe is actuated to keep a quasi-constant pressure. A commercial computer controlled pump controls a 1 mL syringe. The resulting volume step is 28 nL. A typical calibration requires 1000 steps or more, depending on the targeted accuracy. This corresponds to about 10 min calibration time for a 5g/year leak.

The major uncertainty contribution is related with the temperature time stability of the whole system. Since we use an absolute pressure gauge, small temperature drifts produce easily detectable expansions misleading the results. Calibration systems using differential gauges minimize this effect if the reference volume is maintained at the same temperature and has a similar volume. However, in those systems the user cannot select or adjust the calibration pressure as in the one we describe. Moreover, we use a piezoelectric sensor with no heat load for the calibration system, instead of those more common capacitance gauges.

Temperature stability is therefore the main requirement to achieve good uncertainties. The first version of this calibration system showed an overall uncertainty ($k=2$) of $\pm 3.4\%$ for a leak of 3.5 g/year (R134a) and of 8% for a leak of 7.8×10^{-6} mbar.L/s. The temperature drift was about 0.2 K/hour. A second version has been built with an improved temperature control based in a water bath temperature controlled case. This version is actually being evaluated with an expected improved accuracy.

Synchrotron facility is a one of great laboratories to developing a new technology. Increasing numbers of projects of new facilities gives a signal how it is important for innovations. 3rd generation synchrotron light facility give a wide range to studying discipline like physics, chemistry, medicine, etc. Polish National Synchrotron Radiation Centre - SOLARIS is first unique facility in Poland [1]. Centre will be equipment with a synchrotron machine setup based on the Maxlab technology [2, 3, 4].

The partial pressure in the Solaris storage ring will be lower than 10^{-9} mbar in order to guarantee an overall lifetime of 13 hours (taking into account Touschek events). Synchrotron radiation from both bending magnets and insertion devices will be used. The innovative design of achromat magnets requires precision engineering of the vacuum chamber. Most vacuum chambers will be made of stainless steel with different cross sections inside the magnet section. In this work we present a common description of the vacuum chamber design of both Solaris and the MAX IV 1.5 GeV storage rings. The conceptual layout of the vacuum chambers in the achromats and straight sections have designed by the CELLS ALBA group (Figure 1) and it has optimized by the finite element analysis. Some details of design of the vacuum chambers including the beam position monitor, discrete absorbers and pumping system (including the Non-Evaporable Getter strips) will be presented. Also, we show predictions for the static and dynamic pressure.

Windowless Gas Attenuator for LCLS-II SXR (Soft X-ray FEL - Free Electron Laser)

T15 Vacuum Science and Technology

#VST-P2-26

D. Schafer, M. Ferreira, D. Gill.

SLAC National Accelerator Laboratory - Menlo Park (United states).

The principal function of the LCLS-II Gas Attenuator is to provide variable attenuation from 1 (no attenuation) to 10^6 over the operating range of the LCLS-II SXR (Soft X-ray) undulator (250 to 2500[eV]). It is currently proposed to use Argon (Ar) primarily or Nitrogen (N_2), Neon (Ne), or possibly Krypton (Kr) gas (if needed to avoid Ar absorption edges) with the LCLS-II beam passing through to accomplish the attenuation. The absorption and damage thresholds preclude using solid windows to contain the gas at the lower beam energies. On either end of the gas filled cell (upstream and downstream) the gas must be removed with a differential pumping system down to the beamline base pressure of 10^{-7} [Torr].

Differential pumping sections have been designed utilizing adjustable aperture plates and fixed tubes to achieve a pressure drop in the range of ~ 50 [Torr] (2500[eV] X-rays with 4mm diameter aperture) and $\sim .2$ [Torr] (250[eV] X-rays with 22mm diameter aperture) in the gas cell to 10^{-7} [Torr] beamline output.

Numerical simulation of pressure distribution in vacuum chambers for the design of vacuum systems of the DC-280 cyclotron complex

T15 Vacuum Science and Technology

#VST-3-Or-8

A. Tikhomirov, G. Gulbekyan, B. Gikal, I. Kalagin, M. Khabarov.

Joint Institute for Nuclear Research, Flerov Laboratory of Nuclear Reaction - Dubna (Russian federation).

The DC-280 cyclotron complex [1] is presently created at the FLNR, JINR. It is intended to accelerate the wide range of ion beams with ion mass $10 \div 238$, ion mass to charge ratio $4 \div 7$, energy $4 \div 8$ MeV/nucleon and intensity up to 10 pmcA. It will be launched in 2015. The main parameters of vacuum systems for the DC-280 accelerator complex are determined by means of computer programs GENAP and VACLOS. The results of simulation researches are presented. The given modelling programs have been developed and tested on the basis of experiments in four cyclotrons of heavy ions at the FLNR. They have been used for design of the vacuum systems for the number of new cyclotron complexes: the DC-72 cyclotron complex for the Slovak Republic, the DC-60 cyclotron complex for the Republic of Kazakhstan, the DC-110 cyclotron complex for the Dubna Centre of Nano and Nuclear Technology and some others. The given simulation programs estimate ion beam losses based on the numerical simulation of pressure distribution in vacuum chambers practically of any arbitrary geometry as well as on calculation of cross sections for a recharge of ions during acceleration in exchange reactions by electrons with molecules of the residual gas. Simulation results have the good accordance both to experimentally measured pressure distributions and to accelerated ion beam transmission efficiencies.

Numerous applications such as X-ray tubes, electron microscopes, power vacuum switches, particle accelerators etc., use vacuum for the insulation of high voltages. Their performance reliability is limited by the risk of unpredictable breakdown event between the electrodes. In order to better understand the origin of such phenomena, numerical modeling has been performed to simulate the main elementary mechanisms (e.g. field and thermionic electron emission following the Murphy and Good's theory) occurring before the cathode-initiated breakdown.

The present study focuses on the quasi-two dimensional modeling (1D1/2) of the heat transfer along a micro-protrusion of given axi-symmetrical geometry, accounting for Joule and Nottingham effects. This self-consistent modeling provides temperature profile and voltage breakdown predictions, depending on the macroscopic parameters which are inter-electrodes distance, applied voltage drop, and cathode material properties. Comparison between different micro-protrusion geometries is presented and emphasizes the importance of heat conduction within the cathode material in the voltage breakdown assessment.

The present achievements can take this study towards the development of the macroscopic simulation of a realistic cathode surface roughness using Monte-Carlo approach.

Long Term Stability of 10 Torr Full Scale Ceramic Capacitance Diaphragm Gauges with 13 mm Diameter

T15 Vacuum Science and Technology

#VST-2-Or-2

C. Strietzel ¹, C.H. Wüthrich ².

¹INFICON, Product Management - Balzers (Liechtenstein), ²METAS, section mass, force, pressure - Bern (Switzerland).

Our present 10 Torr full scale capacitance diaphragm gauges (CDG) have a diameter of 38 mm and the membrane is sandwiched between two housing parts. We have now developed a 10 Torr full scale CDG with an asymmetric design, where the membrane is mounted on a base without the use of a cover part. Astonishingly, the asymmetric design is almost as stable in full scale as the traditional design. A full scale stability of 0.03% per year has been demonstrated that compares well with the 0.01% that has been achieved with the traditional design [1].

[1] Jousten and Naef, On the stability of capacitance-diaphragm gauges with ceramic membranes, J. Vac. Sci. Technol. A 29, 011011 (2011) doi:10.1116/1.3529023

M. Tosa ¹, T. Maruyama ², J. Nakagawa ², K. Endo ², A. Kasahara ¹, M. Goto ¹.

¹National Institute for Materials Science - Tsukuba (Japan), ²Toyama Co., Ltd. - Zama (Japan).

High resolution surface analysis and high quality thin film growth processes have required high quality vacuum environment, where lubricants become an important issue on sliding surfaces in manipulators for smooth motions. Low outgassing grease is generally used as lubricants in a vacuum, but in an ultrahigh vacuum, where pressure is $10^{-6} \sim 10^{-8}$ Pa, liquid lubricants become an outgassing source and ultrahigh vacuum pressure cannot be maintained stably. In an ultrahigh vacuum manipulation, some solid lubrications have been widely used, especially molybdenum disulfide (MoS_2). Low friction and low outgassing during sliding are also required for a precise and smooth sliding motion without any surface contamination. Friction characteristics of MoS_2 have been reported to be suitable in a vacuum, but not yet been investigated much in an ultrahigh vacuum region and outgassing characteristics during sliding have not been also known in detail. We therefore investigated the characteristics of MoS_2 sputtering coatings in order to develop high performance ultrahigh vacuum motions. Friction and outgassing characteristics were evaluated of MoS_2 coating films prepared under different sputter coating conditions and we have found out suitable film coating parameters. Friction of the films was measured with a vacuum friction measurement apparatus at an atmospheric pressure and in an ultrahigh vacuum [1]. Outgassing characteristics of the films were evaluated with an outgassing measurement apparatus, which was based on the throughput method [2]. Under ultrahigh vacuum pressure, outgassing rate was measured during a loaded metal indenter was slid on the MoS_2 film.

It was shown that the optimum thickness coating can offer longer lifetime good for ultrahigh vacuum lubricant but film thickness has little effect on the outgassing rate. Large outgassing of argon (Ar), that was used as sputter coating gas, was observed in early stage of sliding. Ar and other adsorption gas (CO and CO_2) can be decreased by annealing during sputter coating process as shown in fig.1.

Indigenous development of standard helium permeation leak artifact with different wall thickness and variable filled pressure

T15 Vacuum Science and Technology

#VST-P1-15a

T. Sattar, M. Maqsood, J.A. Bhatti, Z.A. Khan, H.M. Akram.

NINVASt - Islamabad (Pakistan).

With the advancement in nanotechnology, nano-leaks have become very important in high tech research and development. Fabrication and optimization of standard leaks (artifacts) have always been remained a hectic and sensitive issue, such standard leak artifacts are widely used for the calibration of helium leak detectors, residual gas analyzers and mass spectrometers etc.

In the present work, three secondary standard helium leak artifacts are indigenously designed and developed with different wall thicknesses and variable filled pressures at National Institute of Vacuum Science & Technology (NINVASt), Islamabad – Pakistan. These artifacts consist of mainly two parts: Pyrex glass tube as a leak element that restrict the flow of helium through diffusion process and helium reservoir which acts as a constant pressure helium source. Stable and reproducible leak-rates have been achieved at different helium filled pressures at room temperature. A decrease in wall thickness of the leak element gives early and higher leak rate value with less helium filled pressure. The properties and reliability of helium permeation standard leaks, based on approximately two years of accumulated calibration data have also been discussed in detail.

A New Inverted Magnetron Pirani Combination Gauge

T15 Vacuum Science and Technology

#VST-1-Or-10

J. Marki, B. Andreaus, R. Enderes, M. Wüest.

Inficon - Balzers (Liechtenstein).

One of our latest products is an inverted Magnetron [1] -Pirani [2] combination gauge with a slim footprint design. The new inverted magnetron is equipped with a novel magnet design that allows for a low external magnetic stray field. In addition, the ion chamber or the entire sensor can be replaced separately, facilitating maintenance. The gauge is the shortest conventionally built inverted magnetron gauge which makes it ideal to embed in analytical instrumentation. This new cold cathode gauge generation's control and onboard data pre-processing are performed digitally, enabling customizable functions. In the talk, pertinent sensor characteristics and features will be presented.

A group of 7 European national metrology institutes and 5 industrial companies formed a consortium and started a joint project EMRP IND12 "Vacuum metrology for production environments". Project is funded by the European Metrology Research Programme (EMRP). Goals of this project are to open new measurement capabilities for vacuum and to help industry to characterize vacuum in industrial environments. Work package 3 of the project addresses the traceability for partial pressure measurement and outgassing rate measurement for materials characterization in industry. Part of this research focuses on the study of time stability of metrological characteristics of quadrupole mass spectrometers, (QMS) widely used in industry for leak detection and measurements and control of gas composition in vacuum processes, which demands highly stable and well defined low pressure environment. Stability over time of QMS is therefore an important parameter for production stability in industry. There is very limited number of such studies available in the literature. To get information about typical quality of commercial instruments, it was necessary to include in the study several instruments from different manufacturers. This task is jointly performed by seven national metrology institutes: TUBITAK UME, IMT, PTB, INRIM, LNE, CMI and CEM and one industrial partner company VACOM. To compare results from different participants, a common measurement protocol has been adopted. Selected parameters are measured at regular intervals. The

parameters were chosen from the mandatory parameters of ISO standard 14291 (Definitions and specifications for quadrupole mass spectrometers) to be provided by the manufacturers. Parameters under study include sensitivity, mass resolution, mass number stability and minimum detectable partial pressure. Check intervals are 3 months. In the time between the measurements, the records of usage of the instruments shall be kept.

Study started in the middle of 2012 and the overall duration will be two years. In this contribution we will present the preliminary results obtained during the first year of the study.

ITER is a magnetic confinement fusion device with the purpose of demonstrating the feasibility of fusion as a clean power source. The machine is being constructed to produce 0.5 GW of fusion power from 50 MW of input power and it is expected to be the first fusion device to produce controlled and sustainable net energy. The successful operation of ITER requires the largest, most complex set of vacuum systems yet to be built. The fusion plasma is heated within the main vacuum vessel which has a volume of ~1400 m³ and will achieve a pre-operation base pressure of the order 10⁻⁶ Pa.

ITER will be fitted with many diagnostic instruments which provide the means to observe, control and measure plasma conditions. There will be seven Diagnostics which are directly connected to the main tokamak vacuum and incorporate dedicated vacuum pumping systems. The direct connection of these diagnostic to ITER primary vacuum and their need to provide radioactive confinement, dictates novel challenging design and qualification requirements.

In this paper the design of the directly connected diagnostic vacuum pumping systems, which have progressed through their conceptual design phase, is presented. The design and operational features to give high integrity and reliability with minimum maintenance are shown. The validation programs to demonstrate that components forming these pumping systems are compatible with the environmental conditions of high magnetic fields and ionizing radiation are outlined. The applicability of special radiation hard turbo molecular drag pumps with built-in magnetic shielding is discussed.

LHC Beam Vacuum System 4 TeV Commissioning and Upgrade

T15 Vacuum Science and Technology

#VST-3-Or-11

V. Baglin, G. Bregliozi, G. Lanza, J.M. Jimenez.

CERN - Geneva (Switzerland).

During commissioning of the Large Hadron Collider (LHC), the 400 mA protons beams collided at 7-8 TeV center of mass before upgrade to nominal intensity and energy after the Long Shutdown 1 (LS1). With high energy circulating beams, synchrotron radiation irradiated the arcs cryogenic vacuum system, held from 5 to 20 K. Moreover, with intense and closely spaced protons bunches, an electron cloud built-up in the cryogenic vacuum system and in the Cu or Non-Evaporable-Getter coated vacuum chambers held at room temperature. During these phases, the beam vacuum system was subjected to stimulated gas desorption induced by photons and electron bombardments. Throughout the years, dynamic pressure rises and conditionings were observed and compared to expectations. Mitigations and innovative solutions were developed and implemented to allow the routine operation or the repair of the machine. This paper discusses the achieved pressure performances with relevant hardware issues and introduces the proposed vacuum upgrade with expected performances following LS1.

VST-3-Or-9

Vacuum system of the large-scale cryogenic gravitational wave telescope, KAGRA

T15 Vacuum Science and Technology

#VST-3-Or-9

Y. Saito ¹, R. Takahashi ².

¹KEK High Energy Accelerator Research Organization - Tsukuba, Ibaraki (Japan), ²Institute for Cosmic Ray Research, Univ. of Tokyo - Kashiwa-No-Ha (Japan).

The large-scale cryogenic gravitational wave telescope, KAGRA, is a Fabry-Perot-Michelson interferometer of 3-km long baseline, using a 1064-nm wavelength laser beam. The site is in an underground tunnel of Mt. Ikenoyama in Kamioka town so that ground vibration due to daily traffic and life noise is suppressed. The project was started in 2011 and the tunnel is being excavated. The aimed sensitivity is $3 \cdot 10^{-24} \text{ Hz}^{-1/2}$ at 100Hz, corresponding to a horizontal mirror displacement of $1 \cdot 10^{-20} \text{ m} \cdot \text{Hz}^{-1/2}$. The predicted noise due to residual gas (water) molecules is $1 \cdot 10^{-21} \text{ m} \cdot \text{Hz}^{-1/2}$, when the pressure in the KAGRA beam tube is kept at $2 \cdot 10^{-7} \text{ Pa}$, with a safety margin of 10.

Two of the 3-km long beam tubes consist of 484 of unit tubes of 12 m long and 800 mm in diameter, having a flexible bellows and flanges. Since the tunnel is inconvenient to apply a baking to the entire system, surface passivation is necessary before installing. In order to realize the ultra-high vacuum, the following manufacturing process of the unit tubes is adopted; 1) Before tube forming, the surface of a SS304L sheet of 8 mm thick is ground by abrasive of Grit #150. The surface roughness after grinding is 8 μm . 2) The bellows is made from a SS316L sheet of 0.8 mm thick and formed by hydro pressurizing. Chemical polishing is applied before welding to the unit tube. 3) The unit tube after welding flanges and bellows is processed by electro-polishing so as to remove 30 μm of the surface degraded layer. The surface roughness is reduced to 3 μm (Fig.1). 4) After rinsing by a pure water of 15 M Ω in electrical resistivity, pre-baking process (200°C for 20hours) is finally performed for every unit tube. The result of outgassing rate measurement for

several tubes during production shows a value of the order of $10^{-9} \text{ Pa}\cdot\text{m}^3\cdot\text{s}^{-1}\cdot\text{m}^{-2}$ for 100 hours of pumping.

Other materials to be planned for installing in the KAGRA vacuum systems are also examined. Outgassing rate of aluminum deposited PET films of $12 \mu\text{m}$ thick, which is to be used as thermal insulation in the cryogenic mirror system, shows drastic decrease after 100 hours pumping, indicating that absorbed water molecules diffuse out of the film. Further, a black-colored plating of NiP compounds for use as optical baffles is found to be available in the ultra-high vacuum when it is pre-baked at 250°C .

VST-P2-15

ITER Cryogenic Guard Vacuum System design and performance

T15 Vacuum Science and Technology

#VST-P2-15

J. Bersier, R.J.H. Pearce, B. Boussier, C. Mayaux.

ITER organization - Saint Paul Lez Durance (France).

ITER is a fusion device which will produce 0.5 GW of fusion power from 50 MW of input power and it is expected to be the first fusion device to produce controlled and sustainable net energy. In ITER, the fusion reaction will be achieved in a "Tokamak" device that uses magnetic fields to contain and control the hot plasma.

The successful operation of ITER requires one of the largest, most complex vacuum systems yet to be built.

The design of ITER requires an extensive cryogenic system with more than 3 km of cryolines, feeding components with helium at 4.5K, 80K and at elevated temperatures of up to 470K. To provide the necessary magnetic fields, the ITER machine is designed with 25 main superconducting coils running at 4.5K and housed within the 14000 m³ cryostat. These coils are protected by a 1000 t, 80K, radiation shield. Other systems requiring cryogenic helium are the 22 ITER cryopumps and up to 10 pellet injection systems.

This paper describes the development of the design of the Cryogenic Guard Vacuum System (CGVS) which provides thermal insulation vacuum for all cryogenic distribution systems including cold valve boxes, magnet feeders, cryolines and cryojumpers. The conceptual design phase of the CGVS has been successfully completed.

The CGVS design contains a discrete but modular network of 70 distributed pumping units which serves the cryolines and more than 60 cold valve boxes and magnet feeders. To achieve the overall reliability target for the ITER machine the CGVS will also provide sufficient pumping capacity to allow a tolerance to cryogenic helium leaks within the distribution system; the analysis of this tolerance is presented.

The value engineering exercises and optioneering studies that were performed in the conceptual design phase to reach the current design solutions are discussed. These

resulted in a common design, with modularity on a few options, for all pumping stations even though there is variation in the environmental conditions seen by different units. The pumping unit architecture, including mechanical pumps, instrumentation, and control is described.

VST-P1-12

Study of influence of operating parameters on quadrupole mass spectrometer sensitivity and linearity

T15 Vacuum Science and Technology

#VST-P1-12

B. Erjavec, J. Šetina.

Laboratory for pressure metrology, Institute of metals and technology - Ljubljana (Slovenia).

A computer controlled quadrupole mass spectrometer (QMS) PrismaPlus™ QMG 220 M2 has been selected to study the influence of operating parameters on QMS sensitivity and linearity in a UHV range. The QMS consists of a grid ion source with a dual W filament, a quadrupole mass filter with rods of a 6 mm diameter and 100 mm length, and an ion detector: Faraday cup (FC) and secondary electron multiplier (SEM). The QMS was mounted on a UHV system for material outgassing characterization while QMS performance characteristics were studied by comparison to a BAG which was calibrated at higher pressures by a reference SRG. The QMS sensitivity and linearity depend on the ionization efficiency and ion fragmentation affected by dimensional tolerances of the ion source, and on electron and ion space charge effects dependent on electron emission current and test gas pressure [1,2], respectively. Both characteristics depend on the ion transmission from the ion source through the mass filter to the ion detector influenced by ion extraction and retarding electric fields resulting in a focused ion beam with a narrow angular distribution at the entrance of the mass filter, and ion energy determining the ion velocity to pass the mass filter. Comprehensive measurements are needed to examine the sensitivity K_P^i for a gas species (i) as a function of instrument (ionizer, mass filter and detector) parameters and pressure expressed as:

where ΔI_{QMS}^i is the change in ion current and ΔP_{ref}^i is the change in pressure of gas species (i), while electron emission current I , electron energy E , ion extraction voltage U_{ex}^+ , ion energy E^+ , ratio of the amplitude of RF voltage to the DC voltage a/d (defining a constant peak width Δm) and SEM bias voltage U_{SEM} are the instrument parameters [2].

User helpful measurements to determine the sensitivity and linearity for a gas species (i) inside the applicable pressure range were arranged in FC mode ($U_{SEM}=0$) at the default peak width ($\Delta m=1$) by varying the remaining instrument parameters (I , E , U_{ex}^+ and E^+).

Temporary interesting results and conclusions were:

- The higher electron emission current the higher sensitivity and the lower linearity response range for a particular gas such as Ar (parameters to be considered for a gas species (i): ionization cross-section and ion velocity)
- Different power-law dependence of transmission factor on mass for atomic and molecular gases calculated from a relative sensitivity K_r^i , relative ionization probability ϵ_r^i and ion fragmentation factor F_f^i (measured in FC mode: a detection factor $D_f^i=1$):

$$\frac{K_r^i}{K_r^j} = \frac{\epsilon_r^i F_f^i}{\epsilon_r^j F_f^j} \left(\frac{m_j}{m_i}\right)^{\alpha}$$

- Similar power-law dependence of the SEM gain on mass of atomic and molecular gases obtained from measurements while operating QMS both in FC and SEM mode
- Deviation of H_2 resolution ($\Delta m < 1$) depressed the H_2 sensitivity resulting in a deviation from the power-law dependence of transmission factor on mass of molecular gases [1,3].

All measurements presented in this work were taken following a programme of the EMRP IND12 Project: Vacuum metrology for production environments: Partial pressure and outgassing rate measurements (2011-2014).

Stationary Coating Materials for Multi-Layered Gas Chromatography Chip Assembly

T15 Vacuum Science and Technology

#VST-P1-13

S. Kim, S. Lim.

Korea Basic Science Institute - Seoul (Korea, republic of).

The microfabrication techniques have advantages in GC column development because it provides better temperature management and better separations that lead to mass spectral deconvolution. Double layered gas chromatography columns in borosilicate wafers have been microfabricated for mass spectrometry. The microfabricated columns were made using a wet chemical etching process that created a 100- μm wide 50- μm deep semi-circular cross section channel. The photoresist SU-8 (for both patterning and etching mask) was applied on a 2000- μm thick 4-inch wafer which was subsequently immersed in a HF etching solution for 3~5 minutes. Using our aligner/exposure, the microfabrication process was repeated on a single wafer to obtain the gas channel dimension. The inlets of the microfabricated columns were made using the micro electric discharge machining technique.

Wet glass etching was performed because the isotropic degradation results in the semi-circular cross section. In addition to gas channels, efficient inlet structures should be fabricated in the wafer. By manufacturing multi-layered channel structures we were able to provide two types of mobile phases with different polarities. Because the film materials were also used as coating materials and were applied prior to bonding the etched wafers, the method was effective in controlling the polarity of the column. The thin film of PDMS (polydimethylsiloxane) and PEG (polyethylene glycol) was applied on the etched surface of channel and the bonding surface of the wafers. PDMS and PEG were also placed on the top side of the wafer by spincoating and it was heated on the hot plate at 150 °C for an hour. Three etched wafers were assembled into a double-layered column containing both non-polar (PDMS) and polar (PEG) mobile phases. The three-dimensional etched profile of the microfabricated columns illustrated that they were comparable to fused-silica capillary columns. The substrate was effectively sealed by applying these materials

on the surface of the silicate wafers. The volatile organic compounds including halogenated organic compounds (chloroform and bromofluorobenzenes) were analyzed using the gas chromatography (mass spectrometry) attached with these micro GC column.

The construction of floats for laser interferometric mercury manometer – new primary standard of Russian Federation in the range 0,1 – 130 kPa.

T15 Vacuum Science and Technology

#VST-P1-14

I. Sadkovskaya ¹, A. Eichwald ².

¹All-Russian D.I. Mendeleev Research Institute of Metrology - St.petersburg (Russian federation), ²St. Petersburg State University - St.petersburg (Russian federation).

The Laser Interferometric Mercury Manometer (LIMM) has been constructed in VNIIM (RF) for the new Russian national standard for pressure measurements in the range (0,1 – 130) kPa. In the main its scheme is similar to one developed in [1]. The manometer tubes are made of stainless steel and have an inner diameter 50 mm. The homodyne interferometer with frequency stabilized He-Ne laser, optical scheme and fringe counting device are the same applied earlier to the Laser Interferometric Oil Manometer [2]. The idea to suppress surface waves and to stabilize interference by creating thin layer of mercury and using cat's eye device [1] has been realized now in the original construction of floats as shown on Fig.1. The float stabilizer 1 is a hollow cylinder (49,8 mm in diameter) made of caprolon (polyamide-6). The stainless steel bowl 2 is fixed to it with screws. The gap between it and the wall of the tube 3 is 3 mm. The mercury 4 penetrates into the bowl through the small hole 5 on the bottom and creates a layer with the depth about 2 mm. The lens holder 6 is fixed to the stabilizer with screw- thread to adjust the cat's eye.

The mercury surface tension affects on the float's plunging and depends noticeably on the impurity (mercury oxide). It was found that when the mercury moved down the impurity deposited on the wall of the tube and the surface became cleaner (and vice versa). That could detune the cat's eyes and disturb the fringe counting. To eliminate this effect the fine caprolon guard ring 7 (Fig.2) was placed into the gap between the float and the wall.

VST-5-Or-7

Application of Tungsten Heavy Alloy to Ultra-High Vacuum Chamber for Radiation Shield: Outgassing Properties and Vacuum Performances

T15 Vacuum Science and Technology

#VST-5-Or-7

K. Tamura, M. Oishi, Y. Okayasu, M. Shoji, S. Takano, Y. Taniuchi, M. Masaki, A. Mochihashi, H. Ohkuma.

Japan Synchrotron Radiation Research Institute - 1-1-1 Kouto, Sayo, Hyogo (Japan).

The outgassing properties of tungsten heavy alloy (WHA) and application of it to an ultra-high vacuum (UHV) chamber with an ability of radiation shielding will be presented.

In the synchrotron radiation (SR) beamlines (BLs), radiation shields are necessary to be installed for BL's components, in order to protect BL components and guarantee radiation safety in the downstream of the BLs. To limit the opening against unnecessary radiation and keep the effective aperture for SR as large as possible, development of a new type of radiation shield equipment, which utilizes WHA as an UHV chamber, has been planned. Although WHA blocks have been widely used as safety shutters in BLs at SR facilities, there has been no previous case in which the UHV chamber itself is made of WHA.

The outgassing rate of WHA was measured by the conductance modulation method. Figure 1 shows the temperature change and the outgassing rate of WHA during the baking process. The outgassing rate of stainless steel 304 (SS304) was also plotted. Although the outgassing rate of WHA at the temperature rising phase is greater than that of SS304, both rates become almost the same as the baking process advances. Examination of the vacuum sealing method was performed by using a flange made of WHA. Taking into account the ease of processing and reliability, the sealing with a metallic O-ring has been decided to adopt. The measured helium leak rate of the sealing was confirmed to be less than 10^{-11} Pa · m³/s.

Figure 2 shows a WHA γ -ray stopper, installed downstream of the double-crystal monochromator of the SPring-8 diagnostics beamline II. The cuboid WHA block with a rectangular through-hole serves as not only a shield of high energy radiation accompanying the incident white X-ray beam to the monochromator, but also a vacuum chamber transporting the monochromatic X-ray. The pressure of the γ -ray stopper successfully reached 10^{-7} Pa in the UHV region after the baking process.

LEAK LOCALIZATION: A MAJOR ISSUE FOR NEXT FUSION MACHINES

T15 Vacuum Science and Technology

#VST-P2-20

J.C. Hatchressian ¹, A. Durocher ¹, M. Chantant ¹, M. Houry ¹, D. Mouyon ¹, D. Anthoine ².

¹CEA (France), ²BERTIN (France).

ITER and future actively cooled fusion devices will very likely be subjected to water or air leaks that will result in high reduction of their availabilities. Due to the complexity and the radioactive environment of these nuclear facilities, manual methods for Plasma Facing Components (PFC) leak localization will no longer be applicable. In this context, remote operations will be mandatory to allow in-vessel interventions in order to limit personal radiation exposures. Hence new methods of leak localization have to be developed to minimize machine down time and operational costs, including R&D and qualification activities.

An attractive option for leak localization process would be to use a device carrying a sensor and allowing a close access to the leak source. Another way could be to instal specific sensors inside the first wall. Consequently CEA has initiated in partnership with industrials a R&D program to define new leak localization concepts, the selection methodology using a compliance matrix and the selected sensor's qualification tests. To perform that under relevant conditions new specific facilities have been built allowing to mesure major criterias such as response time and sensibility.

This paper will present a none exhaustive list of possible concepts, the selection methodology according the technical and environmental issues, and the first experimental promosing results gained.

Key words: leak localization, fusion, sensor, concept, qualification test

EXPERIMENTAL AND PERFORMANCE ANALYSIS OF A TURBOMOLECULAR VACUUM PUMP ROTOR SYSTEM

T15 Vacuum Science and Technology

#VST-P2-21a

C. Hsu.

National Chin-Yi University of Technology - Taichung City (Taiwan, republic of china).

This study is focused on the experimental and performance analysis of a vertical type turbomolecular vacuum pump (TMVP) rotor system. The research approach can adopt methods are numerical analysis and experimental testing. In numerical analysis, it can use the finite element analysis software ANSYS to construct a three-dimensional model of the rotor system. In this analysis process, it can verify the rotor system finite element models under different boundary conditions by using the pump system testing data. Then, it must calculate the Campbell diagram to study dynamic characteristics of the rotor system, and to compare with the experimental results to verify the models. It can establish the relationship between the rotor critical speed and the bearing stiffness in order to study the design of the turbomolecular pump rotor system. The experimental can adopt the static and dynamic testing. The static modal testing can provide the natural frequencies of the rotor system. The waterfall diagram of the dynamic testing can measure the pump system operating critical speed from zero speed up to the operating speed, and to insure that the pump operating speed is far from the critical speed of at least 10% in the safe margin. Summary, this results can provide the design tool for turbomolecular pump rotor system in order to identify and prevent vibration. The 1st order and the 2nd order critical speed were 110Hz and 490Hz as obtained from the dynamic testing results for the waterfall shown in Fig. 1. Fig. 2 was created ANSYS to simulate the TMVP Campbell diagram for operating speed.

PLA and LDPE barrier properties improvement by the combination of DBD activation and PECVD-based SiNx deposition

T15 Vacuum Science and Technology

#VST-6-Or-1

P. Leroy ¹, C. Nouvellon ², S. Abou Rich ¹, A. Roobroeck ², S. Benali ³, F. Renaux ², P. Dubois ³, R. Snyders ³, F. Reniers ¹.

¹ULB - Bruxelles (Belgium), ²Materia Nova - Mons (Belgium), ³UMons - Mons (Belgium).

Food packaging allows protecting food from the external environment mainly by reducing the diffusion of moisture and oxygen. In this work, we aim to evaluate the barrier properties improvement of LDPE (Low Density PolyEthylene) and PLA (PolyLactic Acid) using a two steps plasma-based treatment in a roll-to-roll system. The first step consists in an activation of the surface in order to promote the adhesion of the subsequently deposited barrier coating.

In a unique treatment chamber consisting in two reactors connected under vacuum, the polymer substrates are first treated by Dielectric Barrier Discharge (DBD) at 100 mbar in order to clean and activate the surface. The second step consists of depositing, at low pressure ($7 \cdot 10^{-3}$ mbar), a SiNx like layer by PECVD (Plasma Enhanced Chemical Vapor Deposition) using Ar/SiH₄/N₂ mixture. The energy, chemistry and topology of the treated surfaces are evaluated by using contact angle measurements, X-ray Photoelectron Spectroscopy (XPS) and Atomic Force Microscopy (AFM), respectively while the permeability of the treated polymers towards oxygen and water vapor are measured for different treatments.

It is shown that a DBD treatment shorter than one second can significantly improve the wettability of polymers (for example the water contact angle of PLA decreases from 77° to 25° after a Helium/Nitrogen plasma treatment).

Oxygen and water vapor permeability studies are carried out on the polymer film /deposited layer samples with and without DBD pretreatment. Without DBD treatment, it is shown that very thin SiNx-like layer (< 20 nm) leads to the best results. In that case, for thicker films, cracks appear in the deposited film, reducing the barrier effect. If the polymer is DBD treated before SiNx-like layer deposition, the experimental windows allowing for good barrier properties is affected demonstrating the positive impact of this step. These results are understood in view of XPS depth profiling allowing characterizing the polymer-thin films interface.

VST-2-In-1 PRESSURE MEASUREMENTS AND CALIBRATIONS IN EXTREME HIGH VACUUM (XHV) RANGE

T15 Vacuum Science and Technology

#VST-2-In-1

J. Setina.

Institute of Metals and Technology - Ljubljana (Slovenia).

In demanding vacuum devices, like ultra fast photoemission electron sources for free electron lasers, there is a need for reliable vacuum measurements down to XHV range. Accurate measurements of any physical quantity are possible only if instruments are properly calibrated. Many national metrology institutes (NMIs) around the world maintain primary vacuum calibration systems down to 10^{-8} Pa, but there are only few systems which operate below 10^{-9} Pa. Institute of Metals and Technology (IMT) has recently built an experimental calibration system with a base pressure close to 1×10^{-10} Pa. This very low base pressure was achieved by the use of nonevaporable getter (NEG) in the calibration chamber. Calibration pressure is generated by orifice flow method. Because of NEG only inert gases like Ar can be used for calibration. The lowest generated calibration pressure is in the 10^{-11} Pa range. In the talk the XHV calibration system of IMT will be presented and compared with similar systems at other NMIs.

VST-7-Kn-1

VACUUM GAS DYNAMICS: STATE OF ART AND PERSPECTIVES

T15 Vacuum Science and Technology

#VST-7-Kn-1

F. Sharipov.

Departamento de Física, Universidade Federal do Parana - Curitiba (Brazil).

Modelling of gas flows under low pressures is an important part of vacuum science. Two main approaches are employed in vacuum gas dynamics, namely, probabilistic and deterministic. The first one is based on the Monte Carlo methods, while the second approach consists of numerical or analytical solution of the kinetic Boltzmann equation. In the lecture, a review of recent results based on both approaches will be given with examples of their applications to practice, i.e. modelling of gas flow in vacuum systems, mathematical models of vacuum pumps, theoretical support of vacuum metrology etc. Directions of further developments of vacuum gas dynamics and its perspectives will be pointed out.

VST-4-In-1 SURFACE TREATMENTS FOR VACUUM SYSTEMS OF PARTICLE ACCELERATORS

T15 Vacuum Science and Technology

#VST-4-In-1

P. Chiggiato.

CERN, European Organization for Nuclear Research - Geneva (Switzerland).

Surface treatments are the last step in the production of all components installed in vacuum systems of particle accelerators. They encompass primarily chemical and electrochemical processes, and coating by both electrolytic and plasma techniques. They have multiple functions that depend on the specific applications. The traditional example is the reduction of surface outgassing both without and with circulating beams, i.e. in presence of particle bombardment onto the beam-pipe walls. Thin film coatings have become a crucial surface treatment in the last two decades. They transform conductance-limited beam pipes into distributed pumps. They decrease the global impedance imposed to beams, modify particle reflectivity and optical emissivity, reduce secondary electron emission, and allow the achievement of very-high accelerating electrical fields. The design of future high-intensity, high-energy and low-emittance accelerators relies on the present surface treatments and trigger challenging developments. The state of art is reviewed, with emphasis on applications for the LHC and new synchrotron light sources. The need for further development is pointed out.

VST-6-In-1 VELOCITY MEASUREMENTS IN LOW PRESSURE CONFINED GAS FLOW BY MOLECULAR TAGGING VELOCIMETRY

T15 Vacuum Science and Technology

#VST-6-In-1

S. Colin.

INSA Toulouse - Toulouse (France).

A significant effort has been recently made to develop accurate models for the low pressure flows of gases in confined situations, covering the different rarefaction regimes. There is currently, however, a crucial lack of experimental local flow data (pressure, concentration, velocity and temperature fields). Molecular Tagging Velocimetry (MTV) is a non-intrusive flow characterization technique, which can avoid some limitations of the particle image velocimetry (PIV) technique. In order to analyze velocity fields in confined internal gas flows, a new experimental setup has been developed. First experimental data obtained in mini channels at atmospheric and low pressures are presented. The ability of the technique to measure local slip at the wall and to perform local temperature measurements is discussed.

VST-P2-21

A high sensitivity neutral atom detector based on electron impact ionisation

T15 Vacuum Science and Technology

#VST-P2-21

D. Ward, D. Chisnall, A.P. Jardine, J. Ellis, W. Allison.

Cavendish Laboratory - Cambridge (United kingdom).

The unrivaled surface sensitivity of neutral atomic and molecular beams has continually driven the development of scattering instrumentation [1]. A major challenge in detection of neutral beams is their high ionisation energies leading to low detector efficiency [2].

Applications that require time sensitive measurements require a small ionisation volume; however, when high temporal resolution is not required, ionisers having a much larger volume are possible. Here we describe a detector for helium-3 spin-echo experiments [3], based on principles recently established [4] and having a sensitivity of 0.83 Ambar^{-1} , the highest yet reported for helium atoms. A solenoidal magnetic field is used to confine electrons within an extended ionisation region (~800 mm long), allowing a large proportion of the incident atom beam to be ionised. Careful design of the electric and magnetic fields allow us to utilize electronic space charge to extract ions quickly, without introducing ion trapping, while minimising multiple ionisation. We present experimental results from the detector as well as simulation results and possible improvements for application in a helium atom microscope currently being developed [5].

VST-3-In-1 PROGRESS IN THE CONSTRUCTION OF THE ITER VACUUM SYSTEM

T15 Vacuum Science and Technology

#VST-3-In-1

R. Pearce.

ITER Organisation - Saint-Paul-Lez-Durance (France).

The ITER project has the purpose of demonstrating the feasibility of fusion as a clean power source and is being constructed in the south of France. It is one of the world's largest scientific and engineering collaborations. The successful operation of ITER requires some of the largest, complex vacuum systems yet to be built.

ITER will utilise approximately 400 vacuum pumps of 10 different technologies with many pumps and other vacuum technologies being specifically developed to meet operational and environmental challenges of the fusion machine.

In this talk the progress of the project, the progress in construction of the vacuum systems and the new developments in the area of vacuum technology are presented.
